THE indigo plant can assimilate nitrogen either through the agency of *B. radiclecola* present in its root nodules or from nitrates present in the soil. The nodules are numerous and functionally very active in poor, well-aerated soils, but their development and activity are arrested and inhibited in rich ground, the nitrogen in this case being derived from nitrate. The formation of indican is dependent upon the activity of the nodules and is greatest in the high-lying areas; in the rich low-lying swamp tracts and in fields treated with *seeth*, the nitrate cycle predominates, the plants yield heavy leaf crops, but their indican content is low and they afford only a dye of inferior quality. The indican may be regarded as representing the difference between the total nitrogen assimilated and that consumed in growth. The essence of successful indigo cultivation is adequate soil-aeration. Saltpetre soils dressed with potsherds (*thikra*) or brick-refuse (*sarkhi* and *roras*) grow remarkably fine indigo, and the value of adding such aerating agents to other soils is now being investigated; so far, it has been ascertained that they are best applied in comparatively small fragments. All the evidence to hand points to the conclusion that wilting is a starvation effect due to inhibited development of the nodules and fine roots; it cannot well be cured, but it may be prevented by cultivating early plants which grow rapidly and which have shallow roots, all weak, late-flowering plants being exterminated, and by adequate drainage. The introduction of new seed from Java would be useless, as the cultivation in that island is now in the hands of natives who do not select the seed carefully; they grow chiefly deep-rooting, late types. The Java plant, however, does not breed true, and if the early, quick-growing forms were selected and cultivated continuously, the old type of Java plant which formerly flourished in Bihar could be recovered. Both Javan and Sumatran varieties can be cultivated during the hot season, thorough weeding and the formation of a surface mulch of several inches being effected with the Canadian lever-harrow. When the first crop is gathered, a branch should be left to maintain the transpiration current, thereby causing the quick growth of shoots for a second cut; after the latter, the plants should be dug out and the land prepared for *rabi* crops, as it does not pay to grow the old stumps for a seed crop. The value of a good drainage system cannot be over-emphasised: an improved system for northern Bihar is *sine qua non* of the re-establishment of the indigo industry. A special seed crop, well spaced, should be sown early in August and kept for leaf afterwards. Should floods intervene, the soil must be aerated by deep cultivation, and the application of *thikra* and the provision of sub-soil drainage would also assist. Storage of seed is also to be recommended. Attempts to grow Sumatran indigo for seed have not been encouraging, as although the seed was good in quality the yield was small; possibly selection might lead to improvement. Java indigo

from Natal is unsuitable for cultivation in Bihar. The Java plants are fertilised by bees, and cross-pollination is the rule. Artificial self-fertilisation is difficult, and leads to degeneration. The mixed types composing the ordinary crops vary greatly, the late slow-growing kinds yielding the most indican. The chief means of improvement consists in controlling natural crossing. To this end, the seeds of a large number of good, early plants are collected and sown, the best plants are picked out and the weakest removed. The seeds of the former are mixed and sown on a large scale, and again the undesirable individuals are eradicated. Alternatively, the selection may be started from a single plant. Improvement by selection on the basis of indican content would be difficult and probably unsuccessful in Bihar, for those plants which contain most are late, deep-rooting sorts and are liable to wilt. Attempts to improve Sumatran indigo from Madras by selection did not succeed, but the possibility of crossing a high-yielding Java type with a good strain of Cawnpore Sumatran needs investigation. As regards indirect means of improvement, Java indigo might be rotated with *rakar* (rice), as this tends to conserve the soil organic matter and to open up the sub-soil; the rice is also improved by the rotation. The value of wheat as a cover crop was demonstrated by a very successful test with the rapid-growing Pusa 4 wheat; the flour produced was of the finest quality and, after the stubbles had been thoroughly harrowed, the next crop of indigo developed well.—E. H. T.

Indigo. Rept. Agric. Res. Inst., Pusa, 1915-16, 94-96.

THE success or failure of indigo manufacture depends largely upon the nature of the bacterial inhabitants of the steeping vats. Two distinct types of fermentation have been identified, one involving the evolution of nitrogen (usually in large excess) and carbon dioxide, and the other producing hydrogen, nitrogen, and carbon dioxide in about equal proportions. These fermentations do not give rise to methane. Numerous species of bacteria have been isolated and some of them have been classified definitely as beneficial or deleterious. The presence of one bacterium has been correlated with the unfortunate production of "green vat" which occurs sometimes in the "heating" or oxidising process. It is hoped that the manufacture may be improved by artificially controlling the bacteria in the vat.—E. H. T.

Indian indigo crop.

THE final general memorandum on the 1916-17 indigo crop, issued by the Department of Statistics, India, and based upon reports received from provinces containing practically the whole area under indigo in British India, states that the total area is estimated at 756,400 acres, which is 114% in excess of the acreage (353,100 acres) of last year. All the provinces show an increase in the area sown, the largest increases being in the United Provinces and in the Punjab. The total yield of dye is estimated at 95,500 cwt., as against 55,100 cwt., last year, or an increase of 73%. The present estimate of yield, as against the final figures of last year, shows an increase of 267% in the Punjab, 252% in the United Provinces, 117% in Bombay and Sind, 53% in Bihar and Orissa and 46% in Madras. The season has not, on the whole, been favourable for the crop except in the Punjab and Bombay and Sind. Heavy rainfall and floods adversely affected the crop in the United Provinces and in parts of Bihar and Orissa and Madras. The exports by sea to foreign countries in each of the last five years have been (in cwt.): 1911-12, 19,155; 1912-13, 11,857; 1913-14, 10,939; 1914-15, 17,142; 1915-16,

41,942 cwt. The imports of synthetic and natural indigo into the United Kingdom in the last five calendar years are stated below. Of the total amount of natural indigo (25,157 cwt.) thus imported 1915, 22,322 cwt. was imported from India, 824 cwt. from Java, and the rest from other countries.

	Synthetic indigo.	Indigo.	Total.
	cwt.	cwt.	cwt.
1911	24,287	4,917	29,204
1912	28,302	7,073	35,375
1913	23,889	4,174	28,063
1914	15,517	5,314	20,831
1915	6,542	25,157	31,699
1916 (10 months)	—	28,245	28,245

V.—FIBRES; TEXTILES; CELLULOSE; PAPER.

Cotton stalks; Paper pulp from—. W. B. Nanson. Paper-making, 1916, 35, 371—374.

It has long been known that an excellent fibre suitable for paper pulp or for spinning purposes can be produced from the mature stalks of the cotton plant, although the matter has not been developed beyond the experimental stage. The Southern States of America produce 52 million tons of cotton stalks annually, sufficient for 21 million tons of bleached fibre, but the collection of these for industrial utilisation would require some organisation. So far as laboratory trials go, it would appear that the stalks should be chopped in a fodder-cutter into pieces from 2.5—3 ins. long; such a machine would chop 2 tons per hour. The material would then be conveyed to digesters holding 5000—7000 lb. of stock and digested with 4000—5000 galls. of caustic soda liquor at 7°—10° B. (sp. gr. 1.052—1.072) for 10—12 hours;

it is most advantageous to employ a high steam pressure for the digestion, e.g., up to 120 lb. per sq. in. The treatment of the digested pulp would be similar to that of wood pulp. If the fibre is to be treated for spinning purposes, the digested stalks should be washed and passed between steel rollers, such as are employed in cottonseed oil mills, to crush the stalks and separate the fibres. The cotton-stalk pulp is particularly adapted for the permanganate bleaching process, the material being steeped overnight in a solution of sodium permanganate of 0.5°—2° B. (sp. gr. 1.003—1.011); this liquor should be run off and the stock boiled, without washing, in a 5% solution of soda ash for 6—8 hours; the permanganate treatment may be repeated, and the material steeped in sodium carbonate solution before being finally cleared in a bath of sulphurous and sulphuric acids.—J. F. B.

Friedel-Crafts reaction. [Decomposition of poly-alkylbenzenes.] Baedeker and Halse. See III.

PATENTS.

Wool and other fibrous materials or the like; Machinery for washing—. T. Rhodes, Shipley, Yorks. Eng. Pat. 17,613, Dec. 17, 1915.

IN a wool-washing machine in which the material is carried forward through a trough by means of prongs, inverted funnels closed at the top are attached at their small ends to the cross-members of the rake frame, being either secured to an extension at the base of the prongs or substituted for prongs; valves may be provided in the funnels to regulate the pressure of the enclosed air. The vertical reciprocating motion of the funnels agitates the liquid and air, forcing and sucking them through the goods.—J. F. B.

Artificial silk, yarns, tow, rope, etc. [from casparlo]; Manufacture of—. L. N. Trigos. Fr. Pat. 480,606, Jan. 3, 1916.

ESPARTO is treated in a boiler with steam or boiling water in presence of 1—6% of its weight of soda or potash until the material becomes soft and pliable. It is then treated in a pressing machine which squeezes out the excess of liquid and separates the fibres from each other, converting the material into a kind of tow which is washed, dried, and combed. The fibre may be bleached with sulphur dioxide and applied to various textile uses.—J. F. B.

Osier-bark; Process for utilising—. N. V. Stoom-Touwslagerij en Spinnerij, voorheen onder J. M. Van der Lely. Fr. Pat. 480,637. Jan. 8, 1916. Under Int. Conv., Nov. 16, 1915.

OSIER bark is boiled in a solution of sodium carbonate until the bast tissues are separated into filaments; the latter are washed and dried, with or without bleaching, then combed and spun like hemp or employed as a stuffing for mattresses, cushions, etc. The solution, which contains the tannic acid of the bark, may be employed for tanning or mordanting, and a brown colouring matter may be prepared therefrom.—J. F. B.

Cellulose and its derivatives; Manufacture of—, and application of the same in various chemical and other industries. A. C. Vournasos, Athens. Eng. Pat. 17,318, July 22, 1911.

CELLULOSE of fine staple and superior in absorbent power to ordinary cotton may be produced from the fibres of *Hibiscus cannabinus* and its various species of the order *Malvaceae*. The green stems are retted, e.g., by immersion in running water for 30—40 days, and the fibres are opened, scutched, and combed, bleached for 30—40 hours in a solution yielding chlorine, e.g., of potassium hypochlorite, washed free from chlorine, and finally dried in sunlight.—F. Sr.

Cellulose ; Process of manufacture of— and utilisation of the waste liquors of the manufacture. C. Harist. Fr. Pat. 177,895, July 6, 1914.

RAW cellulose material is treated with boiling water to expel the air; the vessel is then closed and connected with a supply of ammonia gas; a quantity of ammonia is introduced equivalent to one-sixth of that necessary to form the ammonium sulphite it is desired to have in the final exhausted lye, which is generally 2–5% of the weight of the liquor. Ebullition is maintained by indirect heating for $\frac{1}{2}$ –1 hour under a pressure of 2–4 atmos. At this stage a preliminary removal of organic matter may be effected, e.g., recovery of tannins, resins, etc., by precipitation, on neutralising with sulphur dioxide. After separating the precipitate, the liquor is treated with a further quantity of sulphur dioxide equal to two-sixths of the desired total and digestion of the material continued for 2 hours at 2–1 atmos. The liquor is gradually strengthened with five-sixths of the total ammonia and after one hour this is neutralised with three-sixths of the total sulphur dioxide, and digestion completed in 4–6 hours at 6–8 atmos. The waste liquors are treated for recovery of the reagents or for use as a fertiliser. J. F. B.

Luminous [cellulose] product. Soc. Anon. de Traitements Chimiques. Fr. Pat. 480,230, Nov. 13, 1915.

A FINELY powdered luminous (phosphorescent) substance is suspended in a "collodion," either nitrocellulose, cellulose acetate, or viscose, etc., in appropriate solvents, and the solution is converted into the form of sheets or threads, which can be used for the manufacture of luminous devices. As luminous substances, phosphorescent zinc sulphide, calcium sulphide, barium platino-cyanide, etc., may be employed, either with or without the addition of a salt of radium, mesothorium, or other radioactive substance.—E. W. L.

Pulp ; Process of treating—. G. Moore, Joplin, Mo. U.S. Pat. 1,207,978, Dec. 12, 1916. Date of appl., Jan. 23, 1915.

FOR recovering paper pulp from water containing the particles in suspension, a filter cell is submerged in the water and the latter is passed through the submerged cell until a layer of pulp solids has been deposited thereon; the coated cell is exposed to the atmosphere and air is drawn through the coating into the cell; the cell is again submerged and the layer of pulp discharged from it. The paper pulp suspended in the water may be thickened by the means described and the thickened pulp delivered to a body of similar pulp from which a cake is formed on a screen by a difference in pressure on opposite sides; the cake thus formed is moved into the atmosphere, held in position and drained on the screen by the difference in pressure, and discharged from the screen beyond the body of thickened pulp by reversing the difference of pressure. Water containing pulp in suspension may be treated to thicken the pulp and then aerated to cause the pulp to float by means of bubbles.—J. F. B.

Waterproofed material and method of producing same. A. O. Tate, Montreal, Assignor to Tate Electrolytic Waterproofing Co., Inc., New York. U.S. Pat. 1,208,100, Dec. 12, 1916. Date of appl., Dec. 31, 1911.

FIBROUS material is impregnated with a saponaceous liquid and a metallic sulphate, e.g., aluminium sulphate, and then subjected to the action of an electric current passed between electrodes one of which is soluble, whereby a metallic "palmitate" and metallic hydroxide are electrolytically incorporated in the fibres, and co-act therein to make them non-capillary.—J. F. B.

Paper and the like ; Manufacture [sizing] of—. C. W. Fish, Rawcliffe, Yorks. Eng. Pat. 16,742, Nov. 27, 1915.

PAPER pulp is treated with resin size and 0.5–1.0% of an aluminium salt calculated on the dry weight of pulp. When the mixture is thoroughly incorporated, nitre cake is added in quantity about equal to the aluminium sulphate which would be required if the nitre cake were not employed. The order of adding the size and aluminium salt is immaterial, but it is essential that the nitre cake or sodium bisulphate be added last. J. F. B.

Process of producing nitrocellulose. Eng. Pat. 9547. See XXII.

VI.—BLEACHING ; DYEING ; PRINTING ; FINISHING.

Dyeing of wood ; Theory and practice of the—. F. Moll. Z. angew. Chem., 1916, 29, 405–409.

OWING to the cells in wood being kept together by a layer of hemicelluloses, the dyeing of wood is not the same as the dyeing of cotton cellulose, in which the cells are completely separated; the process also differs from the impregnation of wood with preserving agents, which must be soluble to be effective as antiseptics, whereas the aim in dyeing is to convert the dyestuffs into an insoluble form. By immersing wood in a solution of the dyestuff in a solvent, such as water, alcohol, turpentine, benzene, or acetone, and allowing the solvent to evaporate, the colour penetrates to a depth of 0.5 to 2 mm. This process is not satisfactory for oak, but by continued immersion in aqueous solutions pinewood is penetrated to a depth of 5 to 20 mm. in 8 days; the penetration may be accelerated by using warm solutions, and the wood may be steamed before dyeing. Maple, lime, and poplar give good level light shades; pear tree wood is used for making imitation ebony; oak is shaded to resemble "old oak," or green; walnut, mahogany, and birch are "aged" by such a process. For technical purposes red beech is generally used on account of the readiness with which it is penetrated. A veneer only requires quite a small pressure; beech and pine require about 5 atm.; oak and similar wood is only penetrated to a depth of 1 mm. even at 100 atm. For complete penetration of pieces of larger cross-section, the filtration (Boucherie) process is used, in which the dye solution is introduced under pressure in the direction of the wood fibre to replace the sap in freshly hewn wood, after steam-

ing until the condensed water is clear. The air in the interior is considered to dissolve when a certain pressure is attained. The structure of wood is considered in relation to the dyeing process. It is preferable to use dyestuffs of a colloidal character that are readily coagulated; the greater their colloidal nature, the less the diffusibility, but the greater the fastness to water and, generally, to light. Additions may be made to the dyebath in order to accelerate diffusion by increasing the colloidal condition of the cell walls; this may also be done by steaming, which does not, however, penetrate sufficiently in the case of hard woods. In order to prevent coagulation, acids are added to solutions of acid dyestuffs and ammonia to those of basic dyestuffs. After treatment in the dyebath, the wood is allowed to stand for 6—12 hrs. to allow the dyestuff to coagulate, and is then allowed to dry or is steamed. Basic dyestuffs of low molecular weight are not fast to light, and coagulate too rapidly on the fibre, so that it is difficult to obtain level shades.—F. W. A.

Dyeing and cleaning; Studies in—D. B. Lake. *J. Phys. Chem.*, 1916, 20, 761—808.

WHEN a dyed material is treated with a solution of another dyestuff, the colour of the first dyestuff may, under suitable conditions, be masked by that of the second dyestuff, but the apparent displacement is due merely to the solvent or peptising action of the water and is independent of the second dyestuff. Probably on account of coagulation of the dyestuff, dyeings made at a high temperature do not bleed so readily as those obtained at a lower temperature. Examples are given of selective adsorption by wool from mixtures of dyestuff solutions at different temperatures. Probably due to the coagulating effect of acid, acid dyestuffs (on wool) bleed less in hot water if dyed from an acid bath. The laws of adsorption of an acid dyestuff in various acid baths as suggested by Bancroft (this J., 1914, 197, 349) hold when the "saturation capacity" of the fibre has been so decreased that the "cutting down" effect of the various anions can be manifested. In the case of the dyestuffs examined, the more the dyestuff is irreversibly adsorbed the less completely and readily is that dyestuff adsorbed at a low temperature, and the less it will bleed, other factors being the same.

The methods used for the removal of stains have been classified as follows: (1) mechanical removal; (2) solution in a liquid; (3) peptising in a liquid, e.g., removing dyes with hot water; (4) peptising with a solution, e.g., removing dyes with sodium carbonate solution; (5) peptising with peptised colloid, e.g., removing stains with soap; (6) peptising in two stages, e.g., removing paint by treatment first with oil and casein and then with soap; (7) adsorption by solid, e.g., in removing grease with fullers' earth or blotting paper, which is considered of special interest; (8) peptising with a liquid and adsorption by solid; and (9) change of substance forming the stain. A large number of examples of practical importance are tabulated, e.g., the removal of soot from cotton by dilute caustic soda is explained as due to the peptisation of the soot by the preferentially adsorbed hydroxyl ions forming a caustic soda-soluble colloid of soot.—F. W. A.

PATENTS.

Cotton fabrics; Production of figured effects on—Heberlein et Cie. First Addition, dated Nov. 30, 1915, to Fr. Pat. 468,642, Feb. 19, 1914 (this J., 1914, 960). Under Int. Conv., July 6, 1915.

The cotton fabric, previously mercerised, is submitted in places to the action of sulphuric acid above 50–55° B. (1.54 sp. gr.) in strength, then washed and again mercerised.—B. N.

Weighting, fixing, mordanting, dyeing and bleaching natural silk, artificial silk, cotton, linen, and other textile materials [by means of foam]; Process for—Soc. de Teinture et d'Apprêt ci-dev. A. Clavel, and F. Lindenneyer. Fr. Pat. 480,761, Jan. 25, 1916.

For the production of foam by means of acid, neutral, or alkaline liquids, saponins, agglutinants, tannins, resins or other analogous substances are added to the liquids.—B. N.

Silk; Protective treatment of weighted—in order to increase its strength and elasticity. Schadd & Korteling. Fr. Pat. 480,206, Nov. 12, 1915. Under Int. Conv., Nov. 23, 1914. (See also Fr. Pat. 478,007, Mar. 12, 1915; this J., 1916, 1167.)

SILK, after weighting with tin phosphosilicate, for instance, is treated with organic compounds containing nitrogen or sulphur, or both, which are non-volatile and which are oxidised more readily than the fibroin but do not stain nor injure the feel and appearance of the silk; the compounds employed may be fixed in the fibre by precipitation in an insoluble form. Suitable substances are choline, betaine, and the alkaloïds; for example, the silk after weighting is treated with a solution containing 5% of choline and hydrazine hydrochloride.—J. F. E.

VII.—ACIDS; ALKALIS; SALTS; NON-METALLIC ELEMENTS.

Sulphuric acid from copper-smelting gases. E. L. Larison. Eng. and Min. J., 1916, 102, 1121–1125.

FIVE important American copper smelting works manufacture acid from furnace gases. The Mount Copper Co. (Mococo, Calif.), the Anaconda Copper Co. (Anaconda, Mont.), and the Garfield plant (Utah) use gas from McDougall furnace-roasting sulphide ores. The Tennessee Copper Co. (Copperhill) and the Ducktown Sulphur, Copper, and Iron Co. (Isabella, Tenn.) use gas from blast furnaces in which pyritic smelting is carried out with addition of 1–6% of coke on undressed ores carrying about 30% of pyrrhotite, 6 of pyrite.

and 8 of chalcopryrite. The normal composition of the gas from the blast furnaces is SO_2 8–9, CO_2 6–7, CO 0.8–1, and N 84%. Air is admitted at several points in the acid plant by low-pressure blowers to furnish the necessary excess of oxygen without unduly diluting the sulphur dioxide. Much skill and attention is required at the furnaces, especially in charging, to keep the quality and quantity of the gas as uniform as possible. The nitre consumption in the two plants is 6–8%. All the smelters use the chamber process because it is cheaper and the gas too impure for the contact process; the use of the latter would involve the removal of moisture, arsenic, and dust.—W. R. S.

Phosphoric acid evolved in the volatilisation method of treating phosphatic rock; Use of the Cottrell precipitator in recovering—, W. H. Ross, J. N. Carothers, and A. R. Merz. *J. Ind. Eng. Chem.*, 1917, 9, 26–31.

In the Cottrell precipitator (this J., 1911, 1037) used in the authors' experiments on a manufacturing scale (this J., 1916, 1154) the sheet iron pipes were replaced by glazed terra-cotta tile pipes, within which were suspended wires of Monel metal or nichrome wires weighted at the ends. The exhaust-fan for drawing off the fumes was made of antimonial metal, the surface of which was protected from the action of the phosphoric acid by a coating of Bakelite enamel. Air was admitted to the furnace through openings round the electrodes, whilst the charge was introduced through openings round other electrodes. The rock used in the experiments was unground Florida land-pebble phosphate, containing 32.44% of phosphorus pentoxide and 2.33% of fluorine. The amount of moisture in the charge and in the admitted air was sufficient to convert the phosphorus pentoxide into phosphoric acid, and by increasing or reducing the moisture in the air, acid of any degree of dilution could be obtained. When the fumes were passed through a baffle tower so that the precipitation was made at a low temperature, the acid first collected from a charge containing about 1% of moisture had a concentration of about 60%, but by reducing the flow of air the concentration was increased to about 80%. By omitting the baffle tower and passing the fumes directly into the precipitator, precipitation of the phosphoric acid took place at about 100° C., and the solutions obtained either with a maximum or minimum flow of air were more concentrated than those obtained under corresponding conditions at a lower temperature (e.g., 90–82 and 95–23% as compared with 63.07 and 80.23% respectively). The extreme limits of impurities found in samples of phosphoric acid (about 63%) collected in the precipitator were as follows:—Sulphuric acid, 0.01 to 0.21; hydrofluoric acid, trace to 0.40; hydrochloric acid, *nil* to 0.01; silica, 0.03 to 0.26; calcium oxide, *nil* to 0.03; ferric oxide and alumina, trace to 0.06; arsenic, trace; heavy metals, none; and residue on ignition, 0.11 to 0.85%. Under the conditions of the precipitation the greater part of the hydrofluoric and sulphuric acids present passed through the precipitator in the form of gas. The phosphoric acid collected when the baffle tower was omitted contained a larger amount of suspended matter and was somewhat coloured probably by carbonaceous matter carried over with the air.

Hydrogen bromide: The absolute density of gaseous —, C. K. Reiman. *Comptes rend.*, 1917, 164, 44–46.

DETERMINATIONS of the density of gaseous hydrogen bromide prepared by three different methods gave as the result of a large number of experiments a mean value of 3.6432 grms., ± 0.002 as the weight of a litre under normal conditions.—G. F. M.

Salt; Removal of barium [chloride] from brines used in the manufacture of —, W. W. Skinner and W. F. Baughman. *J. Ind. Eng. Chem.*, 1917, 9, 18–26.

SAMPLES of the brine from different wells in the Ohio River District contained from 61.73 to 85.13 grms. of sodium chloride, 0.28 to 0.60 grm. of barium chloride, and 0.01 to 0.11 grm. of ferrous bicarbonate per litre. The brine, which has a density of 8.5 to 10° B., is concentrated in an evaporator to about 19° B., and is then passed through filters into settling tanks containing copper steam pipes, whence, after concentration to about 20 to 21° B., it is run into a "draw settler." Here a little salt is allowed to crystallise to remove the last traces of iron in suspension, and the clear brine is then drawn off to the crystallising tanks, or "grainers," which contain a system of copper steam pipes. As the salt crystallises more brine is run in until the concentration reaches about 30° B. From these grainers, in which No. 1 or "Table and Dairy Salt" is made, the brine is drawn off into the "bitter water grainer," where it is concentrated to 38° or 40° B. and yields No. 2 or "off-grade" salt, whilst the final mother liquors are drawn off and treated for the recovery of bromine, and calcium and magnesium chlorides. Samples of No. 1 salt contained from 0.02 to 0.23% of barium chloride (calculated on the anhydrous salt), whilst "off grade" salt contained from 1.02 to 18.52%. The "off-grade" product constitutes from 7 to 12% of the total salt produced by a works, and is sold for the manufacture of ice, salting of hides, etc., but notwithstanding its dangerous character, it has not infrequently been substituted for the No. 1 salt. Experiments on the precipitation of the barium by means of sodium sulphate showed that by the addition of the equivalent quantity of the reagent only 81.9% of the total barium was precipitated from the brine, whilst by the addition of 30% in excess 93.7% of barium was removed. The presence of the ferrous bicarbonate, the iron in which was partially precipitated on aeration or boiling, promoted the subsidence of the barium sulphate, and for this reason the sodium sulphate solution was added to the brine before heating. In practice the sodium sulphate (salt-cake free from arsenic or lead) was dissolved in water and its acidity neutralised by the addition of slaked lime which had been rubbed to a paste. The calculated quantity of solution was added to the brine, which was then agitated by the admission of compressed air for an hour, until the ferrous bicarbonate was decomposed. After standing for 16 hours practically the whole of the barium sulphate had deposited, and the brine was ready for the evaporator. After 3½ months' work scale due to calcium sulphate began to form on the pipes in the grainers, and it was therefore decided to reduce the proportion of sodium sulphate to the amount equivalent to the barium. Under these conditions No. 1 and No. 2 salts were whiter than before owing to more complete removal of the iron, and they crystallised more rapidly in the grainers. The highest proportion of barium found in No. 2 salt was 0.06%, whilst a sample of the mixed No. 1 and No. 2 salts contained only 0.02% of barium sulphate. The cost of treatment is estimated at about 1 cent per barrel, and the increased value of the product more than compensates for this. In the works which adopted this treatment about 400 lb. of barium sulphate per day was obtained as a by-product.—C. A. M.

Ammonium salts: Exportation of —.

AN Order in Council, dated January 1916, orders that the Proclamation of May 10th, 1916, prohibiting the exportation of certain articles from

the United Kingdom, be altered as follows:—The heading “²Ammonia and its salts, whether simple or compound (except ammonium nitrate, perchlorate, and sulphocyanide),” is deleted and replaced by the headings “²Ammonia and its salts, whether simple or compound (except ammonium nitrate, perchlorate, sulphate, and sulphocyanide)” “³Sulphate of ammonia.”

(Note: The effect of this order is to permit the exportation of ammonium sulphate to France and its possessions, Russia, Italy and its possessions, Spain, and Portugal, and to any other destination not in Europe nor on the Mediterranean and Black Seas.)

Ammonium nitrate solutions of any desired strength; Tables for the preparation of —. C. Gautsch, Chem.-Zeit., 1916, 40, 1049—1050.

TABLES are given showing the quantities, by weight and by volume, of ammonia solution of concentration from 9.91 to 30.37% NH_3 (sp.gr. 0.960—0.894 at 15° C., 16°—27° B. at 12.5° C.) and of nitric acid of concentration from 10.68 to 98.90% HNO_3 (sp.gr. 1.060—1.514 at 15° C., 8.17—48.99° B. at 15° C.) to furnish 1 gram. of ammonium nitrate. The following figures have been selected from the tables:—

Ammonia solution.

Sp. gr., 15° C.	0.960	0.950	0.940	0.930	0.920	0.910	0.900	0.894
Amount required for 1 gram ammonium nitrate {	grms. 2.1489	1.8716	1.6255	1.4425	0.9791	0.8522	0.7517	0.7012

	c.c. 6.9522	3.4736	2.2702	1.6577	1.2749	1.0052	0.7941	0.6180	0.5256

Seaweeds [; Japanese —]. K. Miyama. Kōgyō-Kwagaku-Zasshi, 1916, 19, 1044—1065.

IN Yezo different species of *Laminaria* and *Arthrothamnus* are collected for use as edibles and in large quantities as raw material for iodine manufacture; potassium salts are also obtained as a by-product. The cost of potassium chloride from seaweed is less than £1 per ton. Some of these seaweeds are rich in iodine, e.g., *A. bifidus*, Rupr. contains 0.6% on the dry weight. Near the coast of Saghalin seaweeds are as abundant as in Yezo and equally rich in iodine. Other varieties commonly used as a source of iodine are *Ecklonia cava* and *E. bicyclis*. Kelp made from seaweed in Japan is not porous, but obviously over-roasted. According to experiments, the seaweed may lose 12.5% of its iodine-content by unsuitable roasting. Japan produces 1700 tons of potassium salts per annum, or about one-fourth of the total consumption, but the proper utilisation of the seaweed gathered should afford over 6000 tons.

—J. F. B.

Cyanides [of the alkali and alkaline-earth metals]; Synthesis of — in the electric pressure-furnace. IV. Reactions at high pressures. A. Stähler, Ber., 1916, 49, 2292—2291.

MIXTURES of alkali carbonate and carbon, heated in the presence of nitrogen, at 60 atmos. pressure, in the author's high-pressure electric furnace (this J., 1913, 789), furnished a product containing at least 74% of alkali cyanide (yield 95%), and lithium cyanide was obtained by the same method in 80% yield, whilst a product containing about 74% of barium cyanide, with no appreciable proportion of cyanamide, was similarly prepared from barium oxide, the yield of cyanide being over 80%.

Attempts to prepare magnesium cyanide and glucinum (beryllium) cyanide were unsuccessful; and, as regards yield, the synthesis of aluminium nitride was unaffected by working under high pressure, no cyanide being formed.—F. SODX.

Ammonium silicate. R. Schwarz, Ber., 1916., 49, 2358—2361.

HYDRATED silica was slowly dissolved by 3 N ammonia solution at 18° C. until a maximum concentration representing about 1/50th of that required for the conversion of all the ammonia into metasilicate was reached. On heating, the silica dissolved more rapidly, but the solutions obtained were opalescent, and the solubility varied with the degree of hydration and character of the silica used. The formation of ammonium silicate was however proved by the steady rise in electrical conductivity which accompanied solution. Ammonia solution had no appreciable effect on finely powdered quartz at the ordinary temperature, but anhydrous amorphous silica underwent slow hydration and therefore dissolved. Tetraethylammonium metasilicate was obtained as a white amorphous hygroscopic mass by dissolving hydrated silica at 80° C. in a 10% solution of tetraethylammonium hydroxide and evaporating the solution in a vacuum desiccator.—F. SODX.

Iron ammonium alum; Hydrolysis of —. W. N. Rae, Chem. Soc. Trans., 1916, 109, 1331—1339.

THE precipitate, formed by hydrolysis, which separates on keeping a solution of iron ammonium alum, has been shown to have the composition $2\text{Fe}_2\text{O}_3 \cdot \text{SO}_3$. The intensity of the colour of iron ammonium alum solutions, alone and in the presence of other substances, such as sulphuric acid, ammonium sulphate, sucrose, potassium chloride, and alcohol, has been measured, and is shown to be in agreement with the supposition that the colour is due to the presence of a soluble form of the above basic sulphate. On adding concentrated sulphuric acid to a solution of the alum, a white precipitate is formed which is found to be the anhydrous alum. Several density determinations of aqueous iron ammonium alum solutions are recorded.—B. N.

Compounds formed by the interaction of glacial acetic acid and ferric chloride; Constitution of —. R. Weiland and K. Kessler, Tübinger Chem. Ges., June, 1916, Chem.-Zeit., 1916, 40, 1002.

ON dissolving ferric chloride in a small amount of glacial acetic acid the compound $\text{Fe}(\text{CH}_3\text{COO})_2 \cdot \text{Cl} + 2.25\text{H}_2\text{O}$ is formed, whereas when much acetic acid is present the product has the composition, $\text{Fe}(\text{CH}_3\text{COO})_2 + 0.25\text{CH}_3\text{COOH} + 0.75\text{H}_2\text{O}$. In both compounds the complex hexa-acetato-dihydroxyferric cation is present (Ber., 1909, 42, 3881) since the concentrated aqueous solutions yield the characteristic platinum-chloride of that cation. Treated with alcohol both salts yield a new red rhombohedral compound, $[\text{Fe}_2(\text{CH}_3\text{COO})_4(\text{OH})_2] \cdot (\text{FeCl}_3) + 5 \text{C}_2\text{H}_5\text{OH} + \text{H}_2\text{O}$, whilst when crystallised from a little water both

form the chloride of the hexa-acetato-ferrie base $[\text{Fe}_3(\text{CH}_3\text{COO})_6(\text{OH})_2]\text{Cl} + 7\text{H}_2\text{O}$. An analogous compound also separates from a concentrated aqueous solution of 1 mol. of ferric chloride and 1 mol. of sodium acetate, while a solution of 1 mol. of ferric chloride and 2 mols. of sodium acetate yields the above-mentioned chloride of the hexa-acetato-ferrie base. C. A. M.

Refractory oxides. R. B. Sosman, J. Ind. and Eng. Chem. 1916, 8, 985-990.

THE author quotes the melting points of silica, alumina, magnesia, lime, and ferrosilicic oxide previously determined by C. W. Kanolt (this J., 1913, 1155) and reproduces the phase rule diagrams of all possible two and three-component systems made from the foregoing oxides and ferric and ferrous oxides. He concludes that the stable compounds of the oxides with each other are all made up of these oxides in simple proportions, usually 1:1 or 2:1 and that the stable compounds are molecular compounds of the oxides (Werner's compounds of the second and third order). He suggests that certain compounds which exist in the crystalline state may be entirely dissociated when converted into the liquid or glassy state. "The maximum melting points in all of the systems are those of the pure stable compounds, and the highest melting points are those of the pure oxides, Al_2O_3 , CaO , and MgO , so that the addition of any substance to a refractory oxide will lower its melting point. Kaolinite $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, is not the hydrate of any high temperature compound and when heated it breaks up into a mixture of Al_2SiO_5 and SiO_2 with a softening point below that of either constituent, i.e., below 1625°C . If alumina is added to a pure kaolin to make a mixture equivalent to Al_2SiO_5 , sillimanite will form and will not melt below 1815°C . The formation of this compound is the basis of the manufacture of Marquardt porcelain. Magnesia spinel, $\text{MgO} \cdot \text{Al}_2\text{O}_3$, is a similar product; it melts at 2135°C . and its eutectics with MgO and Al_2O_3 melt respectively at 2030°C . and 1925°C . Fused silica or "quartz glass" is only stable above the melting point of cristobalite (1625°C). Below this temperature it tends to crystallise (devitrify), but as the high temperature form of cristobalite has the same density as the glassy form, the material remains transparent and homogeneous and only breaks up into the familiar devitrified mass when passing the $\alpha - \beta$ inversion point at $200^\circ - 275^\circ\text{C}$. Future progress in the use of refractory oxides must follow two principal lines: (1) control of the purity of the materials and (2) accurate control of high temperatures.

—A. B. S.

Hydrogen-oxygen mixtures: Catalysis of— at the ordinary temperature by moist contact substances. K. A. Hofmann and R. Ebert, Ber., 1916, 49, 2369-2389.

THE catalysis of a gaseous mixture of oxygen and hydrogen brought about by the action of contact substances moistened with aqueous solutions (see Hofmann and Schneider, this J., 1916, 45) is shown to be an electrochemical process, similar in character to that taking place in a Groves' gas battery. It is supposed that parts of the contact surface (of palladised or platinised earthenware) are converted into oxygen electrodes and parts into hydrogen electrodes by contact with the gases. With surfaces of platinum, iridium, or palladium, the activity of the oxygen develops very slowly as compared with that of the hydrogen, and hence, since the rate of catalysis depends on the product of these activities (that is, on the E.M.F. of the system), the maximum effect is only reached by employing more than one contact substance, so as to secure rapid activation both

of oxygen and hydrogen. The best results were obtained by using a palladium film (on earthenware) in conjunction with small quantities of finely divided palladium (reduced by hydrogen from palladium chloride solution), in presence of sodium bicarbonate solution. With such combined catalysts, the extent of the action is far greater than with both catalysts working singly. Under the most favourable conditions, about 70 c.c. of gas was catalysed in 10 minutes with 15 sq. cm. of contact surface. A palladium film alone gave the highest figures in an acid solution, which raises the oxidation potential of the oxygen, and the effectiveness of the catalyst was increased by charging it with oxygen, but no rise in activity was induced by adding an oxygen-carrier.

PATENTS.

Hydrochloric acid: Process for the manufacture of pure— M. Lucron and C. E. Riche, Fr. Pat. 480,217, Nov. 16, 1915.

THE impurities of ordinary commercial hydrochloric acid, consisting of iron, arsenic, antimony, sulphurous acid, and anhydride, can be removed by treatment of the acid with persalts, notably permanganates. The impurities are thus converted either into insoluble compounds, or into non-volatile compounds not carried away under the conditions of operation. The process can be applied in the ordinary course of manufacture so as to yield, directly, a pure acid.—J. B. C. K.

Sulphuric acid: Manufacture of— L. Laufer, Fr. Pat. 481,131, Mar. 7, 1916.

THE gases escaping from the Gay-Lussac towers are treated with water sprays or the like to absorb acid fumes, etc., and the water containing the recovered products is introduced into the acid-making system.—T. H. B.

Ammonia from coke: Process for production of— J. G. Aarts, Dongen, Holland, Eng. Pat. 101,154, Aug. 8, 1916. Under Int. Conv., Aug. 9, 1915. (Appl. No. 11,202 of 1916.)

A HOT mass of coke, after its discharge from the carbonising chamber, is exposed over its whole length and at both sides, to jets or streams of steam, preferably superheated, directed towards the middle of the mass, under constant conditions of quantity, velocity, and temperature, both for the steam and coke. The ammonia is recovered in any known manner by the aid of hoods, connected if desired with suction apparatus. The velocity and quantity of the steam should be regulated in accordance with the velocity and temperature of the coke, so that a sufficient quantity of nascent hydrogen is formed to give the maximum yield of ammonia, and that the temperature of the coke is reduced sufficiently to prevent as far as possible decomposition of the ammonia formed. In many cases, especially when the coke is moving slowly, the steam is introduced intermittently.—J. B. C. K.

Sodium bicarbonate and ammonium nitrate; Process of manufacture of—F. Ricard. Fr. Pat. 480,082, Oct. 20, 1915.

THE process is based upon the reaction between ammonium bicarbonate and sodium nitrate, and yields sodium bicarbonate and ammonium nitrate. One-third of the sodium nitrate is left undecomposed in the mother liquor, together with ammonium nitrate. The patent covers several alternative methods and apparatus for carrying out the reactions, and for separating the salts from the mother liquor. The ammonium bicarbonate and sodium nitrate may be allowed to react under pressure at 50° C. in the presence of only a small amount of water, or a saturated solution of the one salt may be allowed to act under the same conditions as regards temperature and pressure, upon the other salt in the dry state. The dried salt mixture obtained from the mother liquor is treated with hot water, which dissolves ammonium nitrate in preference to sodium nitrate, and the refined salt obtained by recrystallisation of this solution, is extracted with cold water, to remove sodium nitrate. The residual ammonium nitrate can be separated and dried by filtering under pressure of hot air. In order to facilitate the extraction of the raw or refined mother liquor salt by cold water, the latter is passed repeatedly through the salt by means of a pump, a jet of compressed air, or some mechanical form of agitator. —J. B. C. K.

Ammonium nitrate; Manufacture of—P. L. Hulín. Fr. Pat. 480,150, Feb. 11, 1915.

AN aqueous solution of calcium nitrate obtained, e.g., by the electric arc process of fixing atmospheric nitrogen, is allowed to react with ammonium sulphate at a temperature of 120° C. or higher. The solutions are preferably raised to this temperature separately, and the preliminary heating and the reaction are effected under pressure in a series of autoclaves. The apparatus may be applied to other reactions at high temperatures under pressure, notably those producing a precipitate of calcium sulphate. —J. B. C. K.

Ammonium chloride; Direct process of manufacture of—from chlorine, nitrogen, and hydrogen. C. L. Mayer. Fr. Pat. 480,232, Nov. 15, 1915.

A MIXTURE of hydrogen, nitrogen, and chlorine gases in definite proportions by volume, is submitted to the action of the silent electric discharge. In order to facilitate the reaction and to remove the products before decomposition can occur owing to its reversal, water or steam is injected under pressure into the chamber in which the reaction occurs. The following proportions are given as suitable for the process:—nitrogen 1 vol., hydrogen 4 vols., chlorine 1 vol.—J. B. C. K.

Sodium perborate; [Electrolytic] manufacture of—Deutsche Gold- und Silber-Scheideanstalt vorm. Roessler, Frankfurt, Germany. Eng. Pats. (A) 100,154, Mar. 2, 1916. Under Int. Conv., Mar. 10, 1915. (Appl. No. 3181 of 1916.) (B) 101,620, Mar. 2, 1916. Under Int. Conv., Sept. 24, 1915. (Appl. No. 3186 of 1916.) Additions to Eng. Pat. 100,153 of 1916 (this J., 1917, 83.)

(A) IN the preparation of sodium perborate by electrolysis of a solution of alkali carbonate and alkali borate, the solution, which may be saturated or not with borax, is kept saturated with alkali carbonate by maintaining the latter as a "bottom substance" (solid phase). (B) During electrolysis under the above conditions, a substance or mixture is added which will produce on the cathode a precipitate lowering the reducing action. Chromic acid may be used for this

purpose, and such of its salts the base of which does not decompose alkali perborate, e.g., chromates of alkali and alkaline earth metals, including magnesium, aluminium, beryllium (glucinum), etc. Other alkaline earth salts may also be used. With chromic acid 0.5 gm. per litre, and with calcium chloride 1 gm. per litre may be used. Protective colloids, e.g., albumin, starch, gum arabic, &c., may also be introduced to increase the action of the added chromic acid or salts.—T. H. B.

Iodine; Direct method of extraction of—from green sea-weed. V. Vincent. Fr. Pat. 480,014, Oct. 16, 1915.

GREEN sea-weed is extracted in the undried state with a solution of aluminium sulphate, preferably in sea water, and slightly acidified, which has the property of dissolving the alkali iodide from the weed, while leaving undissolved the gelatinous organic matters. The solution of alkali iodide is treated with copper sulphate and with sulphur dioxide or sulphites, and the precipitated cuprous iodide is separated from the solution by centrifugal force. An alternative method of extraction is to use a solution of iron sulphate for lixiviating the dried sea-weed.—J. B. C. K.

Sulphur dioxide; Synthetic manufacture of—R. P. Pietet. Fr. Pat. 480,294, Nov. 22, 1915.

SULPHUR or pyrites is burnt in a special furnace by means of pure oxygen, and to prevent the formation of products other than sulphur dioxide, the oxygen is mixed with sulphur dioxide before coming in contact with sulphur, and cooling coils are embedded in the walls of the furnace to moderate the temperature. A baffle-plate is fixed longitudinally in the furnace to divert the gaseous stream in a suitable manner. A compressor and exhauster are used to work an injector for mixing the oxygen with the sulphur dioxide produced in the process before bringing it in contact with the sulphur. Sulphur is kept in slight excess during the process so that all the oxygen is consumed. —T. H. B.

Zinc sulphate; Production of—from zinciferous minerals. E. Ferraris. Fr. Pat. 480,499, Dec. 21, 1915. Under Int. Conv., Dec. 7, 1915.

THE roasted and desulphurised ore or natural zinc oxide is treated with sulphur dioxide produced, e.g., by the roasting of a sulphide ore, and the precipitated zinc sulphite is treated with moist air to convert it into sulphate, which is dissolved by lixiviation with pure or acidulated water. The two stages of the process may be combined in one operation, treating the roasted ore with sulphur dioxide, together with air and moisture (or steam) in such a way as to produce directly zinc sulphate, the residue being afterwards extracted with acidulated water. —T. H. B.

"Mixed cream of tartar" [potassium and sodium bitartrates] and "soda cream of tartar" [sodium bitartrate]; Industrial preparation of—T. Gladysz. Fr. Pat. 480,620, Mar. 12, 1915.

CRUDE tartar is treated with hydrochloric acid, the acid solution is partially neutralised with lime or calcium carbonate, the precipitate of potassium and calcium bitartrates is separated and boiled with sodium carbonate solution, the resulting solution is decolorised with animal charcoal, and treated with a mineral acid to precipitate a mixture of sodium and potassium bitartrates ("mixed cream of tartar"). By exact neutralisation of the first mother-liquors with calcium carbonate, decomposition of the precipitated calcium tartrate by sodium carbonate, and treatment of the lye as described above, a crystalline precipitate of sodium bitartrate ("soda cream of tartar") is obtained.—T. H. B.

Carbon dioxide: Process for absorption of — from gaseous mixtures. Naaml. Vennootschap Anton Jurgens' Vereenigde Fabrieken. Fr. Pat. 480,774, Jan. 26, 1916. Under Int. Conv., Nov. 8, 1915.

The gaseous mixture is led into a solution capable of absorbing carbon dioxide, and which can be afterwards regenerated by boiling. The solution is one of alkali carbonate in which magnesium hydroxide, or a highly basic carbonate of magnesia or a mixture of these compounds, is held in suspension. This solution is obtained by adding an excess of a solution of an alkali carbonate to one of a magnesium salt, and afterwards boiling for some time.—T. H. B.

Alumina and hydrochloric acid: Simultaneous production of—. L. G. Patrouilleau. Fr. Pat. 481,106, Mar. 2, 1916.

SILICO-ALUMINIUM, produced by reduction of siliceous bauxite in an electric furnace, is heated to dull redness in a refractory vessel, and chlorine is brought into contact with it. A mixture of the chlorides of aluminium and silicon results, which is led into suitable condensers, the excess of chlorine which accompanies it being led away and used again. Subsequent treatment of the chlorides is based on the facts that silicon chloride decomposes in aqueous solution into silica and hydrochloric acid, whilst the very soluble aluminium chloride decomposes only after total evaporation of its solution and roasting of the residue at a red heat, then becoming converted into alumina and hydrochloric acid.—T. H. B.

Oxygen compounds of metals or metalloids and carbonaceous substances; Manufacture of an intermediate product for use in processes based on heating together — [e.g., in production of calcium carbide]. Alby United Carbide Factories, Ltd., and K. Hylland. Fr. Pat. 480,020, Oct. 18, 1915. Under Int. Conv., Oct. 31, 1914.

SEE Eng. Pat. 11,186 of 1915; this J., 1916, 963. The process may be applied to other oxygen compounds of metals or metalloids, besides lime, and the product may be used in the manufacture of metals, alloys, nitrates, silicates, cyanides, and cyanamides, as well as of carbides.

Sulphuric acid: Process and apparatus for the manufacture of—. L. P. Bassot, Paris. Eng. Pat. 100,597, May 31, 1916. Under Int. Conv., May 31, 1915. (Appl. No. 7724 of 1916.)

VIII.—GLASS; CERAMICS.

Bricks: Yellow —. L. A. Keane. J. Phys. Chem., 1916, 20, 731—760.

It has been found that the yellow colour of bricks is due to ferric oxide in a very finely divided form (not to compounds of the latter with lime or silica): when the ferric oxide is in a coarser condition the colour of the bricks is red. Alumina appears to be the important peptising agent in bricks, which are yellow when the ratio of free alumina to iron is high; lime acts indirectly by setting free alumina. Anhydrous yellow ferric oxide has never been obtained in the pure state, but it is stabilised by other substances. The buff colour of the product obtained by igniting aluminium hydroxide containing a small percentage of ferrous hydroxide is undoubtedly due to ferric oxide, as also is the yellow colour of slightly impure quicklime. Clay deposited in the presence of organic matter, and therefore likely to contain very finely divided iron oxide, may burn to a buff colour without the lime or alumina content being high. As agglomeration increases with the temperature, yellow bricks might be expected to turn red if heated sufficiently; but the peptising action of alumina also increases with the temperature, and the latter appears to be the predominating factor, since red bricks become paler or even buff when reheated. The changes of colour which result from the heating of yellow bricks are complicated by the dissociation of the contained ferric oxide, and heating in oxygen is suggested as a means of eliminating this factor. —W. E. F. P.

Committee on Glass and Optical Instruments. See page 119.

Refractory oxides. Sosman. See VII.

PATENTS.

China clay: Apparatus for drying —. C. A. Battiscombe and N. O. Walker, London, and G. L. Bates, Playden, Sussex, Eng. Pat. 102,781, May 11, 1916. (Appl. No. 6747 of 1916.)

THE soft clay paste passes through a hopper and forms a film, $\frac{1}{16}$ in. to $\frac{1}{8}$ in. thick, on an absorbent endless band, made of canvas, which conveys it through a shallow tunnel heated by steam-pipes fixed beneath the upper part of the band. After reaching the further end of the tunnel, the clay is loosened by a scraper and falls on to another band, similarly heated, which conveys it again through the tunnel and discharges it in a dry state.—A. B. S.

Refractory materials resistant to corrosion: Manufacture of —. Mineral Products Co. Fr. Pat. 480,491, Dec. 18, 1915. Under Int. Conv., Dec. 21, 1911, and Aug. 9, 1915.

SEE Eng. Pat. 17,447 of 1915; this J., 1916, 692. The proportion of finely divided carbon specified is from 10 to 30% of the weight of alumina. A material resisting the action of hydrofluoric acid is obtained by heating the products at a high temperature.

Abrasives: Manufacture of — for cleaning and polishing. Naamlooze Vennootschap West Borneo Cultuur Maatschappij. Fr. Pat. 481,099, Mar. 1, 1916. Under Int. Conv., Mar. 4, 1915.

AN abrasive, cleaning, or polishing material is made of acid salts of the heavy metals, such as ferric titanate or chromate (ferro-titanic sand or chrome iron ore), which have been freed from coarse impurities by sifting and then mixed with corundum, charcoal, rouge or other abrasive and with a bond such as rubber, oil, grease, cement, or clay. If great strength is required (as in the manufacture of grinding wheels), the mixture may be moulded and then burned.—A. B. S.

Recuperative kiln. U.S. Pat. 1,207,209. See 1.

PATENTS.

Paving composition, and method of producing same. E. H. Staber, Calcutta, India. Eng. Pat. 13,753, Sept. 27, 1915.

A PAVEMENT composition consists of grains of a mineral aggregate of different sizes, graded so as to give the maximum density, and not less than 4% of bitumen. The softening temperature of the bitumen is increased by mixing it with an impalpable powder so that the paving material does not soften under the highest sun temperature. Details of the method of grading, with graphs of seven mixtures, are given.—A. B. S.

Metallic coating on artificial stones and articles of artificial stone mass; Process for the production of a thick or compact —. H. Wette, Znaim, Austria. Eng. Pat. 17,862, Dec. 21, 1915. Under Int. Conv., Apr. 10, 1915.

THE surface of the unset mass is strewn with a powdered metal, such as lead, tin, zinc, aluminium, or their alloys, preferably composed of globular or angular particles, before being subjected to the final pressure in the mould by which the desired shaping is produced. A soft and a less soft metal powder may be used in succession, or a mixture

of powdered metals or alloys may be employed, with or without a small proportion of graphite in either case.—W. E. F. P.

Artificial stones; Manufacture of —. J. Voisembert and F. H. Keudel. Fr. Pat. 480,285, Apr. 7, 1915.

ARTIFICIAL building stone is made by crushing or grinding natural stone, adding 1–4% of a bond such as felspar, clay, ground glass, or quartz, and sufficient water to make a stiff paste. The latter is pressed hydraulically or mechanically into the desired shapes and the blocks produced are burned in an electric or gas-fired kiln. The blocks are laid in a mortar made of the same materials together with cement or lime.—A. B. S.

Magnesian cement. E. Ruch. Fr. Pat. 480,338, Nov. 27, 1915.

MAGNESIAN cement is made by adding sufficient dilute hydrochloric acid to calcined magnesia and inert materials such as stone, sawdust, etc., to form a paste, and then stirring the mixture vigorously.—A. B. S.

Wood; Bleaching exotic —. P. E. Simon. Fr. Pat. 481,155, June 15, 1915.

ROSE-WOOD, violet-wood (palisander wood), or other exotic wood is soaked in dilute nitric acid, for about a fortnight if cold acid is used or four days if the acid has a temperature of 40° C. It is then washed in a stream of water for a fortnight or more until all traces of nitric acid have been removed.—A. B. S.

Lumber: Treatment of — to increase its density. F. Pfeumer, Dresden, and H. Pfeumer, Loschwitz, Germany. Eng. Pat. 100,792, June 24, 1916. Under Int. Conv., June 25, 1915. (Appl. No. 8916 of 1916.)

SEE Ger. Pat. 291,945 of 1915; this J., 1916, 843.

Cement: Process and furnace for manufacture of — for preparing concrete of great strength. E. Longan. Fr. Pat. 480,542, Dec. 9, 1915. Under Int. Conv., Dec. 11, 1914.

SEE Ger. Pat. 293,121 of 1914; this J., 1916, 966.

X.—METALS; METALLURGY, INCLUDING ELECTRO-METALLURGY.

Gold in copper matte: Assaying —. R. E. Chase, jun. Eng. and Min. J., 1916, 102, 1139.

THE method is especially adapted for mattes rich in gold. One-quarter assay-ton is divided between two 3 in. scorifiers containing 35 grms. of test lead and 2 grms. of silica, and a second sample of the same weight is divided between a second pair of scorifiers, the assay being run in duplicate. The contents of the scorifiers are mixed and each charge is covered with 35 grms. of test lead and 2 grms. of borax glass. The lead buttons are combined two and two, made up to 65 grms. with test lead, and re-scorified with 2 grms. of silica. The silver beads are combined two and two and the assay finished in the usual way.—W. R. S.

Mineral and metal production of the United States. Eng. and Min. J., Jan. 6, 1917.

THE subjoined tables show the estimated amounts of certain important metals and minerals produced in the United States in 1916, together with the figures for 1914 and 1915:—

Metals.

Metal.	Unit.	1914.	1915.	1916.
Copper (a)	Pounds	1,158,581,876	1,423,698,160	1,941,900,586
Ferromanganese	Long tons	185,118	226,957	355,356
Gold (b)	Dollars	94,531,800	101,035,700	92,315,363
Iron	Long tons	23,147,226	29,016,213	39,484,000
Lead (c)	Short tons	538,735	535,922	583,498
Nickel (c)	Pounds	30,067,064	44,139,826	61,675,438
Quick-silver	Flasks	16,300	(f) 21,033	28,912
Silver (b)	Troy ounces	72,455,100	67,485,600	72,883,748
Zinc (d)	Short tons	362,261	492,495	672,500

(a) Production from ore originating in the United States. (b) The statistics for 1914 and 1915 are the final and those for 1916 are the preliminary statistics reported jointly by the directors of the Mint and the U. S. Geological Survey. (c) Production of refined lead from ore and scrap originating in the United States; Antimonial lead is included. (d) Total production of smelters, except those treating dross and junk exclusively; includes spelter derived from imported ore. (e) Imports; for 1914, 1915 and 1916 first 10 months only. This nickel is refined in the United States for the production of metal, oxide and salts. (f) As reported by U. S. Geological Survey.

Mineral and chemical substances.

Substance.	Unit	1914.	1915.	1916.
Coal, anthracite (a)	Short tons	90,821,507	88,912,000	88,500,000
Coal, bituminous (a)	Short tons	422,703,970	432,500,000	509,000,000
Coke (a)	Short tons	34,555,914	41,600,000	51,300,000
Iron ore	Long tons	42,911,897	58,843,804	81,035,000
Petroleum (a)	Barrels	265,762,535	281,104,194	292,300,000

(a) The coal and coke and petroleum statistics are the estimates of the U. S. Geological Survey.

Brass: The failure of —. I. *Microstructure and initial stress in wrought brasses of the type Cu 60, Zn 40%.* P. D. Merica and R. W. Woodward. U. S. Bureau of Standards, Technical Paper No. 82. J. Franklin Inst., 1916, 182, 803—805.

As the result of examining some 250 samples of used and unused wrought brass of the above type, the initial stresses in rods and bolts were found to vary greatly in distribution and magnitude. Average stresses of 1000—30,000 and fibre stresses of 0—80,000 lb. per sq. in. were obtained (mainly by the Heyn method; see this J., 1914, 596); and whereas the outside layers of extruded and forged rods were found to be under compressional strain, those of drawn rods were in tension. Some of the results obtained for typical materials are given in the following table: samples 85, 136, 172, 174, and 205 were new, 3 and 160 had season-cracked in service, while 187 and 189 had been in service under moderate stress for months without showing signs of failure.

5000—10,000 lb. per sq. in., an average initial stress value of 500 lb. per sq. in. is a safe stress limit for rods and bolts of usual size; and failure is likely to occur in cases where the initial stress value, or the sum of initial stress in tension and the tensional service stress, approaches the elastic limit of the material. The initial stress in rods is relieved by annealing for 1—2 hours at 300°—400° C., at which temperature the physical properties are not appreciably affected.—W. E. P. P.

Zinc, cadmium, and mercury; Vapour pressures of —. A. C. Egerton. Phil. Mag., 1917, 33, 33—48.

The method employed by Knudsen (Ann. Phys., 1909 (4), 29, 179) for determining the vapour pressure of mercury (depending on the kinetic flow of molecules through small apertures and tubes) was adapted to the requirements of the present investigation, the original procedure being simplified by the use of tubes having accurately circular holes the diameters of which

No.	Material.	Percentage composition.				Tensile strength (lb. per sq. in.).		Percentage elongation in 2 ins.	Initial stress (lb. per sq. in.).		Stress in outer layer.
		Cu.	Zn.	Sn.	Fe.	Ultimate strength.	Proportional limit.		Average stress.	Maximum fibre stress.	
3	Manganese bronze	60.0	38.6	0.78	0.5	70,000	17,000	33	25,000	44,000	Tension
85	Naval brass	59.8	39.3	0.61	—	61,000	16,000	46	2,000	7,000	Tension
136	Manganese bronze	59.1	39.3	0.78	0.70	72,000	27,500	44	22,000	34,000	Tension
160	Manganese bronze	57.3	40.7	0.94	1.08	61,000	14,000	28	30,000	81,000	Tension
								(on 3 ins.)			
172	Muntz metal	59.4	40.2	—	0.62	61,000	36,000	40	4,000	8,000	Compression
174	Manganese bronze	56.9	40.1	1.63	1.18	81,000	36,000	22	4,000	9,000	Compression
187	Naval brass	60.0	39.6	0.10	—	61,600	28,700	33	6,000	14,000	Compression
189	Manganese bronze	56.6	40.8	1.00	1.50	61,600	21,000	—	8,000	12,000	Compression
205	Manganese bronze	58.8	39.6	0.39	1.06	81,600	52,000	22	5,000	9,000	Tension

Failures by fracture or fissure were found to have occurred as the result of (1) the presence of initial stresses of large magnitude, (2) service over-stress due, for example, to the drawing up of bolts too tightly, and (3) improper and faulty practice in forging bolt heads, flanging plates, etc. Under normal service conditions, in which the service stresses are themselves not greater than

could be measured by a micrometer; the condensed metal was weighed instead of measured. The vacuum was obtained by means of a charcoal tube kept in liquid air, and also by the use of a Rose oil pump. The apparatus was standardised by means of mercury; and details of the observations made with all three metals are given in a series of tables. The values of log. p. for cadmium

and zinc were found to be $10.5979 - 0.5 \log. T - \frac{6060}{T}$ mm. and $10.9443 - 0.5 \log. T - \frac{7176}{T}$ mm., respectively; the corresponding value for mercury, as found by Knudsen, being $10.5721 - 0.817 \log. T - \frac{3342.26}{T}$ mm. The angle of slope of the vapour pressure curve for mercury was slightly less than half that of the slopes of the zinc and cadmium curves, which were very similar. The values of $\frac{dp}{dT}$ at the melting points of the elements were: Zn 4.11×10^{-3} , Cd 3.70×10^{-3} , and Hg 2.81×10^{-7} mm.; while at a point of equal pressure, 2.0×10^{-6} mm., the corresponding values were 1.25×10^{-7} , 1.39×10^{-7} , and 2.81×10^{-7} mm. at the absolute temperatures 502° , 436° and 231° respectively. At the melting points, the vapour pressures of zinc and cadmium were nearly equal (Zn 1.13×10^{-1} , Cd 1.0×10^{-1} mm.). The physical constants of these two elements are closely similar, but those of mercury have a much smaller value throughout. The results obtained so far show the method to be capable of general application.—W. E. F. P.

Aluminium; Official price of —.

THE selling price of aluminium ingots of ordinary commercial purity of 98–99% has been fixed by the Ministry of Munitions at £225 per ton, carriage paid to consumers' works. The maximum selling price of re-melted aluminium scrap and swarf ingots of 98–99% purity has been fixed at £210 per ton, carriage paid to consumers' works. The maximum price must not be exceeded, but a lower one may be fixed by agreement between the seller and the buyer, based upon the metallic aluminium content. These prices are to take effect as from 1st January, and permits under Regulation 30 A of the Defence of the Realm Regulations will be granted only for such dealings in the above-mentioned materials as are in accordance with the above prices. The above prices are subject to alteration, at any time, as may be directed by the Minister of Munitions.

Gallium; Electrolysis of —. H. S. Uhler, Amer. J. Sci., 1917, 43, 81.

THE electrolytic deposition of gallium by the process described recently (this J., 1916, 1221) is considerably retarded by the presence of nitrates. Chlorides, on the other hand, appear to have no effect on the rate of deposition.

Antimonial lead; Analysis of —. C. R. McCabe, J. Ind. Eng. Chem., 1917, 9, 42–44.

THE following modification of Demorest's method (J. Ind. Eng. Chem., 1913, 8, 842) obviates the error caused by occlusion of antimonious sulphate by the precipitated lead sulphate:—One gram. of the alloy is dissolved in 50 c.c. of strong sulphuric acid, and the solution boiled for 5 mins. to oxidise the tin, and allowed to cool. It is then diluted with 50 c.c. of water, boiled for 10 mins., allowed to cool somewhat, and a further 50 c.c. of water added. The precipitated lead sulphate is washed twice by decantation with 25 c.c. of water, the washings being passed through an asbestos filter in a Gooch crucible, and it is then dissolved in a solution of 10 grams. of ammonium acetate in 50 c.c. of water. The solution is treated with 25 c.c. of strong sulphuric acid, the flask shaken, and the lead sulphate left to settle for 5 mins. and then collected in the Gooch crucible, in which, after being washed with water, it is dried at 120°C ., ignited for 5 mins. over a Bunsen flame, cooled in a desiccator, and weighed. The antimony in the two filtrates is separately determined by adding a large excess of N/10 potassium permanganate

solution (standardised on pure antimony dissolved in sulphuric acid) and titrating the excess with standard ferrous sulphate solution. The total amount of permanganate used, less 0.3 c.c., the quantity consumed in a blank test, corresponds with the amount of antimony. Tin is determined in the first filtrate by reduction with iron, filtration of the liquid through cotton wool, which is then washed with dilute (1:5) sulphuric acid, and titration of the filtrate with standard iodine solution.—C. A. M.

Burma's wolfram output. U.S. Commerce Reports, No. 303, Dec. 27, 1916.

COMPLETED figures for 1915 show that the total production of wolfram from all sources in Burma amounted to 46,293 cwt., compared with 43,752 cwt. in 1914, 32,991.5 in 1913, 32,224.5 in 1912, and 25,357 in 1911. These figures do not include production from the southern Shan States, where wolfram is worked in conjunction with tin, and separate statistics are not recorded.

Hitherto the greater portion of the wolfram ore produced in Burma was taken up by Germany, but English smelters are now in a position to handle all the ore coming forward. Late figures show that from January 1 to October 7, 1916, 2702 tons of wolfram was exported, compared with 1844 tons in the corresponding period of 1915. (See also this J., 1916, 119.)

Silver-tellurium; Metallographic investigation of the system —. M. Chikashige and I. Saito. Mem. Coll. Sci., Kyoto Imp. Univ., 1916, 1, 361–368.

MIXTURES of silver and tellurium in varying proportions and, in each case, of a total volume of 2.5 c.c., were melted in an atmosphere of hydrogen in a porcelain tube contained in an electric furnace. During the progress of cooling, temperature readings were taken by means of a calibrated thermo-element. An allowance was made for the volatilisation of tellurium, which was found to be appreciable when the proportion present in the mixture exceeded 40%. The formation of homogeneous crystals and eutectoids was followed by maxima and constant temperature points in the cooling curves, and by microscopic examination of the reguli. Formation of the compounds Ag_2Te and Ag_7Te_4 was established. Ag_2Te is a brittle, greyish-white, crystalline substance melting at 957°C ., which is immiscible with silver in the solid state and thus forms an eutectoid with this metal, but reacts with tellurium in the molten condition at 443°C . to form $\beta\text{-Ag}_7\text{Te}_4$, which, at 403°C ., changes into the α -form. Ag_7Te_4 was found to be insoluble in Ag_2Te but remains mechanically mixed with the latter, and immiscible with tellurium in the solid state, so forming an eutectoid when separating together. Regulii containing 70% of silver give an alloy of fine structure which may have technical importance.—J. N. P.

Metals; Emulsions and suspensions with molten —. H. W. Gillett. U.S. Bureau of Mines. J. Phys. Chem., 1916, 20, 729–733.

FROM a consideration of numerous cases in practice where emulsions or suspensions of molten metals or alloys with solids, liquids, or gases are produced unavoidably, as in the refining of aluminium chips, "floured" or "sickened" mercury, dirty molten sodium, and "blue" zinc powder, or intentionally as in sherardising and in the production of the lead-copper mixture used for packings, bearings, etc., it is suggested that, if procurable, many stable emulsions of metals normally immiscible in the liquid state might prove of use industrially. Although useful emulsions of gases with metals are rare, it is known that lead made porous by an indirect method is

much more efficient than solid lead plate for storage batteries; and it is probable that other metals, if rendered uniformly porous by emulsification with gas while in the liquid state, would find many industrial applications. Investigation of the colloid chemistry of molten metals and alloys would doubtless yield much valuable information.

—W. E. F. P.

Antimony sulphide and cuprous sulphide; Metallographic investigation of the system—. M. Chikashige and Y. Yamauchi. Mem. Coll. Sci., Kyoto Imp. Univ., 1916, 1, 341—347.

AN investigation was made of the crystallisation of mixtures of antimony and cuprous sulphides. Mixtures of varying proportions were melted by means of an electric furnace in tubes of Jena glass or porcelain. Temperatures during the gradual cooling were read by a platinum-platinum-rhodium thermo-element and an atmosphere of nitrogen was maintained round the tube containing 30 grms. of the mixture. Maxima in the cooling curves were obtained with a mixture corresponding to the composition $4\text{Cu}_2\text{S} \cdot 5\text{Sb}_2\text{S}_3$ and with $3\text{Cu}_2\text{S} \cdot \text{Sb}_2\text{S}_3$ (orthothioantimonite). Metallographic examination showed that homogeneous crystallisation took place at these compositions, and the compounds gave no mixed crystals with each other or with either of their components. Indications were obtained of the separation of $\text{Cu}_2\text{S} \cdot \text{Sb}_2\text{S}_3$ (metathioantimonite), but this formation remained uncertain as the crystallisation was accompanied by the separation of a eutectoid containing $3\text{Cu}_2\text{S} \cdot \text{Sb}_2\text{S}_3$, which gave a heterogeneous structure to the regulus. On account of the uncertainty of this crystallisation, the composition of chalcostibnite still remains unsettled. An analysis of the mineral gives 46.81% antimony, while $\text{Cu}_2\text{S} \cdot \text{Sb}_2\text{S}_3$ contains 48.5% and $4\text{Cu}_2\text{S} \cdot 5\text{Sb}_2\text{S}_3$, 45.9%.—J. N. P.

Sulphuric acid from copper-smelting gases. Larison. See VII.

Overvoltage tables. IV. Theories of overvoltage and passivity. Newbery. See XI.

PATENTS.

Tool-steel alloy. R. Furness, Jenkintown, and R. H. Patch, Assignors to The Midvale Steel Co., Philadelphia, Pa. U.S. Pats. (A) 1,206,833, (B) 1,206,834 and (C) 1,206,902, Dec. 5, 1916. Dates of appl., Dec. 11, 1915, Jan. 19, 1916, and Sept. 16, 1915.

High speed tool steels are claimed containing (A) Cr, 2.5—5 (4); Mo, 4—11 (8); Co, 2—20 (5); C, less than 1% (1); (B) Cr, 2—6; W, 9—15 (less than 15); Co, 5—20 (not less than 10%); (C) Cr, 15—20 (19.5); C, about 1.35%.—W. E. F. P.

Iron for castings; Method of preparing—. W. G. Kranz, Sharon, Pa., Assignor to The National Malleable Castings Co., Cleveland, Ohio, U.S. Pat. 1,206,861, Dec. 5, 1916. Date of appl., Nov. 17, 1915.

A PORTION of the molten iron, high in carbon, manganese, and silicon, is treated in a Bessemer converter to reduce the amounts of these elements, and the molten iron is then mixed with the remaining portion of the charge, whereby the amounts of the elements are reduced and equalised, though the carbon remains above 1.5%. The metal is refined in an electric furnace, without further substantial reduction of the carbon.—B. N.

Ferrotungsten; Process of treating—. P. M. McKenna, Washington, D.C. U.S. Pat. 1,208,596, Dec. 12, 1916. Date of appl., Aug. 11, 1916.

FERRO-TUNGSTEN alloy obtained by smelting is treated for the removal of non-metallic impuri-

ties, such as sulphur, by grinding the mass and subjecting it to the action of hydrochloric acid of approximately 20° B. (sp.gr. 1.16). The acid does not combine with the metallic tungsten alloy, but forms hydrogen compounds, such as hydrogen sulphide, with the impurities. The excess of acid is removed by washing, and the finely-divided product dried.—B. N.

Tin from cassiterite and oxidation products of tin; Process for facilitating the extraction of—. G. Michaud and E. Delasson, Montreuil sous Bois, France. Eng. Pat. 17,743, Dec. 18, 1915. Addition to Eng. Pat. 611, Jan. 14, 1915 (this J., 1916, 313).

THE reduced metal, obtained as a concentrate or fine powder or in the form of "carbo-metallic plates," by the original process, is dissolved in a solvent composed of hydrochloric acid (40 litres), water (60 litres), and stannous chloride (20 kilos.) at a temperature between 50° and 70° C. The solution is electrolysed for the production of metallic tin, and the spent electrolyte used for dissolving a further quantity of the crude metal. The stannous chloride for the solvent is obtained by treating the partly exhausted carbo-metallic plates with hydrochloric acid and evaporating the solution.—W. E. F. P.

Roasting furnace. F. Fouarge, Swansea, Eng. Pat. 102,595, Sept. 4, 1916. (Appl. No. 12,491 of 1916.)

THE furnace has superimposed hearths with openings at the ends so disposed that the material travels along a sinuous path. Each roasting chamber is provided with lateral shelves or flanges which do not extend quite to the ends of the chamber. Reciprocating rakes are carried by rods extending across the chambers and their ends slide upon the inwardly projecting flanges or below these. The rakes on alternate hearths work in opposite directions, pushing the material towards the shoot leading to the next lower floor as well as to one side. Dust-chambers communicating with the upper hearth are situated at the top of the furnace. Additional side shoots may be provided to prevent the channel from getting clogged.—W. R. S.

(A) *Furnace and allied structure*. (B) *Furnace*. (C) *Feeding device for furnaces*. (D) and (E) *Metallurgical furnace*. U. Wedge, Ardmore, Pa. U.S. Pats. (A) 1,208,216, (B) 1,208,247, (C) 1,208,248, (D) 1,208,249, and (E) 1,208,250, Dec. 12, 1916. Dates of appl., (A) Jan. 12, 1914, (B) Feb. 11, 1914, (C) Feb. 28, 1914, (D) Nov. 21, 1914, and (E) Mar. 1, 1915. All renewed Apr. 27, 1916.

(A), IS a furnace having a series of superposed annular hearths, each hearth is provided with an inner and an outer charge-receiving surface, side by side, each having a separate outlet. A charge is fed to each surface independently and moved over the surface towards the outlet. The outlets of alternate hearths are at the outer periphery, and midway between the outer and inner peripheries respectively. (B) Two concentric cylindrical walls are provided with superposed annular hearths projecting into the annular space towards one another. A girder rotating in a horizontal plane about a central pivot carries depending from its outer end a series of annular hearths intermediate with the fixed hearths and projecting equally between the members of the two series. (C) In a furnace as in (B) the outer end of the girder carries a feeding hopper above a circular pivoted distributing plate over the hearths. The plate engages with fixed members on the furnace as the girder revolves, and is caused to rotate upon its own axis to distribute the

material (ore) on to the uppermost hearth from which it passes to the lower hearths. (D) In a metallurgical furnace a tubular vertical shaft is surrounded by a hearth having a treating chamber above it. A hollow rabble arm with a return passage therein communicates at one end with the tubular shaft and at the other end with a concentric tubular member within the shaft. An air distributing arm projects into the working chamber from one of the tubular members independently of the rabble arm. It is provided at its inner end with a valve to regulate the flow of air to the working chamber, the air being supplied to the other tubular member. (E) A rabble blade is supported by its enlarged head in jaws projecting downwards from a hearth or equivalent support. A rib or flange on the support bears upon the rear face of the rabble blade. A filling body occupies the space in the support above the rabble blade.—W. F. F.

Metal articles; [Preventing] scaling, and annealing of — F. Perry, and Metalloids, Ltd., Tipton, Staffs. Eng. Pat. 102,660, Mar. 25, 1916. (Appl. No. 4445 of 1916.)

IN the treatment of metal articles in a muffle or other annealing chamber containing an atmosphere of Mond gas or similar gas for reducing or preventing the formation of scale, the gas is freed from water vapour, sulphur, and unsaturated and saturated hydrocarbons before admission to the muffle. The saturated hydrocarbons (e.g., methane) are eliminated by passing the gas through an iron tube, or a chamber containing loose pieces of iron, heated to about 250° C., after removal of the other impurities by known means.—W. E. F. P.

Metals [copper] from ores; Process for the recovery of — C. S. Vadner, Butte, Mont. U.S. Pat. 1,207,243, Dec. 5, 1916. Date of appl. May 23, 1916.

THE oxide or roasted sulphide ore mixed with a hot chloride solution is treated with sulphur dioxide. The clear liquor is freed from the excess of sulphur dioxide, partially neutralised, and iron and arsenic are precipitated by introducing air in presence of a carbonate. After completely neutralising, the copper is precipitated as cuprous chloride by heating. Sodium sulphate is recovered from the liquor.—W. R. S.

Copper and nickel ores; Treatment of — by electrolysis. V. Garin, Fr. Pat. 481,079, Feb. 29, 1916.

ALBUMINOUS or gelatinous materials, such as albumin, gelatin, dextrin, etc., are employed in the electrolytic deposition of copper and nickel from poor impure solutions, charged with sulphurous acid, particularly those obtained by the lixiviation of copper ores. Filaments of albumin, gelatin, etc., are applied by rubbers of soft fibrous wood, obtained from the cotton plant, coconut palm, etc., covered with organic material, such as skins, etc., in order to remove the hydrogen bubbles from the rotating cylindrical cathodes, or the albuminous or like material may be employed as pieces floating in the electrolyte. The formation of copper sulphide is prevented, and a sound and compact deposit is maintained, even up to the point at which the bath is exhausted.—B. N.

Zinc, copper or other metals; Electrolytic production of — Soc. de Métallurgie Electrolytique. First Addition, dated Sept. 21, 1915, to Fr. Pat. 472,764, May 28, 1914 (this J., 1915, 497).

SEVERAL rotary mandrel-cathodes, of small diameter but great length and supported on bearings so that they may be easily removed, are arranged in a shallow rectangular tank, each cathode being partly surrounded by a perforated lead anode in

the form of an open trough. Adjacent anodes are bound together by rivets, and they rest on supports fixed to the bottom of the tank. Impregnated wiping pads, of soft supple animal membranes, prepared from skins, bladder, etc., rendered insoluble by immersion in aldehyde, acetone, etc., are employed to remove bubbles of hydrogen from the cylindrical cathodes, and the action of the gelatin, added to the bath to improve the deposit, is thus made more regular. The animal membranes may be replaced by vegetable materials impregnated with insoluble gelatin. The pads, resting lightly on the upper surface of the cathodes, are displaced by an irregular reciprocating motion. The electrolyte, filtering between the rotating shafts of the cathodes and their supports, is collected in a receiving vessel, and led off from the bottom of the latter, to prevent the liquid coming into contact with the turning mechanism.—B. N.

Melting metals [copper, bronze, and cuprous metals] which fuse at high temperatures; Process for — in iron or steel ladles. J. Cookerley, Inglenook, Ala., Assignor to E. Shelton, Birmingham, Ala. U.S. Pat. 1,208,717, Dec. 12, 1916. Date of appl. Feb. 21, 1916.

THE metal is melted, in contact with a bath of fused sodium chloride, in an iron or steel ladle or crucible, the inner surface of which has been previously coated with the fused sodium chloride.—W. R. S.

Brass surfaces; Process of crystallising — O. R. Hasenohr, Assignor to J. Debeck, Terre Haute, Ind. U.S. Pat. 1,207,910, Dec. 12, 1916. Date of appl. Oct. 14, 1914.

THE brass is immersed for 5–10 secs. in a solution containing 1 part of nitric and 2 of sulphuric acid, then washed in cold water and immersed for 5–10 secs. in an aqueous solution of potassium cyanide (8 oz. per gall.), again washed in cold water and placed for 1–5 mins. in sawdust impregnated with a solution made by dissolving 10 oz. of ammonium chloride and 2 oz. of copper sulphate in $\frac{1}{2}$ gall. of water, and subsequently washed in cold water and dried after immersion in boiling water.—W. E. F. P.

Gold; Process of recovering — J. H. Alling, Columbia, Cal., Assignor to F. M. Wright, San Francisco, Cal. U.S. Pat. 1,207,261, Dec. 5, 1916. Date of appl. Oct. 18, 1910. Renewed Aug. 18, 1911.

THE ore pulp is mixed with a solution of common salt, and a continuous supply of the mixture passed once only through a series of alternate electrolytic and non-electrolytic cells. The stream of mixture is thus repeatedly subjected to electrolytic action at intervals sufficiently long to permit combination of the gold with the liberated chlorine: the gold is deposited on the cathodes.—W. R. S.

[Zinc] retorts; Method of recovering clay and slag from used — C. C. Conover and A. N. Detweiler, Springfield, Ill. U.S. Pat. 1,207,503, Dec. 5, 1916. Date of appl. June 27, 1916.

OLD clay retorts, which have been used for zinc distillation, are coarsely crushed, and the powder is subjected to a weak magnetic power which separates the more magnetic constituents of the slag. The coarse powder, after re-crushing, is treated by strong magnetic power to separate the less magnetic constituents of the slag from the clay. The material is subjected to the process before the magnetic properties of the slag constituents have been materially altered through oxidation.—W. R. S.

Zinc: Manufacture and condensation of volatile metals, more especially — in the electric furnace. A/S Metallforedling. First Addition, dated Nov. 6, 1915, to Fr. Pat. 478,770, Jan. 27, 1915 (see Ger. Pats. 289,493, 290,499, 290,690, and 291,492 of 1914; this J., 1916, 427, 606, 695).

THE gaseous products from the treatment of the slag, as described in the main patent, are conducted into the condensation chambers, thus enriching the vapour in zinc and facilitating the condensation in liquid form.—B. N.

Metal: Process of carbonising and hardening —. N. H. Bray, San Francisco, Cal. U.S. Pat. 1,207,818, Dec. 12, 1916, Date of appl. Apr. 29, 1914.

METAL is heated to a high temperature by direct application of an oxyacetylene flame containing an excess of acetylene. Potassium cyanide and a solution of salt and copper sulphate are then applied to the metal.—W. E. F. P.

Ores: Process of smelting metallic —. H. L. Doherty, New York. U.S. Pat. 1,207,881, Dec. 12, 1916. Date of appl. June 22, 1909.

A MIXTURE of ore and flux is heated in a rotating chamber, by direct contact with a flame of combustible gas and preheated air, until combination is effected between the gangue and flux; it is then transferred to a rotating reducing chamber in which an atmosphere of carbon monoxide is maintained by the partial combustion of carbonaceous matter in aerial suspension. The charge is mixed with solid reducing material at the point of entry into the second chamber, in which the heating is continued until complete reduction and fusion are effected. The hot reducing gases from the second chamber are employed in admixture with preheated air for heating the first chamber.—W. E. F. P.

Galvanising wire: Furnace for —. G. L. Meaker, Joliet, Ill. U.S. Pat. 1,208,485, Dec. 12, 1916. Date of appl. June 27, 1913.

IN an apparatus having a fire-box at one end and a shallow container for the coating metal (zinc) at the other, the container is provided with a long side tube to serve as an annealing bath; this extends through a horizontal flue to above the fire-box and is then bent upwards to prevent escape of the molten metal and provide an outlet for the treated wire. One end of the horizontal flue communicates with the fire-box and the other with a flue beneath the container, the arrangement being such that the annealing bath is cooled externally by a downward current of air at that part adjoining the container, and heated most strongly at the exit end.—W. E. F. P.

Tinning, tading, and galvanising [small articles]: Mechanical process for —. C. Ziegler. Fr. Pat. 479,970, Oct. 8, 1915.

THE articles to be coated are placed in or upon a perforated vessel or horizontal grid support adapted to be rotated about a vertical axis and, after immersion in the molten metal, drained and whirled to remove excess of the latter. The coated articles are then separated from each other before solidification of the coating metal occurs.—W. E. F. P.

Metals: Method of separating fusible — [from alloys] by fractional distillation. J. Thomson, New York. Assignor to John Thomson Press Co., Jersey City, N.Y. U.S. Pat. 1,208,237, Dec. 12, 1916. Date of appl. Feb. 8, 1916.

THE alloy is heated in one compartment of a container to eliminate the metal having the lowest vaporising point; the residue is displaced by additional charges of alloy, and made to flow

into an adjacent compartment where it is vaporised by a higher temperature. The fumes of the different metals are condensed separately.—W.R.S.

Soldering composition. H. Hess. Fr. Pat. 480,197, Nov. 11, 1915. Under Int. Conv., Oct. 15, 1915.

A PASTE composed of soldering metal powder 85.616—90.97, ammonium chloride 2.53—2.59, glycerin 5.43—5.85, and glue (aqueous) 0.59—1.16%. The glue is prepared by soaking 1 part of glue in 2 parts of water, heating to about 50° C., and mixing the jelly with 1½ times its quantity of glycerin.—W. E. F. P.

Bronze powder: Process of manufacturing —. M. J. Fuchs. Fr. Pat. 480,504, Dec. 23, 1915.

THE coarse alloy is pulverised by stamping in a mill consisting of a series of compartments arranged at successively lower levels. The weight of the stamps decreases in successive compartments, and in each of the latter the dies or anvils are arranged in steps, down which the charge is caused to travel by the vibration produced.—W. E. F. P.

Metal [aluminium]: Manufacture of powdered or granulated —. H. J. Jack and A. G. Løbley. Fr. Pat. 480,563, Dec. 29, 1915. Under Int. Conv., Dec. 6, 1915.

A VERTICAL stream of the molten metal is subjected to the action of a horizontal blast of air or other gas under high pressure, whereby subdivision and solidification of the material is effected.—W. E. F. P.

Tungsten or other analogous metal [for incandescence filaments]: Process and [electric] fusion furnace for the manufacture of coherent ductile —. Soc. Anon. ci-dev. Gimur et Cie. Fr. Pat. 480,819, Jan. 31, 1916. Under Int. Conv., Jan. 15 and July 11, 1914.

COHERENT ductile tungsten is obtained by fusing the metal, and then rapidly cooling by directing a current of air on to the crucible containing it. The fusion furnace is composed of a crucible resting on a fixed base-plate forming one electrode, and surrounded by two concentric heating jackets connected to a common electrode. The tuyères for the cold air are arranged outside the heating jackets along the whole length of the crucible, and within an external insulating jacket. The heating jackets may be raised out of the furnace, a commutator, bound to the lifting arrangement, automatically cutting off the current at the same time, whilst the valve for the air is opened simultaneously.—B. N.

Bronze: New —. E. A. de Lisle and N. A. Hélois. Fr. Pat. 480,928, May 5, 1915.

COPPER-VANADIUM alloy, containing 4 to 5% of vanadium, reduced from the oxides by aluminium, is mixed with electrolytic copper and aluminium to give an alloy containing 0.1 to 0.3% of vanadium and 1% of aluminium, and, when melted, 4% of aluminium is added. The copper-vanadium may be replaced by copper-uranium, or preferably, copper-uranium-vanadium, so as to introduce into the copper, 5 to 7% of aluminium, 0.1 to 0.3% of vanadium, and 0.2 to 0.4% of uranium; a hard resistant alloy is produced, capable of taking a high polish.—B.N.

Metals [aluminium and silicon]: Process and apparatus for obtaining — [from clay, etc.]. Weaver Co. Fr. Pat. 481,056, Feb. 25, 1916.

A MIXTURE of clay, etc., with carbon is heated in an electric furnace in a stream of chlorine and the volatilised aluminium and silicon chlorides are separated by fractional condensation, all the

operations being conducted in an atmosphere free from moisture. The silicon tetrachloride produced is decomposed by intimate contact with molten aluminium with formation of aluminium chloride and silicon; the aluminium chloride is electrolysed in molten sodium chloride, the chlorine liberated in the latter operation being used for treating a further quantity of clay. The process is continuous, the apparatus consisting of a closed system comprising furnace, condenser, receiver, electrolytic vat, and gas reservoir (for chlorine) connected in series, the gas reservoir also communicating with the furnace inlet. The condenser consists of two parts adapted to be cooled to different temperatures; and the interior of the receiver is maintained above atmospheric pressure.—W. E. F. P.

Zinc; Extraction of —. E. S. Berglund. Fr. Pat. 480,633, Jan. 7, 1916. Under Int. Conv., May 31, 1915.

In a process for smelting zinc ores by electrical means, the bulk of the zinc vapour is condensed as liquid metal and the remainder as zinc dust which is subsequently volatilised out of contact with air and re-condensed in the same system. The condenser has two communicating compartments, the first connected with the outlet and the second with the inlet of the electric furnace. Liquid metal is condensed in the first compartment, zinc dust being deposited in the second and conducted therefrom to the interior of the furnace, out of contact with air, by means of a screw conveyor.—W. E. F. P.

Furnaces; Tilling or rolling —. D. F. Campbell, London, and Soc. Electro-Métallurgique Française, Froges, France. Eng. Pat. 102,902, Aug. 9, 1916. (Appl. No. 11,250 of 1916.)

XI.—ELECTRO-CHEMISTRY.

Overvoltage tables. Part IV. The theories of overvoltage and passivity. E. Newbery. Chem. Soc. Trans., 1916, 109, 1359—1368. (See this J., 1916, 1265; 1917, 38.)

ELEMENTS in the same group of the periodic system show the same overvoltage, and when the overvoltage of a metal changes in such a way as to correspond with the typical overvoltage of another group, compounds of that metal are generally known in which the metal has the valency characteristic of the new group. Overvoltage is therefore stated to be probably due to the high solution potentials of compounds of the electrode material with the discharged ion, or with a product of the discharged ion. These compounds tend to form solid solutions in the electrode substance, and are usually stable only under the influence of high pressures or high temperatures. A slight fall of overvoltage is probably due to physical forces, such as the inductive action of escaping ionised gas at high current densities, whilst greater diminution of the overvoltage is more probably due to chemical forces, resulting in the breakage of the electrode surface, the release of internal pressures, and subsequent decomposition of the compounds present. It is probable that compounds of the nature described play a considerable part in the production of thermionic currents. Passivity is stated to be due to the insolubility and good electrical conductivity of the above compounds, which form a protective coating either over the whole surface or over the more easily soluble amorphous phase only. The coating may consist of the pure compound, or of a solid solution of the compound in the electrode substance. The chemical stability of the higher oxides or hydrides formed on the surface of the electrode is of greater importance than the overvoltage, when dealing with substances which are only slowly oxidised or reduced.—B. N.

Sulphuric acid and normal potassium sulphate; Ionisation of — in aqueous solutions of medium concentration. J. A. Muller. Bull. Soc. Chim., 1916, 19, 438—441.

By the electrolysis of dilute sulphuric acid in a divided cell in which the anode was surrounded by a solution of barium chloride, it was shown that the amount of barium sulphate formed in the anode compartment compared with the hydrogen liberated at the cathode corresponded to a molecule of the former to 2 atoms of the latter. This points to the ionisation of the sulphuric acid at the dilution employed (2N) into SO_4'' and 2H^+ , and not into $\text{SO}_4\text{H}'$ and H^+ , since in this latter case the formation of 1 mol. of barium sulphate, according to the equation, $\text{SO}_4\text{H}' + \text{BaCl}_2 =$

$\text{HCl} + \text{BaSO}_4 + \text{Cl}$ would be accompanied by the liberation of only 1 atom of hydrogen, unless the complete electrolysis of the hydrogen chloride were postulated, which however was shown not to be the case by suspending barium carbonate in the anodic solution in a second experiment, when although no free hydrochloric acid could be formed, still the same volume of hydrogen was liberated at the cathode. By a similar method potassium sulphate was shown to be ionised into SO_4' and K' to the exclusion of KSO_4' ions.

—G. F. M.

Electrolyses; Remarks on certain ——. J. A. Muller. Bull. Soc. Chim., 1916, 19, 111–114.

ALTHOUGH in the electrolysis of the system sulphuric acid, barium chloride (see preceding abstract), no barium passes into the cathode compartment, and sulphuric ions equivalent to all the hydrogen liberated are found in the anode compartment, when potassium hydroxide is substituted for the barium chloride a complete interchange of ions is observed, and a considerable difference exists between the hydrogen liberated and that corresponding to the migration of potassium and sulphate ions; this is attributed to an ionisation of the hydroxide into both K' and OH' and also H' and OK' ions. The electrolysis of the system sulphuric acid, hydrochloric acid, gives chlorine at the anode until the concentration of the hydrochloric acid falls below $N/100$, when principally oxygen is liberated. In this case the discrepancy between the observed and calculated volumes of hydrogen liberated is due to the formation of oxygen compounds of chlorine. When a molar solution of auric chloride is placed in the anode compartment, with sulphuric acid in the cathode compartment, neither chlorine nor gold is liberated at the electrodes, and the process resolves itself into an electrolysis of water, catalysed by the auric chloride. This may be due to the formation, decomposition, and re-formation of small quantities of hydroxychlorides of the type $\text{AuCl}(\text{OH})_2$. It is otherwise when a solution of auric chloride alone is electrolysed; in this case gold is deposited and, at the commencement, ozonised oxygen liberated at the anode, accompanied later by chlorine as soon as the concentration of free hydrogen chloride exceeds $N/100$.

PATENTS.

Electrolytic apparatus. R. L. Whitehead, Perth Amboy, N.J., Assignor to American Smelting and Refining Co., Maurer, N.J. U.S. Pats. (A) 1,206,963, and (B) 1,206,965, Dec. 5, 1916. Dates of appl., (A) Feb. 19, 1913 and (B) Apr. 17, 1916.

(A) ELECTRODES are suspended from a bar of conducting material which extends across an electrolytic refining tank, the bar being supported at the ends by suitable members. Contact is made between these members and the bar, and between the bar and electrodes, or between electrodes, by means of a ridge on the one and a recess on the other, the walls of the recess coming into wedging contact with the sides of the ridge. (B) Several electrolytic vats are each provided with sets of anodes and cathodes, the set of anodes having lateral projections for supporting them on

the walls of the vat, whilst the cathodes are each provided with a lateral projection extending beyond the wall of the vat, and making direct contact with an anode in an adjacent vat by bearing thereon by gravity. The set of cathodes may be raised vertically out of the vat, and thus disconnected electrically from the anodes.—B. N.

Separator for storage batteries. W. L. Bliss. Assignor to U.S. Light and Heat Corporation, Niagara Falls, N.Y. U.S. Pat. 1,206,983, Dec. 5, 1916. Date of appl., Mar. 27, 1914.

A FINELY-DIVIDED acid-resisting material, such as asbestos fibre, and a finely-divided soluble material, are mixed with a phenolic condensation product, such as bakelite. The mass is hardened under the combined action of heat and pressure, and treated to dissolve the soluble material.—B. N.

Electrolytic cell. D. Shaw, New York. U.S. Pat. 1,208,722, Dec. 12, 1916. Date of appl., June 22, 1915. Renewed Oct. 11, 1916.

A RECEPTACLE, forming an electrode, is provided with a flange extending laterally from its upper edge; a support, with a central opening closed by a cover plate, is mounted upon the receptacle serving partly to close it, and the support is secured by suitable means to the flange. A sleeve, depending from the edge of the opening of the support, is secured to the top of a porous bag-shaped flexible diaphragm, and an electrode secured to the cover but insulated therefrom, is disposed within the diaphragm. Both the support and the cover plate are provided with gas outlets, for conducting gas from the interior of the receptacle externally of the diaphragm, and from the interior of the diaphragm respectively.—B. N.

Furnaces; Combined plug and cooler for electric arc — working under high pressure. Norsk Hydro-Elektrisk Kvaestofaktieselskab. Fr. Pat. 480,302, Nov. 23, 1915. Under Int. Conv., Dec. 10, 1914.

IN electric arc furnaces working under a high pressure, a hollow plug is attached directly to the outlet tube of the furnace, and is connected with an arrangement for producing an external pressure, and for cooling. For example, the plug may form the flame tube of a steam boiler, whilst in an alternative arrangement, the upper part of the furnace is cooled by a water jacket connected to, and serving as a preheater for, the boiler.—B. N.

Resistance of carbon electrodes; Reducing the ——. Soc. Franç. des Electrodes. Fr. Pat. 480,803, May 3, 1915.

THE resistance of carbon electrodes is diminished by incorporating with the electrode material powdered metals, such as copper, aluminium, etc., or metallic oxides and salts which will yield nascent metals under determined conditions, or natural mineral substances, such as graphite, or a mixture of these.—B. N.

Electrode for electrolytic purposes; Wire ——. M. Huth, Charlottenburg, Assignor to Siemens and Halske A.-G., Berlin. U.S. Pat. 1,209,710, Dec. 26, 1916. Date of appl., July 7, 1916.

XII.—FATS; OILS; WAXES.

Olive pomace; Utilisation of —. W. V. Cruess and A. W. Christie. J. Ind. Eng. Chem., 1917, 9, 45—47.

It is estimated that about 1000 tons of residue ("pomace") are left each year after expression of the oil from olives in California, and at present most of this is wasted. Pomace from eighteen olive factories contained from 7.89 to 20.23%, or 20.98 to 53.81 galls. of oil per ton of the fresh product. This oil could be best extracted by four extractions with petroleum spirit (gasoline), the minimum yield from air-dried pomace being 25.5 galls. per ton. Oils thus extracted from two samples had sp. gr. 0.903 and 0.890 and saponification value 173.8 and 163.2, and contained 11.77 and 64.63% of free acids (as oleic acid) respectively. For soap-making they compared favourably with pure olive oil. Distillation by direct heat removed practically the whole of the solvent from the residual pomace, but it could not be completely separated by distillation with steam. Air-dried samples of the fresh and extracted pomace contained:—Potassium oxide, 0.24 and 0.26; phosphoric acid (P_2O_5), 0.12 and 0.11; and nitrogen 0.86 and 1.00%, respectively. The nitrogen was shown by practical tests to be "unavailable," whilst the amounts of potash and phosphoric acid were no greater than are present in average California soils. Hence the pomace is of no commercial value as a fertiliser.—C. A. M.

PATENTS.

Oil from whale blubber; Process and apparatus for extracting —. Myrens Verksted. Fr. Pat. 479,962, Oct. 8, 1915. Under Int. Conv., Oct. 10, 1914.

WHALE blubber, preferably cut into small pieces, is heated for a short time to coagulate and separate the blood, prior to the expression of the oil. The heating is effected partly by direct and partly by indirect means, to prevent condensation of the steam. For this purpose the vessel is provided with two series of steam conduits, one of which is perforated to allow the steam to escape into the interior of the vessel, whilst in the other the steam is not allowed to escape. After heating, the blubber is conveyed to a press by means of a screw conveyor or the like.—C. A. M.

21	Wolf's "Royal Sovereign"	London	1916	2.91	65.35	32.74	62.56	2.79

The dyestuff was determined by treating the dried powdered pigment with successive small quantities of warm 95% alcohol, and drying the insoluble residue in the water oven. In all the pigments of violet colour the extracted dyestuff gave the reactions of Methyl Violet. The soluble blue pigment in No. 1 was an aniline dyestuff, whilst the pigment of No. 11 contained Prussian blue and Methyl Violet. As part of the ash is derived from impurities in the graphite it is only possible to make an approximate estimation of the relative proportions of graphite and kaolin from the analyses. Impure graphite may contain only about 50 to 70% of carbon, but the better kinds used for pencils generally contain not more than 3 to 4% of impurities (iron oxide, silica, etc.). When the ash is less than 5% (Nos. 4, 12, 13, 16, 17, 20, and 21), it is probable that the mineral matter was derived solely from the graphite. The ash of No. 14 (8.76%), consisting largely of ferric oxide, was also probably due to the graphite. By attributing about 5% of the mineral matter (calculated on the original pigment) to the graphite, and adding this to the loss on ignition, a result approximating to the proportion of impure graphite originally used would be obtained. These pigments may therefore be classified into four main groups, viz.: (1) Those composed of graphite and dyestuff only; (2) those in which the dyestuff has been mixed with approximately equal proportions of graphite and kaolin (Nos. 2, 3, 5, and 8); (3) those in which the kaolin is largely in excess (Nos. 1, 6, 7, 9, 10, 18, 19); and (4) one case (No. 15) where the graphite predominates. Some of the pigments contained alumina (0.59% in No. 3, to 19.37% in No. 18). This affected the extraction of the dyestuff with alcohol, and caused the pigments containing it to give poor copies in copying tests. The copying properties appear to depend on the proportion of the dyestuff, and on the nature of the graphite, as well as on the character of the kaolin. The best copying results were obtained with No. 3 "Ink Eau" and No. 12, Hardtmuth's; the worst with No. 16 "Lapis Tinta" and Nos. 18 and 19 (Swan). The behaviour of the written characters on treatment with a drop of water, or, in other words, their copying properties in miniature, may be used as a means of differentiating between the pigments in writing. Solution tests with drops of acetic acid and of ether may also be applied to the writing, whilst chemical tests with nitric acid and various reducing and oxidising agents will also enable the writings done with the different pigments to be distinguished. A further test with potassium ferrocyanide solution depends on the fact that the iron oxide in these pigments may range from nil to upwards of a third of the total ash. Writing done with these pencils upon wood was sufficiently permanent to resist immersion for over two months in strong salt water, which was frequently shaken and exposed to sunlight.—C. A. M.

Rosin; Sources of — in Germany. [Artificial seasoning of wood.] E. R. Besenfelder. Chem.-Zeit., 1916, 40, 997—1000.

The total production of utilisable conifer wood in 1913 in Germany is estimated at 12,462,000 metric tons, whilst 5,840,563 tons of resinous wood in various forms was imported. By the general adoption of the rapid method of seasoning timber, and by the extraction of sawdust, waste wood, etc., it would be possible to render Germany independent of imported rosin and oil of turpentine. In Schilde's rapid seasoning process (*Der Holzmarkt*, 1916, No. 124) the freshly-sawn timber is heated in a closed vessel and subjected to the action of a steady current of vapour from an organic liquid, preferably a good solvent for resins and fats. This causes the sap to exude from the

wood, and while part falls as liquid to the bottom of the vessel, the remainder passes with the vaporised solvent to a condenser, where the aqueous portion separates and is drawn off. The condensed solvent, charged with rosin, turpentine, fat, etc., is conducted to an evaporator, whence the vapours are returned to the seasoning vessel. The drying process is continued until the water only separates in drops, and it is essential that the solvent should not be allowed to condense within the pores of the wood, since this affects its firmness. So long as moisture is present in the wood the temperature in the vessel keeps below the boiling point of the lower boiling constituent, e.g., at 75° C. when the mixture consists of water and trichlorethylene (b.pt. 88 to 90° C.). After removing the last traces of solvent, and cooling, the wood, which is quite free from cracks, is completely seasoned and sterile, and ready for immediate use for polishing, etc. The process entirely prevents the blue discoloration which is responsible for a considerable loss of timber in the ordinary seasoning process. The extract from the wood varies with the origin, species, and age of the tree. On the average fir yields about 1% of rosin, oil, etc. The thinner the planks of wood the greater the proportion of rosin obtained and *vice versa*. The value of this extract is estimated at not less than M. 1.40 per kilo. (about 7½d. per lb.) Taking it as only M. 1 per kilo. (about 5½d. per lb.), the average annual yield of resinous extract from German-grown wood would be worth M. 124,620,000 (about £6,000,000), while the imported wood would give an extract worth M. 46,225,700 (about £2,250,000). About half of the extract would consist of rosin and turpentine, and the remainder (120,200 metric tons) of fat, mainly compounds of oleic acid. This quantity of fat would be nearly a fourth of that contained in the oil-fruits imported into Germany. Sawdust, waste wood, etc., extracted by this process must be treated as soon as possible, since the solubility of the rosin rapidly decreases on oxidation. The extracted sawdust is particularly suitable for packing purposes and may be used as a filling material for fodder. The extracted material is suitable for making paper pulp, and may also be advantageously used for dry distillation, and has the advantage of yielding a strong pyrolygneous acid. It should also be sufficiently pure for nitration.—C. A. M.

Varnish analysis and varnish control. II. Viscosity of varnishes. M. Y. Seaton, E. J. Probeck, and G. B. Sawyer. J. Ind. Eng. Chem., 1917, 9, 35—40.

For the routine examination of varnishes the use of the Doolittle viscometer is recommended, the results being expressed in "degrees of retardation" in the rotation of a standard cylinder immersed in the varnish at 40° C. In the case of varnishes viscous at that temperature, smaller cylinders of ½ to 1 in. are substituted for the standard 1½ in. cylinder, the results being brought to the standard viscosities by reference to curves showing the relationship between the different cylinders. The two types of solution (true and colloidal) which appear to be present in all varnishes differ materially in their viscosity characteristics. The colloids also show pronounced differences, the "suspensoids" having a viscosity but little higher than that of the dispersion agent, whereas the "emulsoids" may show a very high viscosity. The changes which occur in the viscosity of varnishes during ageing or on the addition of certain solvents can usually be traced to changes in the character of the colloids present. The colloidal material in varnishes is generally present in the emulsoid form and hence shows great variations in viscosity when the concentra-

tion of the varnish is increased, or when the degree of dispersion of the colloid is changed. In the case of varnishes of the true solution type, *e.g.*, those containing much soluble gum and but little polymerised oil, the curves showing the changes in viscosity with the temperature from 20° to 60° C. were very similar in form and quite distinct from the viscosity-temperature curves of varnishes of the colloidal type, which were practically straight lines. Hence by plotting the results obtained at different temperatures it is often possible to obtain information as to the nature of the varnish. As a rule the viscosity of emulsoids rises on decreasing the degree of dispersion, and *vice versa*. Hence on adding a suitable solvent, such as rosin acids or acid linseed oil, to a varnish containing an emulsoid, such as polymerised wood oil, the viscosity should be lowered, and in practice this is found to be the case. In like manner, the addition of an active thinner to a colloidal varnish will change the viscosity temperature graph from a straight line to a curve. The changes which are caused by the degree of dispersion of the colloidal material in varnish are seen in the case of a black baking Japan varnish, which, when incorrectly boiled, increased in viscosity from 83 to 110 in a month. The viscosity was reduced by the addition of rosin oil, which was a solvent for the asphalt, the gradual change in the degree of dispersion of which had caused the increase in the viscosity. By altering the method of manufacture a product was obtained, the viscosity of which fell from 91 to 74 in a month, and then remained constant, showing little change even when additional solvent was introduced. The method is also applicable to the investigation of lithographic linseed oils. One sample, for example, with an original viscosity of 81, gave a reading of 69 after a month, whereas a different type of oil increased in viscosity from 68 to 80 in the same time. The second oil was considered less valuable as a medium for paints. In general it has been found that with stable varnishes the viscosity becomes approximately constant after a month. If the viscosity continues to rise materially after that time it will usually be found that the increase will continue for a long time, until, finally, the varnish becomes unsuitable for general use.—C. A. M.

Linoleum: Manufacture of — and its valuation.
A. de Waele. J. Ind. Eng. Chem., 1917, 9, 6—18.

APART from the tests used by the German Government (this J., 1900, 255), and certain tests devised by Ingle (this J., 1904, 1197), there have been few chemical tests applied to linoleum. With regard to the determination of the "acetone extract" and "unsaponifiable matter insoluble in acetone," which appear in specifications for goods to be supplied to the English Government, it is pointed out that acetone, like ether, will extract an indefinite amount of soluble matter, and that the amount of "unsaponifiable matter" will vary with the conditions of saponification. For example, cork when saponified with alcoholic potash in an open basin yielded 33 to 36% unsaponifiable matter, whereas under a reflux condenser it yielded 72%. It is possible, however, to obtain constant results by saponification with 0.25% aqueous sodium hydroxide solution under a reflux condenser, and the amount of unsaponifiable matter multiplied by 1.13 approximates closely to the amount of cork. *Manufacture of linoleum*:—Taylor-Parnacott or Corticene floor coverings differ from true linoleum in the fact that the oil is prepared by a polymerisation as distinct from an oxidation process. "Taylor cloth" or "cork carpet," is hung for several weeks in a steam-heated room at 120° to 160° F. (49°—71° C.), to convert the coating from the "green"

condition into a leathery product. In the Walton processes for linoleum (see Reid, this J., 1896, 75) the linseed oil is oxidised by boiling with suitable driers and pouring in thin successive layers over cotton fabrics or "serims," or the raw oil is mixed cold with a small amount of insoluble drier and made to fall from a "shower bath" in a continual rain on to the bottom of an inclosed vessel heated by means of steam pipes, the thickened oil being afterwards mixed with 5% of whitening and "smacked" in horizontal steam-jacketed drums containing a horizontal shaft with radial arms. In the Wood-Bedford process the whole of the oxidation is effected in the "smacker" within 48 hours at temperatures up to 110° F. (60° C.), but owing to the speed of the reaction the product is greatly inferior to those obtained by the Walton processes. The oxidised oil, by whichever process obtained, is agitated in a steam-heated pan, while first an eighth of its quantity of melted rosin and then the same amount of gum kauri is run in, and the agitation is continued until the mixture thickens to the required degree, when the hot "cement" is poured on to revolving water-cooled rolls or other cooling device, and, after cooling, is allowed to "hang" or mature for a week or two. *Reactions*:—In the equations suggested by Ingle (this J., 1913, 610) for the change produced in linolein, the position given to the double bonds is not in accordance with the commonly accepted structure for that compound, but there is evidence, in the evolution of volatile substances with aldehydic groupings, for the view that the reaction is one of rupture in the chain in the middle of a peroxide group. In the author's opinion the change is not one of polymerisation, but either a molecular rearrangement of complex groupings or a condensation or both. *Action of solvents on oxidised oils* (see this J., 1892, 550):—On extracting with ether a sample of the dried skin obtained by the scrim process, 67.50% was extracted in 24 hours, but the extraction was not complete after 4½ months, when the extract was 85.32%. Similar results were obtained with alcohol, benzene, chloroform, and acetone, but petroleum spirit of b.pt. 35° to 50° C., although also showing no definite end-point in the extraction, yielded extracts which differed in physical and chemical properties from the extracts obtained with other solvents. For the practical examination of these products two extractions give useful results:—(1) Extraction for 24 hours with petroleum spirit, and (2) extraction of the residue with ether. The petroleum spirit extract is a pale greenish-yellow, fairly mobile oil, which thickens but does not form a skin on exposure, whilst the subsequent ethereal extract is a viscous sticky yellowish-brown oil which dries on exposure, forming a fairly hard elastic skin. Taking "linoxyn" to represent the final insoluble residue, the variations in the distribution of the fractions in the "skins" obtained by the "scrim process" were as follows:—

	1	2	3	4	5	6	7
Linoxyn %	49.57	47.08	43.62	48.41	40.22	57.09	42.46
Ether extract %	31.16	26.79	27.93	29.38	25.45	25.16	32.91
Petroleum spirit extract %	19.27	26.13	26.45	22.21	25.33	17.75	24.63

It was proved that the physical properties of the "skins" were better in proportion to the amount of ether extract, and inversely so to the amount of petroleum spirit extract, whilst the residual linoxyn affected the "body" or solidity of the mass. On this basis No. 6 would be classed a

poor sample, whilst No. 7, in which the linseed oil is oxidised with a special drier, would be considered an excellent one, as in practice proved to be the case. In similar tests with oxidised oils prepared by the Walton "shower-bath" process, the following results were obtained:—

		1	2	3	4	5	6
Linoxyn	%	40.2	32.4	50.0	42.2	37.4	37.7
Ether extract	%	35.0	38.1	30.3	31.2	29.6	34.9
Petroleum spirit extract	%	21.7	27.7	18.3	26.3	33.0	26.4

The higher ether extracts of these products compared with those made by the "serim" process account for their superior tenacity and binding power, and explain why they alone are suitable for the manufacture of "Walton Inlaid." The following results obtained with Taylor-Parnacott or Corticine oil show why it is impossible to use that product for making inlaid linoleum and also explain its low covering power:—Linoxyn, 60.4; ether extract, 9.6; and petroleum spirit extract, 30.0%. *Linoxyn and "cyclofin"*:—The substance insoluble in ether which is obtained by polymerising linseed oil by heat has been provisionally termed "cyclofin." It differs in a pronounced way from the linoxyn produced in the oxidation of linseed oil. Thus its saponification value does not exceed that of the raw oil, it is difficult to saponify, and is very stable, whilst it contains no oxidised acid. Again, linoxyn is completely soluble in amyl alcohol at 120° C. (6 to 8 hours), whereas cyclofin swells up but only dissolves to the extent of about 20% in that solvent. Similar experiments with other oxidised oils and with polymerised wood oil showed that as a general rule oxidised oils are completely soluble, whilst polymerised (solid) oils contain an insoluble portion. In every case in which unchanged polymerised wood oil was used in linoleum cement it could be recognised by this method. *Resins and Chinese wood oil in cements*:—From experiments on these lines the following conclusions were drawn:—(1) At least 20% of resins must be present to obtain the maximum conversion of the oily matter into a substance with high binding capacity. (2) If resin is the only resin present, the "body" (as measured by the linoxyn) is liable to fall below the practicable limit. (3) The presence of gum kauri is essential for the reduction of greasiness (petroleum spirit extract). (4) Chinese wood oil (the use of which has been patented as a substitute for kauri gum) has no chemical influence on the transformation, but is disadvantageous as it reduces the amount of oxidised oil in the mixture. (5) The best proportions for the three ingredients are about 80% of oil, 10% of kauri gum, and 10% of resin. —C. A. M.

PATENTS.

Drying rooms especially intended for baking enamel on to metallic surfaces. A. E. White, London. From Reliance Drying Room Co., Chicago, U.S.A. Eng. Pat. 102,539, Feb. 9, 1916. (Appl. No. 1929 of 1916.)

The drying chamber is provided with a turn table floor, part of which (substantially a half) projects outside. This floor is divided into, preferably equal, sections by a vertical partition, which moves with the floor and in one position engages with the walls to close the chamber. The heating compartment surrounding the inner walls of the chamber is preferably made to conform sub-

stantially to the shape of the inner portion of the turntable, whilst a fan or blower may be provided at the top to deliver downward currents of hot air into the drying chamber. Whilst the charge of material on the portion of the floor within the chamber is being dried, a fresh charge is being arranged on the portion of the floor outside the chamber. —C. A. M.

Enamel on metallic surfaces; Air-circulating systems for drying rooms for baking—A. E. White, London. From Reliance Drying Room Co., Chicago, U.S.A. Eng. Pat. 102,685, Feb. 9, 1916. (Appl. No. 7046 of 1916.)

The drying room comprises a drying and heating chamber in communication with each other at the top and bottom of a vertical partition separating them. A pipe system communicating with the chambers at the bottom leads upward therefrom to a fan or blower which discharges air downwards into the drying chamber; ventilating pipes leading from this chamber are provided for removal of foul or saturated air; these converge together into a single flue to a suitable point of discharge. The system is preferably used in conjunction with a drying room provided with a turntable floor (see preceding abstract). —T. H. B.

Phenols, formaldehyde, and salts of sulpho-acids; Process for obtaining solid products of condensation from—K. Tarassoff, Moscow, and P. Shestakoff, Petrograd. Eng. Pat. 102,635, Jan. 20, 1916. (Appl. No. 956 of 1916.)

SOLID, infusible, and insoluble products are obtained by condensing phenols with formaldehyde in presence of ammonium, alkali, or alkaline-earth salts of sulpho-acids (preferably naphtha sulpho-acids or sulpho-aromatic fatty acids), and of an acid which does not decompose such salts. For example, 300 parts by weight of "commercial carbolic acid 99–100% cresols," is gradually mixed with 135 parts of a 40% solution of sodium salts of naphtha sulpho-acids, 9 parts of hydrochloric acid (sp.gr. 1.14), and 150 parts of 40% aqueous formaldehyde, and heated to 65°–70° C. A resinous liquid mass separates with a watery layer on top; the latter is removed and the resinous mass heated until there is a loss of 70–75 parts by weight of the total materials used. After cooling to 35–45° C., 120 parts by weight of aqueous 40% formaldehyde is added and the whole mixed to a homogeneous mobile liquid, which is poured into moulds, left to rest some hours, then gradually heated for one hour to 45° C., then, at intervals, by 10°–15° at a time, to 100° C. —T. H. B.

Hard compositions; Production of—from formaldehyde and phenols with carbohydrates, albuminous materials, and tannins. K. Tarassoff, Moscow, Russia. Eng. Pat. 102,751, Jan. 19, 1916. (Appl. No. 892 of 1916.)

THE process described in Eng. Pat. 7560 of 1914 (see also Eng. Pat. 528, and 6716 of 1914; this J., 1914, 557; 1915, 187, 1201), according to which organic bodies containing no aldehyde, phenol, or sulpho-groups, or substances in which these groups are not essential constituents, may be caused to take part in the reactions between phenols and formaldehyde, in the presence of one or more organic sulpho-acids, is now modified by the inclusion of carbohydrates, albuminous materials, and tannins amongst these "fillers." For example (1) carbolic acid, 100; a 37% solution of naphtha sulpho-acids, 50; egg albumin, 20; and water 50 grms. are heated at 75°–80° C.

until the added water is evaporated. The mass is cooled and formaldehyde (40%), 40 grms., is added. When the reaction, which takes place at 60°–80° C. moderates, a further 50 grms. of water is driven off by heating, the mass cooled to 25°–30° C., and formaldehyde (40%), 50 grms., added. The viscous liquid is poured into moulds and left for 10–12 hrs., and the hardening process is then completed by heating up to 75° C. for half-an-hour, up to 85°–90° C. for 1–2 hours, and at 100° C. for an equal length of time; 205 grms. of a very hard, elastic, non-fusible, non-transparent, bluish-yellow solid is obtained. The egg albumin may be replaced by blood albumin, gelatin, casein, glue, etc. (2) Carbohydric acid, 100; formaldehyde (40%), 50; sulpho-acid solution, 50; and wheat starch, 30 grms. are heated together to 40–45° C.; heat is evolved and a jelly is formed which thins on boiling, the starch being deposited. The mixture is rendered homogeneous by stirring, and 55–60 grms. of water is then evaporated by heating. The mass is cooled to 20–25° C., formaldehyde (40%), 40 grms., is added, and the viscous tarry mass is then poured into moulds and heat-treated as in example (1); 200–215 grms. of hard, rose-coloured, infusible, elastic material is obtained. (3) With carbohydric acid, 100; sulpho-acid solution (40%), 50; crystalline tannin solution (50%), 60; and formaldehyde (40%), 40 grms., heated to 60–80° C., and then until 70–75 grms. of water has been driven off, subsequently cooled, mixed with formaldehyde (40%) 50 grms., and hardened off in moulds as before, a hard, infusible, "chestnut-yellow" mass is obtained.—E. W. L.

Vulcanised oils: Preparation of solutions of —, obtained by the action of sulphur chloride, in amyl acetate. M. Poto. Fr. Pat. 480,939, Feb. 12, 1916.

The oil, e.g., castor oil, 1 kilo., is intimately mixed with amyl acetate, 2 litres, and sulphur chloride, 250 grms., is then stirred in. A stiff, almost colourless jelly is formed, which gives off large quantities of hydrogen chloride, resulting from the decomposition of some acetyl chloride produced during the reaction. When left in a hermetically closed vessel for several days, this product completely liquefies, the vulcanised oil passing into solution. Sodium or barium or other carbonate, or sodium thiosulphate—but preferably barium carbonate—is added to neutralise the free acid present, and the solution is then decanted and filtered. This solution may be used for impregnating fabrics and other materials, or it may be mixed with other solvents, and nitrocellulose, as well as with soluble colours and pigments, and used for varnishing black and coloured leathers and for a variety of other purposes.—E. W. L.

White pigment of the lithopone type: Inalterable —. R. B. Llopert. Fr. Pats. 180,846 and 180,847, Feb. 2, 1916. Under Int. Conv., Feb. 19 and Mar. 16, 1915.

Vulcanisation; Circulation and exhausting apparatus for —. A. E. Alexander, London. From Goodyear's Metallic Rubber Shoe Co., Naugatuck, Conn., U.S.A. Eng. Pat. 102,802, Aug. 29, 1916. (Appl. No. 12,204 of 1916.)

IN apparatus for vulcanising rubber boots and similar articles, in which a difference of pressure is maintained between the inside of the perforated forms on which the articles are mounted and the heated fluid (gaseous) medium surrounding the articles, a certain leakage of the medium (e.g., carbon dioxide) into the interior of the forms occurs. Loss of heat units and of heating medium is minimised, according to the invention, by inserting an exhaust pump in series with the low pressure and the high pressure sides and thus returning the gaseous leakage quickly through a preheater, to the high pressure atmosphere of the vulcaniser. Good circulation is ensured by running a branch pipe from within the vulcaniser, opposite the gas inlet, to the suction end of the pump. The interior of the forms communicates with the hollow frame of the trolley which carries them, and this in turn is connected with the external suction pipe of the pump.—E. W. L.

Vulcanisable composition: Process of manufacture of a —. J. S. Campbell. Fr. Pat. 479,960, Oct. 8, 1915.

FINELY divided leather is heated with oil or fat, and whilst continuing the heating, caustic soda or potash (sufficient to saponify the oil), vegetable fibrous material, magnesia, filling material, such as steatite or chalk, and a binding material such as gum or caoutchouc are successively added at intervals, and the whole thoroughly mixed. The mass is then dried and worked up by passing between cylinders, during which operation sulphur or some other vulcanising agent is added. The material may then be made into sheets, etc., and vulcanised.—F. C. T.

XVI.—SOILS; FERTILISERS.

Phosphoric acid: Valuation of water-soluble as compared with citrate-soluble—E. J. Franke. J. Ind. Eng. Chem., 1917, 9, 51—55.

IN the reports of some of the American experimental stations the "valuations" or "trade-values" for water-soluble phosphoric acid have been put at higher figures than those for citrate-soluble phosphoric acid, although these "values" are not intended to show the agricultural value of the products. Moreover they are not justified by the selling prices. Thus the cost of the available (water-soluble plus citrate-soluble) phosphoric acid in acid phosphate (superphosphate) decreases with the rise in the proportion of water-soluble to citrate-soluble phosphoric acid, whilst citrate-soluble acid in organic phosphates costs more per unit than does the available acid in superphosphate.—C. XVII.—SUGARS; STARCHES; GUMS.

Invertase; Presence of—in cane sugars from Demerara and St. Domingo. H. Pellet. Bull. Assoc. Chim. Sucr., 1916, 33, 263—266.

MAQUENNE has detected the presence of invertase in raw cane sugars from Demerara and St.

Domingo, particularly the former. It originates, doubtless, from micro-organisms, probably bacteria of the type described by Lewton-Brain and Deere (this J., 1909, 845), which develop in the finished sugar under suitable conditions of humidity and temperature. The presence of invertase explains why in order to avoid rapid decomposition of sucrose, liquors should be submitted as soon as possible to a temperature of 90—100 °C., and also why the presence of certain antiseptics is not efficacious in preventing alteration of the syrups and other products. It suggests that to obviate decomposition of solutions of cane sugar products, it is desirable to destroy the enzyme by heating to a moderate temperature in presence of an alkali, and also to operate with highly concentrated solutions.—J. P. O.

Clarification [of sugar cane juices]; Processes for the— with direct filtration through presses. C. Fribourg. Bull. Assoc. Chim. Sucr., 1916, 33, 227—255.

THE author has shown previously that after treatment with kieselguhr and dicalcium phosphate, it is possible to filter defecated cane juice in its entirety through filter-presses and obtain a clear liquor and good cake, instead of following the present more lengthy system of decantation and after-treatment of the "bottoms" and scums. Further details are now given, and it is pointed out that the total filtration of juice in this way is impossible when soluble phosphates alone (that is, phosphoric acid and monocalcium phosphate from concentrated superphosphate and acid phosphate) are added to the juice already sulphited and lined as usual, the effect being to produce a gelatinous precipitate which prevents filtration in presses. On the other hand, kieselguhr alone at the rate of 2.5 kilos. per 1000 litres of juice produces the desired effect, although no appreciable increase of purity results. Soluble phosphates in conjunction with kieselguhr cause an increase of purity, while allowing of direct filtration, but a relatively large amount of kieselguhr is required. Economical and generally satisfactory results with an appreciable increase of purity are stated to be obtained by the use of a mixture of kieselguhr and dicalcium phosphate (insoluble) in the proportion of 2 : 1, and employing 3—4 kilos. (or 4—5 kilos. with low purities) per 1000 litres of the juice after it has been submitted to sulphiting and liming as usual. Under these conditions the filtering surface required will be 50 sqm. per 100 tons of cane worked, the process is rapid and simple, and there is a marked saving in labour and steam. The amount of press-cake (dry state) obtained per 1000 litres of juice, with ordinary sulphitation and defecation, is 6—8 kilos., while with the further addition of both kieselguhr and dicalcium phosphate it is 11—12.5 kilos., and all or almost all the phosphoric acid added can be recovered with that normally present in the juice, giving a cake containing 5 to 14% of phosphoric acid, 7 to 8% of nitrogen, and 10 to 20% of lime, which forms a useful fertiliser in the cane field.—J. P. O.

Sugar; Quantitative determination of minute amounts of— by α -naphthol and the estimation of entrainment losses [in sugar factories]. A. F. Blake. Int. Sugar J., 1917, 19, 26—28.

TRACES of sucrose in water, up to 100 parts per million, can be estimated, with a possible error of 20% for pure solutions, by the following method. Ten c.c. of concentrated sulphuric acid is added carefully to 5 c.c. of the liquid under test containing 5 drops of a 20% solution of α -naphthol in pure alcohol; the mixture is stirred vigorously and after 2 mins. the purple colour

produced when sugar is present is compared with a series of standards. The standards for concentrations of sugar up to 20 parts per million are made by mixing solutions of cobalt nitrate and copper sulphate; those for larger amounts are made from red and blue organic dyestuffs and require to be renewed about once a month. Vessels of uniform size should be employed and should not be wiped with a cloth before use. The presence of iron in the liquid interferes somewhat with the test, and products from the destructive distillation of low-grade materials vitiate it entirely. With the salt water from condensers the test has given perfect satisfaction. The author applies it to the examination of condensed water from evaporation, employing a device (illustrated in the original paper) for taking periodic samples from the condenser fall pipe; by this means the losses from evaporator entrainment are determined regularly.—J. H. L.

Sucrose; Simplified inversion process for the determination of—by double polarisation. H. S. Walker. Hawaiian Chem. Assoc., Oct. 12, 1916. Int. Sugar J., 1917, 19, 31—35.

THE following method of inversion, applied to the determination of sucrose in pure sugar and in waste molasses, gave percentage values rarely differing by more than 0.1 from those obtained by Herzfeld's method. Seventy-five c.c. of the solution to be inverted (normal strength for sugars and half-normal for molasses), in a 100 c.c. flask, is heated in a water bath to 65° C., then withdrawn from the bath, treated with 10 c.c. of a mixture of equal volumes of hydrochloric acid (sp. gr. 1.188) and water, and allowed to cool spontaneously in the air for 15 mins. or as much longer as may be convenient. After being cooled to the ordinary temperature the liquid is made up to 100 c.c. and polarised as usual. In the case of products which have been clarified with a large excess of basic lead acetate, the excess alkalinity is neutralised before heating, e.g., by addition of 1 or if necessary 2 c.c. of the dilute acid. A considerable latitude appears to be permissible as regards the temperature of the sugar solutions when the acid is added (63°—70° C.), and the rate of cooling as influenced by the temperature of the laboratory (in the author's experiments this seems to have been in the neighbourhood of 26° C.) and the thickness of the glass flasks.—J. H. L.

Sugar; Report on—. [Modification of the Clerget process of double polarisation. Use of invertase as hydrolyst in the double polarisation method.] C. A. Browne. J. Assoc. Off. Agric. Chem., 1916, 2, 131—143.

IN the original Clerget process, in which 50 c.c. of the normal or half-normal sugar weight solution is made up to 55 c.c. with hydrochloric acid and inverted, there is a diminution in volume due to the following three causes: (1) the contraction following on inversion; (2) the increase of temperature produced by the addition of the hydrochloric acid; and (3) the evaporation of water from the neck of the flask during heating, the combined influence of these causing the diminution of the volume of the 55 c.c. by 0.33 c.c. for the half-normal weight of 13 grms. In order to eliminate all three sources of error, it is proposed to make up the volume of the solution after and not before inversion, the process being thus made more exact than any modification involving dilution to 100 c.c., in which any error is multiplied by 2. It is further recommended that inversion be made at the ordinary temperature over-night. The sucrose is calculated by the following formula allowing for differences in specific rota-

tion caused by varying concentration when less than the normal weight of 26 grms. is taken; A is the direct polarisation and B the invert polarisation corrected for increase of volume, and t is the temperature at which the invert solution is read:—

$$100(A-B) \\ 144.9 - \frac{t}{2} - 0.01 \left[141.9 - \frac{t}{2} - (A-B) \right]$$

Hudson's method of double polarisation using invertase as hydrolyst (this J., 1910, 143), in which the lead used for the clarification of the product is eliminated by sodium carbonate or potassium oxalate, is shown to give far more accurate results than the method of acid inversion in the analysis of complex mixtures containing sucrose and levulose. For purposes of commercial analysis, however, it cannot at present displace acid inversion, the preparation of the invertase solution being troublesome, and the whole process requiring much care and watchfulness, but it is invaluable as a control upon other methods.

—J. P. O.

Decolorising carbons; Action of different—on pure and impure sugar solutions, and their influence in the analysis of sugar factory products. H. Pellet. Bull. Assoc. Chim. Sucri., 1916, 33, 220—227.

DECOLORISING carbons of different origin vary considerably in their properties. Thus, "Eponit" (this J., 1911, 146, 1177) has a density of 250 grms. per litre, carbon from the shells of cherry-stones one of 573, while ordinary unwashed animal charcoal has one of 895. Similarly, their decolorising power and ash content show wide differences, the latter varying from 1.5% (cherry-stone carbon) to 81.8 (animal charcoal) per 100 of dry substance. When used as clarifying agents in the double polarisation method of determining sucrose, all adsorb a greater or less quantity of sugar, and with 100 c.c. of a pure solution of sucrose, originally polarising 26.85°, the reading after the addition of 2 grms. of the different grades was as follows: "Eponit," 25.80°, animal charcoal, washed successively with hydrochloric acid and water, and dried, 26.20°, ordinary unwashed animal charcoal, 26.20°, and cherry-stone carbon, 26.80°. In the case of solutions of sugar factory products defecated with basic or normal lead acetate, the adsorption is less, while in that of liquids first treated with basic lead acetate and afterwards with excess of sulphurous acid, that is under the conditions of the sulphurous acid direct polarisation method, practically no diminution could be observed. On the contrary, a slight increase, averaging 0.15° with a polarisation of about 28.0°, was noticed, this being apparently due to the adsorption of lead salt, the effect of which on the optically-active amino-acid derivatives causing a levorotation was thus modified. An adsorption of optically-active substances in unfermented cane vinasse by decolorising carbons was also demonstrated, but cupric reducing substances contained in both beet and cane molasses do not appear to be affected.—J. P. O.

Raffinose; Determination of—in presence of sucrose by double inversion using top and bottom fermentation yeasts. H. Pellet. Bull. Assoc. Chim. Sucri., 1916, 33, 255—262.

OWING to the presence in beet sugar factory products of optically-active amino-acids and their derivatives, the rotation of which depends upon the reaction of the solution, whether alkaline or acid, the ordinary method of determining raffinose by acid inversion is subject to an appreciable error. On examining the method of double fermentation by top and bottom yeasts suggested by Bau, and elaborated by Hudson and Harding (this J., 1915,

1905), the author obtained good results, both in pure solutions as well as in the presence of dextrose, levulose, lactose, maltose, and other carbohydrates. In the case, however, of very impure liquids, as molasses, though equally reliable results are obtainable, fermentation is very slow, particularly with the bottom fermentation yeast, and demands about 7 hours, sometimes much longer. It is important that both the fermented liquids should be examined at the same temperature, and in order to avoid any error from adopting corrections, it is advisable to read throughout at 20° C. With a product obtained by the desaccharification of molasses by the strontia process, it was observed that the difference between the ordinary and the acid direct polarisations was very slight, this being due to the fact that the optically-active substances capable of causing differences are almost entirely removed with the mother-liquors, after their decomposition.—J. P. O.

Carbohydrates; Methods for the estimation of mixtures of four or more — involving oxidation with bromine. E. G. Wilson and W. R. G. Atkins. *Biochem. J.* 1916, **10**, 501–521. *Analyst*, 1917, **42**, 19–20.

DEXTROSE and maltose are quantitatively oxidised by bromine at the ordinary temperature when their solutions are saturated with bromine and allowed to stand: the liquid, however, still retains a small amount of its original cupric-reducing power. Levulose is not oxidised at all, or only to a very small extent, under these conditions, whilst in presence of *N*/10 sulphuric acid there is a slight loss of levulose in 68 hours at the ordinary temperature. A mixture of sucrose, maltose, dextrose, and levulose may be analysed as follows:—The sucrose is determined by polarisation and reduction before and after treatment with invertase. The resulting mixture of reducing sugars is treated with bromine under standard conditions of acidity and temperature for a given time (see following abstract), whereby dextrose and maltose are oxidised, whilst levulose remains unaffected: the reducing power of the solution may be taken as due to levulose only, the result being corrected for the portion derived from the sucrose. By subtracting the rotation due to sucrose and levulose from the initial rotation, the rotation due to dextrose and maltose is obtained, and in like manner by subtracting the reduction due to levulose from the initial reduction, the reduction due to dextrose and maltose is obtained. The amounts of dextrose and maltose can then be calculated.

It was observed that addition of dilute alkali (*N*/2 or 2*N* sodium hydroxide) to a solution of dextrose, levulose, or maltose, produces a large temporary increase in the reducing power of the solution.

Honey and other substances containing levulose; Analysis of —. W. R. G. Atkins. *Analyst*, 1917, **42**, 12–13.

THE method of Wilson and Atkins (see preceding abstract) of oxidising sugars other than levulose by means of bromine is rapid, and although less accurate than the fermentation method of Davis and Daish (this *J.*, 1913, 1025), gives fairly good results in the analysis of mixtures of dextrose, levulose, and maltose. An excess of bromine is added to the solution, which should contain sufficient sulphuric acid to make the strength decinormal, and the flask is kept in constant agitation for 12 hours at the ordinary temperature. After the oxidation the maltose retains only a trace of its cupric-reducing power and the dextrose, about 1% thereof, whilst the levulose shows a reduction of approximately 1 to 2% in reducing power

owing to its decomposition by the *N*/10 sulphuric acid and the hydrobromic acid produced during the oxidation of the other sugars. This loss in the quantity of levulose is approximately balanced by the residual reducing power from the other sugars. After removal of the excess of bromine by means of gaseous sulphur dioxide and finally by titration with a solution of sulphurous acid, the solution is rendered only slightly acid or neutral (but not alkaline) by the addition of potassium carbonate, and the reducing power of an aliquot portion is determined. For this purpose Kendall's solution (this *J.*, 1912, 351) is suitable as it does not dissolve the cupric oxide, and the amount of levulose may then be found by reference to the author's table (*Biochem. J.*, 1916, **10**, 137). In the case of honey or other mixtures containing only dextrose and levulose, sufficiently accurate results are obtained by determining the reducing power before and after the oxidation. For the determination of sucrose in honey the reducing power is determined before and after inversion, and the inverted solution afterwards oxidised with bromine, due allowance being made for the dextrose and levulose produced by the inversion. The method of oxidation with bromine affords an easy means of detecting abnormal quantities of dextrose in honey, jams, etc.—C. A. M.

Fructose [levulose]; Evidence indicating the existence of a new variety of —. A reactive form of methylfructoside. J. C. Irvine and G. Robertson. *Chem. Soc. Trans.*, 1916, **109**, 1305–1314.

IN a previous paper (this *J.*, 1915, 627) some derivatives of a new highly reactive form of glucose (dextrose), γ -glucose, differing from the well-known α - and β -modifications presumably in the position of the oxide link, were described. It would now appear that this γ -type is represented also in the case of the other monohexoses, galactose and fructose. One of the characters of this series is the ready formation and equally ready hydrolysis of the methylglucosides and fructosides, which are hydrolysed, like sucrose, on warming with highly dilute acids. There is a strong presumption in favour of the view that the fructose component of sucrose belongs to the new γ -type, whereas the glucose component is of the ordinary type. The evidence on which the view of the existence of " γ -fructose" is based is largely contained in work by Purdie and Paul (*Chem. Soc. Trans.*, 1907, **91**, 289) on the formation of tetramethylfructose from the crude methylfructoside obtained, according to Fischer, by the condensation of fructose with methyl alcohol containing 0.5% of hydrogen chloride. This reaction proceeds readily at 35° C. and in this respect shows a marked difference from the mode of preparation of alkylglucosides where prolonged heating at 100° C. is generally required. The product is obviously a mixture and its resolution is complicated by the fact, now first ascertained, that the portion of the methylfructoside corresponding with the new γ -modification of the sugar combines readily with whatever traces of acetone may be present in the methyl alcohol employed, yielding methylfructoside-monoacetone, which can only be isolated by fractional distillation under the highest vacua afforded by the Gaede pump. Two distinct tetramethylfructoses, a crystalline and a liquid modification, are formed from the mixture, which must contain at least four isomeric methylfructosides: two of the latter correspond to the ordinary form of fructose (α and β) and two to the new γ -form which also is capable of existing in α and β modifications. The specific rotation of these new modifications of fructose when in equilibrium is low and is probably dextro in sign; the melting points of the sugars would be lower than those of the ordinary

form: they may be syrups. Taking the analogy of γ -glucose, it is assumed that γ -fructose contains the ethylene oxide ring, while the ordinary fructose contains the butylene oxide linkage.—J. P. B.

Galactose: Determination of free and combined —.

A. W. van der Haar. Chem. Weekblad. 1916. 13, 1204—1213.

THE galactose is oxidised by means of nitric acid and the resulting mucic acid is weighed, as first suggested by Creydt (*Dissert.*, Erlangen, 1888). From 0.25 to 1 gm. is mixed with 60 c.c. of nitric acid (sp.gr. 1.15 at 15° C.) in a beaker 12 cm. high by 60 mm. in diameter, which is immersed in a boiling water bath. The contents are stirred at intervals and the heating continued until the liquid is reduced to less than 20 grms., when the mixture is cooled and made up to 20 grms. with water. After the addition of 0.5 gm. of dry mucic acid which has been purified by recrystallisation from alcohol, the liquid is left for 18 hours at 15° C., and the deposit of mucic acid is then collected on an asbestos filter in a Gooch crucible, washed with 5 c.c. of water, and dried at 100° C. until constant in weight, the weight of mucic acid added to promote the crystallisation being afterwards deducted. For the determination of galactose in glucosides or polysaccharides, from 0.25 to 1 gm. of the anhydrous substance is hydrolysed with 25 c.c. of 2 to 5% sulphuric acid, and the liquid filtered, after 24 hours, from any insoluble products. The filtrate and washings are concentrated, rendered slightly alkaline with sodium hydroxide solution, made up to 30 c.c., and treated with 30 c.c. of 50% nitric acid, and as much sucrose as corresponds to the non-sugar part of the glucoside (e.g., sapogenins). The oxidation is then effected as described above. From the weights of mucic acid obtained the corresponding quantities of galactose may be found by reference to the following tables (intermediate figures may be obtained by interpolation):—

I. *Galactose alone.*

Mucic acid.	Galactose.	Mucic acid.	Galactose.
mgms.	mgms.	mgms.	mgms.
— 4	0	366	500
+ 0.8	10	455	600

Gum-yielding plants of Brazil. H. Montandon. Chacanas e Quintaes, 1916. 13, 417—421. Bull. Agr. Intell., 1916, 7, 1295—1296.

SUBSTITUTES for gum arabic are obtained from the following Brazilian plants:—(1) Different species of "angico," *Enterolobium ellipticum* (*Pithecolob-*

ium gummiferum); (2) "Arvore da gomma" or "gomma lagrima" (*Vochisia gummifera*), which is common in the province of Rio de Janeiro; and (3) "Vinheiro do Campo" or "Arvore do vinho" (*Vochisia thyrsoidea*), which is common in the State of Minas Geraes. The best quality or "gomma lagrima" is free from impurities and is perfectly colourless and transparent. It is completely soluble in 11 parts of cold water, yielding a colourless, transparent mucilage. A sample with sp.gr. 1.601 at 26° C. had the following composition:—Water, 11.79; arabin, 87.67; yellow bitter substance, 0.03; resinous substance 0.01; insoluble matter, 0.012; and ash, 0.41%. Experiments made by Pizarro showed that the gum of *Vochisia thyrsoidea* has 10 times the adhesive power of gum arabic, and is quite equal to it in medicinal properties. Consignments of Brazil gum have been exported to Liverpool and to Germany from 1900 onwards.—C. A. M.

Utilisation of diseased potatoes as fodder and industrial raw material. Wehmer. See XIXA.

PATENTS.

Fondant [sugar cream]; Manufacture of —.

P. H. Schluter, Chicago, Ill. U.S. Pat. 1,201,357, Oct. 17, 1916. Date of appl. Mar. 8, 1916.

FOR making fondant or sugar-cream for filling sweetmeats, a suitable charge of sugar, e.g., 25 lb. of pure cane sugar and 5 lb. of glucose, is mixed with only sufficient water to effect complete solution on boiling, and the solution is boiled in the open air until it attains a temperature corresponding to 228° F. (109° C.) at sea level. The charge is then subjected to a vacuum as complete as possible (28—28.5 ins.) and as soon as vigorous ebullition has set in, the application of heat is discontinued and evaporation allowed to proceed under vacuum until the syrup reaches a density corresponding to a boiling point of 238° F. (114.5° C.) in the open air. During the evaporation of the syrup without the application of heat, the temperature will have become so reduced that the operation of heating to cream may proceed immediately. The apparatus may consist of a pan and gas-heated furnace mounted on lifting gear beneath a hood connected with a vacuum pump, so that boiling in the open or *in vacuo* may be carried out by lowering or raising the pan.

—J. F. B.

Sugar; Process for the manufacture of —. O.

Carr, Asheville, N.C. U.S. Pat. 1,201,936. Oct. 17, 1916. Date of appl. Sept. 9, 1914.

SUGAR juice, either raw or treated with precipitating agents, is atomised into an air-chamber in which the moisture of the juice is absorbed by the air at a moderate temperature and the solids are rapidly deposited as a dry powder. The non-sugar impurities of the juice in the dried state are soluble with difficulty in cold water and especially after treatment of the original juice with lime, aluminium hydroxide, or metallic salt precipitating agents. The sugar solids are dissolved by lixiviation preferably in the cold; suitable substances may be added to the lixiviating water to prevent solution of impurities, e.g., lime, alcohol, etc. The solution may be clarified by carbonation or decolorising agents, and evaporated either by atomising or boiling to "grain" in the usual manner.—J. F. B.

Sugar beets; Process of treating —, and the product derived therefrom. G. H. Benjamin, New York.

U.S. Pat. 1,207,810, Dec. 12, 1916. Date of appl. Dec. 17, 1911.

BET slices are dried, e.g., by air at about 170° F.

(77° C.) until about 90% of their moisture has been removed, in such a way as to coagulate the coagulable matters without destroying the enzymes, rupturing the cell walls, or rendering them incapable of permitting osmosis when the dried product is subsequently treated by the diffusion process. The dried product may be treated with a material which will prevent fermentation or mouldiness.—J. H. L.

Bleaching liquids [sugar juices]: Apparatus for —, L. J. Foret, Lockport, La., U.S. Pat. 1,208,531, Dec. 12, 1916. Date of appl. Jan. 22, 1916.

The apparatus comprises a vertical cylinder provided with a series of annular ribs fixed to the interior wall, a series of annular shelves loosely mounted on the ribs, each formed of two semi-circular segments, a vertical rotary spindle projecting downwards through the centre of the casing and provided with a series of circular discs overlapping the inner edges of the annular shelves, and means for introducing liquid into the upper part and gas into the lower part of the casing and for discharging waste gas from the upper part and the treated liquid from the lower part.—J. H. L.

Starch: Process for making soluble —, J. Kantorowicz, Breslau, Germany, U.S. Pat. 1,207,177, Dec. 5, 1916. Date of appl. Oct. 19, 1914.

SOLUBLE starch, solutions of which do not solidify or gelatinise at ordinary temperatures, is made by acting on starch with organic acids together with substances which convert starch into soluble starch, e.g., persalts, with or without mineral acids.—J. H. L.

XVIII.—FERMENTATION INDUSTRIES.

Malts: Comparative studies of floor-, drum-, and box —, L. Adler, Z. ges. Brauw., 1916, 39, 201–201, 217–221, 225–226.

THREE malts were prepared from the same barley by germinating (1) on floors, (2) in a Galland malting drum, and (3) by the Kropff system (this J., 1912, 39). All the malts were kilned under similar conditions. In germinating by the Kropff system, the barley, after four days on the malting floors, was transferred to a box in which it formed a layer 3 feet deep on a perforated floor, and in which it was aerated for about an hour after successive resting periods of 6, 6, 10, 10, 21, and 21 hours. The three malts were subjected to a very thorough investigation. In almost all respects the characters of the floor malt were intermediate between those of the other two. The Kropff malt, owing to restricted respiration during the later stages of germination, showed a smaller malting loss than the others, but it was darker in colour. It was further distinguished by the activity of its diastatic, proteolytic, and acid-forming enzymes and its phosphatases, and by rapid saccharification and high yield of extract. The wort from it filtered rapidly and well, possessed a high acidity as determined by titration, and exhibited a coarsely flocculent "break." The drum-malt, on the other hand, was characterised by high malting loss, defective modification, and weak enzymic activity. It saccharified less rapidly than the others and gave a lower yield of extract. The wort from it possessed a lower acidity as determined by titration, but a higher concentration of hydrogen ions, than either of the others; this is attributed to its relative poverty in respect of proteolytic

products, which exert a "buffer" action towards acids. The quality of the drum-malt could probably have been improved by rotating the drum less frequently and reducing the aeration during the germinating process.—J. H. L.

Fermentation: Loss [of sugar] in alcoholic —, L. Lindet, Comptes rend., 1917, 164, 58–61.

THE author designates as "fermentation loss" the proportion of sugar decomposed which cannot be accounted for, in accordance with Gay Lussac's equation, by the quantity of alcohol produced. This loss is due to the formation of various by-products accompanying yeast growth, and its magnitude in relation to the amount of yeast produced varies according to the nature of the nutritive substances present. In fermentation experiments with pure sucrose solutions containing only salts, including ammonium sulphate as source of nitrogen, the fermentation loss was on the average about 17 times as great as the weight of the yeast crop (dry substance) which itself amounted to only about 0.85% of the weight of sugar decomposed, and the loss consisted to the extent of $\frac{2}{3}$ of carbon dioxide. The loss was practically the same when ammonium tartrate, lactate, or acetate was used instead of sulphate, and it was not much less when urea or asparagine was employed. In similar solutions, however, containing also 2% of substances such as gum arabic, tannin, or peat humus, fermentation was much more rapid, the yeast crop was approximately trebled, and the fermentation loss, relatively to the yeast crop, was reduced to one-third of its former value. These results were not very different from those obtained in media, such as beer wort, containing ready-formed proteins. The author concludes that of all the carbohydrates studied, except arabinose and xylose, sucrose is the least readily assimilated by yeast, the latter having great difficulty in synthesising proteins from sucrose and ammoniacal or amide nitrogen. On the other hand, in presence of gum arabic, tannin, etc., and ammoniacal or amide nitrogen, yeast develops almost as readily as in media containing proteins.—J. H. L.

Beer: Pre-mashing and protein-haze. Concentration of hydrogen ions in — and in the course of its manufacture, F. Emslander, Woch. Brau., 1916, 33, 169–171.

THE author's experience with pre-mashing confirms the statement of Windisch (this J., 1916, 1170) that this practice increases the yield of extract from malt, but using a hard brewing water he found that pre-mashing tended to render the beer more difficult to clarify. This difficulty was in large measure overcome by boiling the water before use. An explanation of the influence of pre-mashing on clarification is suggested. In an electric field the constituents of beer which are liable to separate on chilling, migrate towards the anode and are therefore alkaline in character. The author suggests that they consist of compounds of lime or magnesia with proteolytic products which, owing to the severance of peptide linkages and consequent liberation of acid groups, have acquired the power of combining with bases. Since pre-mashing assists proteolysis it is therefore likely to accentuate the formation of protein-haze in beers made from waters rich in lime and magnesia.—J. H. L.

Beer: Sterilisation of — by filtration, E. Zahm, Brewers' J., 1917, 53, 37–40.

THE sterilisation of beer by pasteurisation injuriously affects the flavour and character; it also arrests or

destroys the action of the enzymes, so that much of the value of the beer as a foodstuff is lost. The ordinary pulp beer filters do not sterilise effectively not because the pulp fibres are incapable of holding back micro-organisms, but because of the mobility of the material under fluctuations of pressure: rigid filtering beds are absolutely necessary. These are constructed of kieselguhr compressed in a moist condition into blocks 12 ins. long and 3 ins. square, which are then fired in a kiln like porcelain. The blocks are turned to cylinders of 2 ins. diam., bored, and fitted with a head-piece screwed and cemented into the bore and provided with a tubular neck. These filter cylinders are tested for efficiency by immersing them in water and subjecting them to a gas pressure of 6 lb. per sq. in., it having been determined that resistance to this pressure of gas in water corresponds with an effective resistance to the passage of micro-organisms. The filters comprise a pair of units each containing 55 filter cylinders, the beer is pumped through a pressure-governor into the inlet chambers of the units and passes through the filter cylinders into the outlet chambers and thence to the bottling machine. The governor varies the pressure in the inlet chamber as the demand for beer at the bottling machine increases or decreases the difference in pressure required to force the beer through the filters. The necks of the filter cylinders pass through orifices in two partitions forming an open chamber, so that in the event of any leakage in the fittings, the escaping beer falls into this chamber and not into the discharge chamber. The whole apparatus is sterilised with hot water at 180° F. (82° C.) before use and then tested collectively by displacing the water in the inlet chamber with carbon dioxide under a pressure of 6 lb.; if there is a defective tube bubbles of gas will be seen rising through the water and the cover must be removed and the tube plugged. A filter with 110 cylinders has a capacity of 50 pint bottles per hour. Sterilisation by filtration involves effective sterilisation of the bottles. This is done with hot alkaline solution and water in an automatic machine fitted with brushes. The bottles are cooled gradually with water sprays and pass, without handling, to the beer bottling machine.—J. F. B.

Ammonia [from nitrogen in brewing materials: Determination of—by the boric acid method. L. Adler. Z. ges. Brauw., 1916, 39, 161–161, 169–172. (See Winkler, this J., 1913, 185; 1915, 79.)

In applying Winkler's method to the determination of nitrogen in brewing materials, the author obtained accurate results by using a water-cooled condenser dipping (for the first 15 mins. of distillation) into 50 c.c. of a 1% solution of crystallised boric acid, this quantity of acid sufficing for the quantitative absorption of amounts of ammonia up to 70 mgrms. and possibly beyond. The distillate after addition of a few drops of a 0.05% solution of methyl orange was titrated with standard sulphuric acid with the help of a colour standard prepared by treating 250 c.c. of distilled water with a few drops of methyl orange and 0.15 c.c. of N/10 sulphuric acid.—J. H. L.

Rum distillery: Scientific control of a —. F. L. Seard. Int. Sugar J., 1916, 18, 198–502.

For the complete control of a rum distillery, the data required are as follows: (1) the amount of "sweets" (as dextrose) entering into the process; (2) the degree of attenuation, from which the amount of alcohol formed by fermentation is calculated and compared with the theoretical quantity to be expected from the "sweets" used to set up the wash; (3) the amount of spirit

actually distilled, and the relation between it and the theoretical amount; (4) the examination of the spent wash for alcohol as a check upon the operation of the still; and (5) the amount of esters in the spirit. In addition the observation must be determined, *i.e.*, the error in the determination of the alcohol concentration by the hydrometer due to the colouring matter added to the rum. "Faults" are indicated by diluting the rum with twice or its own volume of water and allowing it to stand in a cylinder for 24 hours, any cloudiness formed being due to: (A) resinous matter from the wood of the cask; (B) the use of a too highly burnt colouring; or (C) the presence of substances of the fusel oil class, which during distillation should have been retained in the low wines.—J. P. O.

Oxydase activity of plant juices and their hydrogen ion concentrations: Relationship existing between—, with a note on the cause of oxydase activity in plant tissue. H. H. Bunzell. J. Biol. Chem., 1916, 28, 315–333.

WHILE the results of the experiments recorded do not establish clearly the quantitative relationship existing between the extent of the oxydase activity of a plant material and the hydrogen ion concentration existing in the medium, it appears that this relationship consists of two factors—one the direct destructive effect of the acidity on the active matter, the other the retardation of the rate of oxidation by the hydrogen ions. The hydrogen ion concentrations corresponding with complete inhibition cover a rather narrow range for each type of plant material (for potato, 3.55 to 3.70; for tulip tree material, 2.30 to 2.80), and it would seem that this acid sensitiveness is nearly constant for different genera of the same family. It would appear that the oxydase activity of plants is controlled by some constituent which is easily destroyed by acids, by heat, or by alcohol, and which changes gradually to an inactive form on standing in aqueous solution, but will keep practically indefinitely when dry. Proteins would fulfil these requirements; like all colloids, the proteins in tissues may exist in a greater or less degree of dispersion and have a more or less active surface accordingly. Condensation of oxygen on the surface of the colloid particles may explain the oxydase activity either by means of the greatly increased rate of reaction due to increased oxygen concentration, or by an increased oxidation potential of the oxygen when in such condition.

—W. P. S.

PATENTS.

Grape juice and process of preparing the same. A. Fonzo, Chicago, Ill. U.S. Pat. 1,207,011. Dec. 5, 1916. Date of appl., Mar. 25, 1916.

THE acid-content of grape juice is increased by a proportion of a palatable acid, *e.g.*, 0.1–1.0% of lactic acid, which may be produced by lactic fermentation.—J. H. L.

Distillation: Apparatus for continuous —. E. A. Chenard. Fr. Pat. 180,558, Dec. 24, 1915.

THE liquid to be distilled, *e.g.*, alcohol, passes by the pipe, 1, to the tubular heater, A, where it is raised to a temperature below 75° C., and thence through the tubes, 3, and pipe, 1, to the cylinder, D. A rotating shaft, E, carries a helical conveyor which transports the liquid to the outlet, F. Steam entering by the pipe, G, takes up vapour from the heated liquid and carries it through the pipe, 5, to the cylinder, H, provided with baffles, 6. Progressive condensation occurs by contact with the

tubes, 3, containing cooler liquid, and the condensed liquid passes by pipes, 7, to the vapour pipe, 5, so that the vapour becomes richer in alcohol as it passes to the outlet, K. An enlarged

mouthpiece, L, admits the vapour to the preliminary heater, A, and the mixture is fractionated by withdrawing separate portions from the pipes, O, N, and condensed liquid from the pipe, M.

—W. F. F.

Alcohol of high strength and strong aroma: Process of manufacturing — particularly colonial rums. P. M. H. Hervé, Fr. Pat. 480,601, Dec. 10, 1915.

THE wash is distilled through any ordinary distillation column so as to produce a distillate containing about 25% of alcohol; the distillate is then re-distilled through a rectifying column to obtain a spirit containing 77% of alcohol.

—W. P. S.

Industrial preparation of mixed cream of tartar [potassium and sodium bitartrates], and soda cream of tartar [sodium bitartrate]. Fr. Pat. 480,620. See VII.

XIXA.—FOODS.

Phosphatides in milk; Distribution of —. T. B. Osborne and A. J. Wakeman, J. Biol. Chem., 1916, 28, 1—9.

ALCOHOL removes from milk casein, which has been precipitated by dilute hydrochloric acid, about the same quantity of phosphatides as was obtained previously from the lactalbumin separated by heating the filtrate from the casein (this J., 1915, 883); since the amount of casein is more than six times that of the lactalbumin, the proportion of phosphatides in the casein is correspondingly less. When skimmed milk, freed from casein and heat-coagulable proteins, is neutralised with sodium hydroxide, the precipitate formed contains a very small amount of the same phosphatides and fatty substances that can be obtained from the alcohol washings of the lactalbumin; the non-protein fractions of fat-free milk contain only minute traces of phosphatides. The total quantity of phosphatides present in 1 litre of whole milk is about 27 mgms. Phosphatides are intimately associated with the protein constituents of milk and are possibly combined with them as "lecithalbumins."—W. P. S.

Casein; Influence of carbohydrates on the accuracy of the Van Slyke method in the hydrolysis of —. E. B. Hart and B. Sure, J. Biol. Chem., 1916, 28, 211—219.

THE presence of carbohydrates during the hydrolysis

of casein by the Van Slyke method brings about a total redistribution of the amino-acids and this varies with the nature of the carbohydrate. The redistribution is particularly marked in the hexone bases and a decided loss of amino-nitrogen also takes place when the protein is hydrolysed in the presence of xylan. The method of direct hydrolysis is, therefore, unreliable when applied to the determination of amino-acids in feeding stuffs; owing to the variation in the nature and quantity of the carbohydrates in feeding stuffs, it is impossible to establish factors of correction for the results. (See also Gortner, this J., 1916, 1030; Roxas, *ibid.*, 1916, 1174.)—W. P. S.

Kafirin, an alcohol-soluble protein from kafir (Andropogon sorghum). C. O. Johns and J. F. Brewster, J. Biol. Chem., 1916, 28, 59—65.

A NEW alcohol-soluble protein was separated from kafir seeds; it constitutes more than one-half of the protein in the seed, and has been named *kafirin*. It resembles zein in its composition, but differs from the latter in that it coagulates readily. Kafirin contains tryptophane and lysine, both of which are lacking in zein, and, when examined by the Van Slyke method, differences are found in the distribution of nitrogen in the two substances. Kafir is now an important cereal crop in the United States. In 1910, three million acres was under cultivation and the value of the crop was \$30,000,000.—W. P. S.

Proteins from the Jack bean (Canavalia ensiformis). D. B. Jones and C. O. Johns, J. Biol. Chem., 1916, 28, 67—75.

Two globulins, canavalin and concanavalin, and an albumin of the legumelin type were isolated from the jack bean. The distribution of nitrogen in canavalin and the albumin was:—

	Canavalin	Albumin
	g.	%
Human nitrogen	0.28	0.23
Amide nitrogen	1.41	1.16
Basic nitrogen	8.17	3.73
Non-basic nitrogen	11.55	11.18
Total nitrogen	16.41	16.30

—W. P. S.

Proteins of the peanut, Arachis hypogaea. The globulins arachin and conarachin. C. O. Johns and D. B. Jones, J. Biol. Chem., 1916, 28, 77—87.

TWO globulins, arachin and conarachin, separated from peanut (earthnut) meal, contained 0.4 and 1.09% of sulphur, respectively. Arachin contained 4.96%, and conarachin 6.55% of basic nitrogen, the latter being the highest percentage of basic nitrogen recorded for any seed protein. Peanut cake will probably prove highly effective in supplementing food products made from cereals and other seeds the proteins of which are deficient in basic amino-acids.—W. P. S.

Protein-copper compounds. T. B. Osborne and C. S. Leavenworth, J. Biol. Chem., 1916, 28, 109—123.

WHEN copper sulphate solution was added to a slightly alkaline edestin solution, the whole of the protein was precipitated when the mixture became neutral; further addition of copper sulphate resulted in the formation of a basic salt; by adding sodium hydroxide solution to a mixture of edestin and copper sulphate solution, edestin free from

copper was at first precipitated, whilst with further addition of alkali the basic copper salt was precipitated. It was possible to obtain an edestin-copper compound containing 35% of copper, but this compound was unstable. A compound which gave the biured coloration in alkaline solution contained 12.7% of copper. Similar results were obtained in the case of gliadin. The precipitates did not represent definite copper compounds of the proteins, the amount of copper hydroxide available for combination being determined by the quantity of sodium hydroxide present in the protein solution.—W. P. S.

Rices of Bihar and Orissa, J. N. Sen, Arg. Research Inst., Pusa, Bull. No. 62, 1916, pp. 1-20.

EIGHTEEN samples of rice grown on Government farms in Bihar and Orissa, India, were examined; the average results obtained were as follows:—

	Husked rice.	Polished rice.
Moisture.....	11.95	10.80
Ether-extract	2.36	0.88
Proteins	7.48	7.25
Soluble carbohydrates ..	75.86	79.99
Woody fibre	0.76	0.20
Ash	1.59	0.79
Phosphoric acid	0.70	0.36
Potash	9.36	0.22

"Husked" rice indicates rice which was simply husked, i.e., rice "in the bran," whilst "polished" rice had had much of the "skin" and germ removed by the polishing operation. The composition of the rices is similar to that of other rices, especially of Burma rice.—W. P. S.

Potatoes: Utilisation of diseased — as fodder and industrial raw material, C. Wehmer, Jahresversamml. Ver. angew. Botanik, Frankfurt, Sept., 1916. Chem.-Zeit., 1916, 40, 1073.

THE normal annual production of potatoes in Germany is estimated at about 50 million metric tons. Assuming the loss through disease, freezing, etc., to be only 0.25%, it would be equivalent to at least 100,000 metric cwt. of starch. Experiments on a large scale have proved the practicability of utilising decomposed potatoes to obtain a sound, tasteless product, containing about 50% of starch and 6% of nitrogen, which has given good results in feeding experiments. The tubers may be treated either by a wet process (separation of starch by disintegration in water) or preferably by a dry process. With slight modification of the process it is also possible to separate the starch in the usual way, but for the preparation of pastes, dextrin, alcohol, etc., this is unnecessary, since the diseased potatoes may be directly hydrolysed with acid.—C. A. M.

Fruits and vegetables: Conversion of — into dried products, V. Valvassori, Atti. R. Acad. Econ.-agr., Florence, 1916, 13, 56-61. Bull. Agr. Intell., 1916, 7, 1353-1355.

In the case of pears and apples, the best results were obtained by subjecting the peeled and halved fruits to the action of sulphur dioxide for 10-15 mins., followed by treatment with steam for 5-10 mins., and then drying them at 80-90° C. for 8 hours. Stoned peaches and apricots were sulphured for 15 mins. and then dried at 80-90° C. for 8 hours. Plums were steamed for 90 secs., or immersed in boiling 5% potassium carbonate solution and then rinsed in cold water; they were dried first at 50° C., then at 70° C., and

finally at 90° C. Good results were obtained by either treatment. Cherries were steamed for 5 mins. and then dried at 85° C. for 12 hours, whilst figs were peeled, cut in halves, then treated with sulphur dioxide for 30 mins. and dried at 50° C. for 2 or 3 days. Vegetables, including potatoes, carrots, cabbage, cauliflower, spinach, celery, peas, beans, onions, leeks, turnips, and turnip tops were scalded or steamed and then dried at 10° to 60° C.—W. P. S.

Cherry by-products: Utilisation of —, F. Rabak, U.S. Dept. Agric., Bull. No. 350, 1916. Bull. Agr. Intell., 1916, 7, 1355-1357.

ABOUT 1400 tons of cherry-stones and 112,000 galls. of juice are obtained as by-products in the cherry-preserving industry of the United States; these products are wasted at present but it would be quite possible to turn them into valuable commercial products. By treating the crushed stones with a solvent 8.3% of a fatty oil (pit oil) can be obtained, or, if the kernels alone are taken, and submitted to pressure, about 30% of fatty oil is obtained; the resulting cake, when steeped in water and steam-distilled, yields about 1% of a volatile oil. The oils have the following characters:—*Stone oil*, Sp. gr. at 25° C., 0.9137; n_D^{25} = 1.4611; solidifying pt., 12° C.; saponif. value, 179.7; iodine value, 93.7; Reichert-Meissl value, 3.7; insoluble fatty acids, 92.5%; acetyl value, 3.45; unsaponifiable matter, 1.12%. *Kernel oil*, Sp. gr. at 25° C., 0.9092; n_D^{25} = 1.4635; solidif. pt., 13° C.; saponif. value, 180.8; iodine value, 92.8; Reichert-Meissl value, 4.7; insoluble fatty acids, 92.8%; acetyl value, 12.67; unsaponifiable matter, 0.44%. *Volatile oil*, Sp. gr. at 4° C., 1.012; hydrocyanic acid, 7.91%; benzoic acid, 67.95%. The fatty oil does not differ essentially from sweet almond oil, whilst the volatile oil is, for all practical purposes, similar to that of bitter almonds. The pressed cake, after removal of the oils, is useful as a cattle food. It contains: Moisture, 1.05; proteins, 30.87; ash, 3.94; cellulose, 8.90; ether extract, 13.10%. The juice from the stones is a bright red liquid; it may be concentrated, after neutralisation with lime and filtration, to a syrup, or fermented to produce alcohol. With the addition of pectin and sugar, the concentrated juice forms an excellent jelly.—W. P. S.

Analysis of honey and other substances containing larvulose, Atkins. See XVII.

Relationship existing between oxydase activity of plant juices and their hydrogen ion concentration, with a note on the cause of oxydase activity in plant tissue, Bunzell. See XVIII.

PATENTS.

Food products: Process of making [fatty] —, T. B. Walker, Austin, Tex. U.S. Pat. 1,206,951, Dec. 5, 1916. Date of appl. Dec. 16, 1914.

A PRODUCT containing about 22% of stearin is made from an edible fatty material by hydrogenation, and then incorporated with a different edible fatty material to impart a flavour and consistency resembling those of a natural edible fat. A product resembling lard may thus be prepared from hydrogenated cottonseed oil and oily lard.—J. H. L.

Alimentary pastes and other products: Drying chamber for —, G. Falchi, Fr. Pat. 480,975, Feb. 15, 1916.

The paste, e.g., macaroni, etc., is placed on trays

or hung on supports arranged on a wheeled carriage and the latter is run into a closed chamber; air is pumped into the chamber and the current is distributed by fans; adjustable ventilators are provided for the escape of the air so that the rate of drying may be regulated.—W. P. S.

Casein; Process for treating —, A. Bartels, Harburg, Germany. U.S. Pat. 1,209,539, Dec. 19, 1916. Date of appl. Dec. 28, 1915. Renewed Aug. 16, 1916.

SEE Eng. Pat. 13,203 of 1915; this J., 1916, 1125.

Artificial milk; Process for the manufacture of —, and treatment of its residues, W. J. Melluish, Upper Parkstone. U.S. Pat. 1,210,667, Jan. 2, 1917. Date of appl. Oct. 22, 1915.

SEE Eng. Pat. 13,903 of 1915; this J., 1916, 1031.

Separation of casein and albumin from creamery sewage. Eng. Pat. 18,023. See XIXB.

XIXB.—WATER PURIFICATION ; SANITATION.

Oxygen (in water); Determination of — by Winkler's method, G. Bruhns, Chem.-Zeit., 1916, 40, 985—987, 1011—1013. (See this J., 1916, 138.)

DETAILS of further small improvements in Winkler's process for the determination of dissolved oxygen are given. *N* 100 Thiosulphate was found to be very satisfactory for titration and to keep well, particularly if made slightly alkaline to phenolphthalein. In the process, after precipitation has been effected, if the liquid completely clarifies upon standing, the greater part may be siphoned off and only the residue treated with potassium iodide and acid; the result is slightly more accurate owing to the small volume of liquid titrated. Long standing, however, is not desirable as the result may be affected by impurities in the water. When potassium bicarbonate is used, some gas bubbles are observed in the liquid after the crystals have dissolved; these bubbles are due to contraction of the liquid and are without influence on the result. The blue colour which reappears a short time after titration is due to delayed decomposition of the iodine-potassium iodide complex; the error thus caused does not, however, amount to more than 0.006—0.008 "per 1000 normal" (*loc. cit.*). A little additional blue colour may be produced subsequently owing to the catalytic action of manganese salts, the action of light, and the presence of nitrites.—J. H. J.

Boiler-feed water; Determination of sodium and calcium bicarbonates in —, M. Monkaupf, Chem.-Zeit., 1916, 40, 1011—1013.

THE case of a boiler water is considered which contains only bicarbonate alkalinity and is therefore neutral to phenolphthalein. The determination consists of two titrations with *N* 10 acid in presence of methyl orange, firstly directly on the water, secondly after addition of *N* 10 caustic soda equal to the acid used and removal of the precipitate by filtration. The acid used in the first titration is subtracted from that used in the second, and the result multiplied by 8.1, gives the amount of sodium bicarbonate in mgrms. per 100 c.c., if 100 c.c. of the water was taken. The acid used in the second titration is subtracted from twice that used in the first, and the result multiplied by 2.8 gives the amount of lime in the form of bicar-

bonate. Should there be a trace of phenolphthalein alkalinity in the water, this is titrated with the acid, and twice the result is subtracted from the second titration before calculating the sodium bicarbonate content. Calcium sulphate can only be present in the absence of sodium bicarbonate, and in this case twice the phenolphthalein alkalinity must be subtracted from the first titration before calculating the lime content. Salts of magnesium cause no irregularities in the method.—J. H. J.

Tobacco smoke; Removal of nicotine from —, J. Tóth and K. Dangehrer, Chem.-Zeit., 1916, 40, 1013.

IT was found that many tobaccos yield a smoke containing large quantities of free nicotine, which can be extracted by passing the smoke through a cotton-wool plug treated with tannin. In some cases as much as 12.3% of the total nicotine can be recovered in this way. It is suggested that the use of such plugs by smokers would be of advantage from a health point of view.—J. H. J.

Flavine and Brilliant Green; new and powerful antiseptics, Browning and others. See XX.

Use of diphenylamine and diphenylbenzidine for colorimetric determinations, Smith. See XXIII.

PATENTS.

Sewage; Method of and apparatus for the treatment and purification of —, E. B. Martin, Eccles, Lancs. Eng. Pat. 17,163, Dec. 14, 1915.

THE apparatus consists of a cylindrical tank, divided into segments, each segment forming a treatment unit. The apparatus may be worked on the continuous flow or on the quiescent system, or on a combination of both. The sewage enters any one segment where it meets with activated sludge, and the mixture is agitated by air blown in from the bottom and evenly distributed by baffle-plates. The treated sewage overflows into a radial trough in which any sludge settles out and is run back into the segment, while the liquid flows over a weir and is led into the next segment for further treatment. One or more of the last segments is used as a settling tank before the completely purified liquid is discharged. One segment is always being emptied and cleaned in the cycle of working. The activated sludge is run out from each segment into a central well. The volume of air supplied to any segment can be varied at will by adjustable valves.—J. H. J.

Creamery sewage; Separation of casein and albumin from —, G. Ebrill and T. Kiersey, Dublin. Eng. Pat. 18,023, Dec. 21, 1915.

CREAMERY sewage, *i.e.*, any waste water containing milk or milk constituents, is treated with sulphuric acid (about 1.5 lb. of acid per 1000 lb. of skimmed milk contained in the sewage) and then led into a tank where it is aerated. The precipitated casein floats on the surface of the liquid and is discharged over the side of the tank into a collecting channel, an inclined baffle-plate being provided to guide the frothy precipitate over the side of the tank. The acidified liquid may be passed through a series of such aerating tanks. To remove albumin, the liquid, from which the casein has been separated, is treated with lime and conducted through a second similar series of aerating tanks. The aerating means are situated at the bottom of the tanks and consist of porous carbon tubes through which the air is forced so that it issues in a finely divided state.—W. P. S.

Sewage: Process of disposing of — A. Potter, New York. U.S. Pat. 1,207,621, Dec. 5, 1916. Date of appl., Oct. 18, 1913.

THE sewage flows at a very slow rate through a tank of such shape as to facilitate the deposition of the sludge, which is allowed to digest, and is then raised, a part allowed to flow away with the liquid from the tank, and a part allowed to return to the sludge space.—J. H. J.

Water-softener: Process for producing a — G. H. Widner, Assignor to Des Moines Refining Co., Des Moines, Iowa. U.S. Pat. 1,207,826, Dec. 12, 1916. Date of appl., Aug. 10, 1916.

A MINERAL containing hydrated aluminium silicate is dried to remove free moisture, ground to a suitable size, mixed with salt, and baked without fusing until hard enough to withstand the powdering action of water. It is then stored in water.—J. H. J.

Water: Process and apparatus for softening — L. Linden. Fr. Pat. 480,108, Dec. 13, 1915.

THE water is conducted into the upper part of a vertical cylinder containing perforated baffle-plates, certain of which are of copper and are connected with a source of electric current; carbon dioxide is also admitted to this part of the apparatus. The water then passes through filters (perforated metal plates supporting a layer of fabric and a layer of coke) placed across the cylinder, and is next distributed over the surface of horizontal plates in the lower half of the cylinder supporting layers of spongy aluminium. Some of these plates are connected with a source of electric current, and if necessary, carbon dioxide may be introduced. The water finally passes through a spongy iron filter and is collected at the bottom of the cylinder.—W. P. S.

Disinfectant, antiseptic, deodorant, and detergent materials. C. Billing, New York. Eng. Pat. 16,410, Nov. 20, 1915.

THE material consists essentially of a mixture of 2 parts of an alkali monoborate with 1 part of an alkali diborate, with or without sodium chloride. A fluid form is prepared by dissolving 136.24 parts by weight of caustic potash (90%) and 115.8 parts of boric acid in 150 parts of water, and when the solution is cold, adding water until the specific gravity is 1.42 at 60° F. (15.5° C.). Chlorides or hypochlorites may be added. A solid form is prepared by dissolving 89 parts by weight of caustic soda (70%) in 90 parts of water, adding 138 parts of borax, and heating with stirring until fluid; then allowing to cool, and continuing the stirring, until granular. About 116 parts of sodium chloride is then added, so that the product shall contain 10% of anhydrous borate.—J. H. J.

Tins: Treatment of waste — in a dust-destroyer. E. J. Lovegrove, London. Eng. Pat. 102,693, June 15, 1916. (Appl. No. 8119 of 1916.)

A CHAMBER for the treatment of the tins is placed beside a dust-destroyer, so that the whole or a portion of the flue gases can be passed through it. The chamber consists of a furnace with hopper at top, an entrance for flue gases below the hopper, and an exit at the bottom of the chamber. On each side wall below the grate, two plates are fixed, sloping towards a trough in the centre. The tins are fed into the chamber through the hopper, which is then closed, and the dampers controlling the gas pipes are opened to allow the flue gas to pass down through the mass of tins, between the sloping plates below the grate, and out. Dirt attached

to the tins is burned off, the solder is melted, drops on to the sloping plates, and runs into the trough. When the solder is all collected, the inlet pipes for the gases are closed, the trough of solder withdrawn, and the tins removed through a side door.—J. H. J.

XX.—ORGANIC PRODUCTS; MEDICINAL SUBSTANCES; ESSENTIAL OILS.

Flavine and Brilliant Green: new and powerful antiseptics. C. H. Browning, R. Gulbransen, E. L. Kenaway, and L. H. D. Thornton. Report to the Medical Research Committee. British Medical J., Jan. 20, 1917. Pharm. J., 1917, 98, 73—74.

IN the case of all antiseptics in common use, a concentration which is sufficient to cause death of the organisms is also detrimental to phagocytosis. Thus, phenol kills organisms and inhibits phagocytosis at a concentration of 1:250 to 1:500, and mercury perchloride exerts both effects at 1:7,000 to 1:10,000. On the other hand, Brilliant Green kills cocci at 1:30,000 and only inhibits phagocytosis at 1:2,000, whilst Flavine kills both cocci and *B. coli* at a concentration of 1:100,000, whereas to affect phagocytosis a concentration greater than 1:500 is required. Of all the compounds examined, Flavine stands out as possessing the highest sum of desirable properties for therapeutic purposes, and tested clinically, the results as regards both Flavine and Brilliant Green have been eminently satisfactory, and the indications are that they will largely supersede the toxic antiseptics at present employed. Flavine (diamino-methyl-acridinium-chloride), which is likely to be the more generally useful of the two, was originally prepared by Benda (see this J., 1912, 678), and was found to have a very marked effect on trypanosome infections. Attention was first drawn by Browning and Gilmore to the powerful action of this substance on bacteria. On account of its trypanocidal action the compound was called Trypoflavine, but as its range of use promises to be much wider it is more convenient to denote it simply as Flavine. It is a fairly stable substance, and solutions may be boiled or heated up to 120° C. in the autoclave. Hitherto the preparation of Flavine has been worked out by Drs. Barger and Ewins in the chemical laboratory of the department of biochemistry and pharmacology of the Medical Research Committee, but arrangements have now been made for the commercial production of the compound on a larger scale. The products will be tested biologically at the Bland-Sutton Institute of the Middlesex Hospital, and will be available for trial on application to Dr. Browning on behalf of the Medical Research Committee.

Alloxan: Preparation of — H. Biltz and M. Heyn. Annalen, 1916, 413, 69—67.

WHILE chlorine has no action on uric acid suspended in boiling acetic acid, oxidation to alloxan occurs in the presence of three or more mols. of water, and by leading a rapid stream of chlorine through a mixture of 300 c.c. of glacial acetic acid and 50 c.c. of water in which 100 grms. of finely divided uric acid was suspended, a yield of 60—65 grms. of alloxan monohydrate was obtained after about 15 mins. chlorination, the completion of the reaction being indicated by the passing into solution of the uric acid and the deposition of coarse heavy crystals of the alloxan monohydrate. By recrystallisation from water, and if crude uric acid has been employed, decolorisation with

animal charcoal, colourless crystals of alloxan tetrahydrate are obtainable. The preparation of alloxan by this method is sufficiently rapid to be adapted to a lecture experiment.

As an addendum to the paper the microscopic identification of the methylated uric acids by the crystal form obtained by precipitation from solution in concentrated sulphuric acid by dilution with water is recommended.—G. F. M.

Urethane: Influence of acid radicles containing different alkyl groups on the narcotic action of —, J. Odaira, Mem. Coll. Sci., Kyoto Imp. Univ., 1916, 1, 319–340.

NUMEROUS acyl derivatives of urethane were synthesised by the action of the corresponding acid chlorides on this substance, and their physiological action was compared by experiments on rabbits and frogs. The narcotic action of urethane was strengthened by the acylation of the amino-group, and more particularly so when the acid residue contained a secondary alkyl group. Thus diethylacetylurethane, or detonal, and ethyl-propylacetylurethane, or epronal, are both more effective than the parent substance, and epronal is almost equal to veronal (diethylbarbituric acid) and hedonal (methylpropylcarbinol) urethane in the duration of narcotic action, and in addition much more rapid in action. It seems probable that a further increase in the number of carbon atoms up to propylbutyl- or dibutyl-acetylurethane still further increases the strength of the narcotic action. The minimum effective dose of epronal, which was studied more closely than the other substances, was 0.3–0.5 gm. per kilo. of body weight for a rabbit, whilst 2.5–3.0 grms. caused death in 20–50 hours. In doses of 1.5 grms. per kilo. the blood pressure remained normal, and the vagus and respiratory centres were not affected, but the action on the heart becomes more and more effective with the higher homologues as the narcotic action increases. N-Iso-amylurethane, which differs from detonal only by the absence of the carbonyl group, although a somewhat stronger narcotic, is far more poisonous than detonal.—G. F. M.

Cyanamide from calcium cyanamide: Preparation of —, E. A. Werner, Chem. Soc. Trans., 1916, 109, 1325–1327.

THE stability of cyanamide in the presence of acetic acid has been utilised to prepare it from calcium cyanamide, 100 grms. of the latter being added, in portions of 15 grms. each, to 125 grms. of pure acetic acid and 120 grms. of water in a cooled mortar with constant stirring. The pasty mass is well kneaded, and dried in the air for 24 hours. The easily-powdered solid is then extracted six or seven times with ether in a Soxhlet, the extract concentrated by distillation at a gentle heat, and finally evaporated to dryness in a desiccator over sodium hydroxide. The yield varied from 91 to 96% of the theoretical value. It is of great importance that the mass, before extraction with ether, be faintly acid throughout.—B. N.

Saurool, a substitute for ichthyol. L. Méran, Vet. Rec., 1916, 287. Pharm. J., 1917, 98, 43.

SAUROOL is an oil obtained by distilling a bituminous shale found in a mine not far from Lake Lugano, Switzerland. The purified oil contains 6–7% of sulphur in organic combination and closely resembles ichthyol in its therapeutic properties.

Sodium citrate: Action of — and its decomposition in the body. W. Salant and L. E. Wise, J. Biol. Chem., 1916, 28, 27–58.

SODIUM citrate is rapidly oxidised and eliminated

when injected intravenously into cats and dogs; large doses when given by the mouth render the urine alkaline, but the urine contains only traces of the citrate. The fatal dose of sodium citrate, when injected intravenously, varies from 0.4 to 1.6 gm. per kilo. of animal, and 70 mgrms. may produce slight symptoms. Only large amounts (more than 3 grms. per kilo.) are toxic when ingested. The toxicity of sodium citrate depends on the rate of its oxidation in the body; it is more toxic for animals in which larger quantities are eliminated unchanged; the rate of oxidation is greater in rabbits than in cats. The presence of 1% of sodium citrate inhibits the coagulation of blood for 4 days at 10°C. The acute effect of sodium tartrate is less than that of sodium citrate.—W. P. S.

Utilisation of cherry hy-products. Rabak. See XIXa.

Estimation of arsenic in organic compounds. Ewins. See XXIII.

PATENTS.

Acetic anhydride: Manufacture of —, H. Dreyfus, Basle, Switzerland. Eng. Pat. 17,920, Dec. 22, 1915. Under Int. Conv., Dec. 23, 1914.

ACETIC anhydride is manufactured by acting on an acetate with sulphuric anhydride (which may or may not be mixed with chlorosulphonic acid), or with a compound of sulphuric anhydride and an inorganic salt, e.g., sodium chloride or sulphate. A diluent such as acetic anhydride is used, and the reaction mixture must be cooled initially to 0–5°C. if sulphuric anhydride is employed directly, or to atmospheric temperature by water-cooling if a compound of sulphuric anhydride is employed. *Example.* 800 kilos. of sulphuric anhydride is added fairly quickly, with constant stirring, to 1600 kilos. of powdered anhydrous sodium sulphate, and when combination is complete the mass is cooled and added to a mixture of 1640 kilos. of powdered anhydrous sodium acetate and 1600 kilos. of acetic anhydride, the mixture being stirred and water-cooled. The temperature may afterwards be allowed to rise to 60°–70°C. to complete the reaction, and the acetic anhydride is distilled off *in vacuo*. The product is of a high degree of purity, and free from chlorine.—F. Sp.

Liniment. C. A. and G. Cofman-Nicoresti, London. Eng. Pat. 18,060, Dec. 28, 1915.

SOLID preparations of volatile oils such as amber oil, eucalyptus oil, camphor oil, terebene, etc., containing from 80% to 95% of the oil, are obtained by incorporating with the oil a salt of one of the higher fatty acids, such as stearic and palmitic acids. The salt as such may be emulsified with the oil, or separate portions of the oil may be mixed with the acid and base respectively and then mixed together. The addition of about 1 part in 500 of paraffin wax assists the solidification.

—B. V. S.

Pharmaceutical products containing arsenic, and process of making same. J. Calsen, Elberfeld, and W. Grütten, Volhwinkel, Germany. Assignors to Synthetic Patents Co., Inc., New York. U.S. Pat. 1,201,692, Oct. 17, 1916. Date of appl., July 29, 1916.

COMPOUNDS containing the following atomic groups are claimed:— $\text{RC}^{\text{R}}\text{As}$, $\text{RCX}^{\text{R}}\text{As}$, $\text{RCX}^{\text{R}}\text{AsO}$, $\text{RCX}^{\text{R}}\text{AsO}(\text{OH})_2$, $\text{RUCl}^{\text{R}}\text{AsO}(\text{OH})_2$ (in which R, R' is hydrogen or a hydrocarbon

radical, and X is a halogen), and in particular the chloroarsinic acids produced by causing arsenic trichloride to combine with acetylene hydrocarbons, treating the product with water to form the arsenoxide, and oxidising the latter. *Example:* 240 parts of heptene (*n*-pentylacetylene) and 900 parts of arsenic trichloride are heated together for 16 hours under a reflux condenser. The excess of arsenic trichloride is removed by distillation *in vacuo*, and the oily residue is dissolved in 3000 parts of wet ether. Aniline is added as long as a precipitate forms, and the aniline hydrochloride is filtered off. The filtrate is washed with dilute hydrochloric acid, then with water until neutral to Congo red, dried over sodium sulphate and freed from ether *in vacuo*. Heptenechloroarsenoxide remains as a thick dark liquid, 44 parts of heptenechloroarsenoxide is dissolved in 400 parts of acetone and treated with 3% hydrogen peroxide until oxidation is complete. The solution is shaken with 500 parts of ether, and the ethereal layer washed with dilute caustic soda and water. The alkaline wash water is acidulated with hydrochloric acid, and evaporated *in vacuo* at 60–70° C. until the heptenechloroarsinic acid crystallises. It is separated, washed with a little ether, heated with animal charcoal in 50 parts of water, and recrystallised. It forms white shining leaflets, easily soluble in water to a neutral solution. It is valuable in the treatment of anæmia, chlorosis, leucæmia, chorea, and skin diseases.—F. Sp.

Auro-mercaptobenzenes, and process of making same. A. Feldt, Frankfurt, and P. Fritzsche, Assignors to Farb. vorm. Meister, Lucius, and Brüning, Höchst, Germany. U.S. Pat. 1,207,284, Dec. 5, 1916. Date of appl. Oct. 17, 1916.

AURO-MERCAPTOBENZENES, of the general formula, X.S.Au , where X is any benzene nucleus, are obtained by the action of double gold chlorides on mercaptobenzenes. They are yellowish solids. The sodium salt of 4-amino-2-auromercaptobenzene-1-carboxylic acid is a yellowish powder, readily soluble in water, insoluble in organic solvents.—B. V. S.

Halogenation of hydrocarbons and other processes of chlorination, and reactions between gases or vapours in general. B. S. Lacy, Fr. Pat. 480,064, Oct. 22, 1915.

SEE Eng. Pat. 14,709 of 1913; this J., 1916, 653. The method is applied to other processes of halogenation and to reactions between gases or vapours in general.

Tobacco-plants: Process for treating the green juice of— T. Oelenheinz, Karlsruhe, Germany. U.S. Pat. 1,209,327, Dec. 19, 1916. Date of appl. July 24, 1912.

SEE Eng. Pat. 17,037 of 1912; this J., 1913, 882.

Olefinic terpene derivatives: Hydrogenising— C. Paal, Leipzig, Germany. U.S. Pat. 1,210,681, Jan. 2, 1917. Date of appl., July 18, 1914.

SEE Eng. Pat. 16,180 of 1914; this J., 1915, 982.

Alcohols: Manufacture of [aliphatic]— C. Bill, Fr. Pat. 177,812, Oct. 6, 1914. Under Int. Conv., Oct. 4, 1913.

SEE Eng. Pat. 20,550 of 1914; this J., 1915, 575.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

Colour sensitising of photographic plates: Preparation of dyes for— W. Harrison and S. E. Bottomley. Preliminary Report of the Investigation carried out at the University of Leeds and the City of Leeds Technical School (Printing Crafts Department). Nov. 1916.

METHODS are given for the preparation of ethyl iodide, quinaldine (Doebner and Miller, Ber., 1883, 16, 2465), toluquinoline (Skraup, Monastsh. Chem., 1881, 2, 158), and toluquinoline, and from these of Formocyanine (Pinaeyanol) (Ger. Pat. 172,118; see Eng. Pat. 16,227 of 1905, this J., 1906, 368), and Tolucyanine (Orthochrome T) (Ger. Pat. 167,159; see Eng. Pat. 9598 of 1903; this J., 1904, 381). Small quantities of the dyes in an impure condition have been prepared; spectra of plates prepared with Formocyanine prepared as described, and with Pinaeyanol of German origin are given for comparison.—B. V. S.

Colour sensitising: Production of dyes for— W. J. Pope. Brit. J. Phot., Jan. 12, 1917.

IMPROVED methods have been devised at the University Chemical Laboratory, Cambridge, for preparing the intermediate products and all the sensitisers in ordinary use, including Pinaverdol, Pinaeyanol, and Orthochrome, and several plate-makers have been supplied with these dyes for some months. Details of the methods in use are not given.—B. V. S.

PATENTS.

X-Ray photography. T. T. Baker, South Croydon. Eng. Pat. 17092, Dec. 1, 1915.

THE time of exposure in taking X-ray photographs is reduced by the use of two intensifying screens, on either side of the sensitive plate or film, the one nearer the X-ray tube being of crystalline calcium tungstate, more transparent to X-rays, and the other one being of the semi-crystalline salt, much less transparent to X-rays.—B. V. S.

Developing and fixing photographic exposures: Composition of matter for— F. W. Hochstetter, Assignor to H. P. Patents and Processes Co., Inc., New York. U.S. Pat. 1,207,042, Dec. 5, 1916. Date of appl. Oct. 7, 1913.

A COMBINED developing and fixing solution contains a reducer, sodium sulphite and thiosulphate, an alkali carbonate, glycerin, and citric acid.—B. V. S.

Photographic process. [Colour photography.] W. E. Fox, Assignor to Kinemacolor Co. of America, New York. U.S. Pat. 1,207,527, Dec. 5, 1916. Date of appl., June 23, 1914. (See also Eng. Pats. 552 and 8728 of 1914; this J., 1914, 1227.)

TWO negatives are taken through screens of complementary colours (*e.g.*, red and green). A print is made through one of the negatives and toned to a colour complementary to that of the taking screen. A second print, through the other negative, is then superposed in register on the first print and stained by mordanting and dyeing to the colour complementary to its taking screen.—B. V. S.

Photographs and photogreasures: Process for producing—J. H. Christensen. Fr. Pat. 184,119, Mar. 10, 1916. Under Int. Conv., Mar. 10, 1915.

AFTER development plates are treated with a fixing solution which acts on the unreduced silver salt to form a compound which fills up the pores of the film. The most suitable substances to use are alkali polysulphides and thiostannates, Schlippe's salt, and similar compounds which easily deposit sulphur in the fixing process, but similar effects can be obtained with iodides, thio-cyanates, and some other substances. The best effect is obtained by a mixture of a sulphur compound and a solvent of silver halides such as thio-cyanate. Collodio-bromide films to be treated in this way are preferably previously made very porous by the addition of a substance such as glycerin, benzoic acid, etc., which washes out during development, while gelatin films should be previously hardened with chrome alum, alum, or formaldehyde. The varying porosity of the films on plates so prepared may be utilised in several printing processes. For example, colour printing plates for a three-colour process may be prepared by printing through the colour negatives on to a composite plate consisting of a lower dyed collodion film on a suitable base and an upper collodio-bromide film. After development and fixation according to this process, the transfer of dye from the lower film to a printing paper varies with the porosity of the upper film, and a coloured print is obtained. —B. V. S.

Colour photography. P. D. Brewster, East Orange, N.J. U.S. Pat. 1,208,739, Dec. 19, 1916. Date of appl. Jan. 29, 1911. Renewed May 11, 1916.

SEE Eng. Pat. 1073 of 1915; this J., 1916, 329.

XXII.—EXPLOSIVES; MATCHES.

Trinitrotoluol: U.S. Navy Department Specifications for—

THE following U.S. Navy Department Specifications for trinitrotoluol (5TT2) have been issued:—
Grade A—Refined. Trinitrotoluol must be a high-grade material, made from a suitable quality of raw materials. It must be thoroughly purified by recrystallisation from an approved solvent, so that the finished product shall have the following characteristics:—The material must be in the form of a slightly yellow, fine, and uniform crystalline powder. At least 99% must pass through a sieve 12 mesh per linear inch. No odour of any by-product or crystallising agent may be present. It shall have a melting point of at least 79° C. It shall be free from acidity and shall not show more than traces of metallic salts or residual solvents. Average moisture of a lot shall not be greater than 0.1%. Average ash of a lot shall not be greater than 0.1%. It shall not contain more than 0.15% of material insoluble in alcohol. It shall contain no free toluol or products giving a nitric-acid reaction with a sulphuric acid solution of diphenylamine. It shall contain not less than 18.20% nitrogen as determined by the Dumas combustion method. It shall give a heat test of at least thirty minutes at 65.5° C. with potassium iodide-starch paper.

Grade B—Crude. Trinitrotoluol must be a high grade material, made from a suitable quality of raw materials. It shall be thoroughly stabilised, and washed free from stabilising materials and by-products of stabilising process, and thoroughly dried. It shall be a yellowish, uniform crystalline powder of such fineness that at least 90% will pass

a sieve 40 meshes per linear inch. It shall have a melting point of at least 75.5° C. It shall be free from acidity. It shall show not more than traces of metallic salts. Conditions as to ash, moisture, percentage soluble in alcohol, and content of free toluol or products giving a reaction with diphenylamine are the same as for the refined product. It shall contain not less than 18% nitrogen as determined by the Dumas combustion method.

The manufacture of the material shall be open to inspection in all its details by the officers and employees of the Bureau of Ordnance assigned to duty for that purpose, and must be satisfactory at all its stages to the inspector at the works or to such one of his assistants as may be designated.

For purposes of inspection 4000 lb. of trinitrotoluol will constitute a "lot," and from each lot the inspector will select a sample of one pound and ship it at the expense of the Government to the Naval Proving Ground, Indian Head, Md., for chemical test.

PATENTS.

P perchlorate explosives. Stockholms Superfosfat Fabriks Aktiebolag, Stockholm. Eng. Pat. 17,584, Dec. 16, 1915. Under Int. Conv., Dec. 23, 1914.

EXPLOSIVES containing perchlorates are subjected to a pressure of not less than 300 kilos. per sq. cm., which diminishes their sensitiveness to shock and increases their specific gravity, thereby making them suitable for charging shells. —F. Sp.

Nitrocellulose: Process of producing—A. C. Vournasos, Athens. Eng. Pat. 9547 of 1915; date of appl. July 22, 1914.

NITROCELLULOSE is produced from cellulose derived from *Hibiscus cannabinus* (see previous abstract) by immersing 30 parts by weight of the fibres in a mixture of 250 parts of nitric acid (sp.gr. 1.381) and 500 parts of sulphuric acid (sp.gr. 1.82) for 24 hours at 15° C. Either the crude or the bleached fibres may be used, the latter yielding a product stated to be superior in stability to the nitrocellulose from pure cotton.—F. Sp.

Matches: Damp-proof—J. W. Mills, Birmingham, and W. Morgan, Bristol. Eng. Pat. 18,028, Dec. 28, 1915.

MATCHES tipped with brimstone or other inflammable material are rendered damp-proof by coating them with a solution of celluloid or nitrated cellulose. In addition to this treatment, the solution may also be applied to the wood prior to the application of the brimstone, etc. —C. A. M.

Match-ignition material. Process of drying the composition heads of matches. W. A. Fairburn, Short Hills, N.J., Assignor to The Diamond Match Co., Chicago, Ill. U.S. Pats. (A) 1,206,827 and (B) 1,206,828, Dec. 5, 1916. Dates of appl. Apr. 6, and July 28, 1915.

(A) Rosin, dextrin, plaster of Paris, antimony sulphide, and amorphous phosphorus are incorporated to form a match-ignition material. (B) An oxidising composition is applied to the match splints, which are then passed through a series of drying zones, where they meet rapid currents of fairly dry air, first at temperatures

increasing successively to about 120° F. (49° C.) and then decreasing successively to about 80° F. (27° C.), after which the heads are coated with the sensitive ignition composition.—C. A. M.

XXIII.—ANALYSIS.

Combustion methods for use in the laboratory. [Determination of sulphur.] J. Hewett. London and Southern Distr. Ind. Gas Assoc., Jan. 5, 1917. Gas J., 1917, 137, 72–73.

SULPHUR may be estimated in volatile liquids, e.g., crude benzols, by drawing air through the liquid and after further diluting the air-vapour

mixture, passing it through a silica tube heated to redness, when complete combustion occurs. The gases then pass through two wash-bottles containing sodium hydroxide. After oxidation of the product with bromine or hydrogen peroxide, sulphur is estimated as sulphate in the usual way. The author indicates the wide applicability of the estimation of sulphur by combustion with sodium peroxide. It is carried out in a nickel crucible (see fig.) fitted with a screwed top and electrical ignition device. A ring of filter paper makes a tight joint. The crucible may be immersed in water when the charge is fired. The substance under test must be thoroughly incorporated with the sodium peroxide in suitable proportions. The reaction should be complete in a few seconds. The contents of the crucible when cold, are extracted with distilled water and after acidification and filtration, sulphur is estimated as sulphate in the usual way. This method may be used for any substance which can be brought to react vigorously with sodium peroxide either alone or with the addition of sulphur-free combustible matter, e.g., wood dust or alcohol. It has been used with tar and tar products, oils, fats, greases, coal, coke, new and spent oxide of iron. With spent oxides, the reaction product is suitable for the estimation of iron and alumina as well as sulphur. The analysis of spent oxide in this way can be conducted much more speedily and conveniently than by the usual methods. The reaction is extremely violent. Not more than 1 gm. of combustible substance should be taken and then 20 grms. of sodium peroxide usually gives a suitable melt. The substance should be approximately free from moisture, as water may cause dangerous premature ignitions.—H. J. H.

Colorimetry by combustions with sodium peroxide. W. G. Mixer. Amer. J. Sci., 1917, 43, 27–31.

A DETAILED account of the construction of a silver bomb-colorimeter (and of the necessary appurtenances) employed by the author in a

series of thermochemical researches. Full directions are given for its use in the determination of the heat of oxidation of elements which do not burn in oxygen and which form oxides insoluble in acids. The method of fusion with sodium peroxide is also adapted to the determination of the heat of combination of certain oxides with sodium oxide. Experimental figures for determination of the heats of formation of Fe_2O_3 and of pyrites are appended. Results obtained by this method are compared with those yielded by other modes of procedure. Some substances when burnt with Na_2O_2 do not evolve sufficient heat to fuse the mixture and some readily combustible body such as sulphur or carbon must be added.—F. C.

Phosphoric acid in qualitative analysis: Removal of —. L. Gattermann and H. Schindhelm. Ber., 1916, 49, 2416–2422.

WORKING with 1 gm. of material, the filtrate from the hydrogen sulphide group is boiled until free from hydrogen sulphide, concentrated to 100 c.c., filtered if necessary, and treated with 5 c.c. of 6% ammonium phosphate solution. It is then nearly neutralised with dilute ammonia (until only faintly acid to litmus), 3 c.c. of dilute hydrochloric acid (7–8%) is added, and the briskly boiling solution is treated with 3 c.c. of a freshly prepared solution containing 3 grms. of crystallised stannic chloride, dissolved in the cold. Stannic phosphate is thus precipitated, and if necessary more of the stannic chloride solution is added, in portions of 0.5–1 c.c., to the boiling solution until no further precipitate is obtained on testing a little of the filtered liquid with ammonium molybdate. The boiling solution is then filtered, using a Büchner funnel and double filter, the precipitate washed with boiling water, the warm filtrate, which should be quite clear, is treated with dilute hydrochloric acid and hydrogen sulphide, to remove excess of tin, and the metals present are detected in the usual way. When the phosphate precipitate has a greenish colour, it is tested with caustic soda and hydrogen peroxide for chromium which, like ferric (but not ferrous) iron, is liable to be carried down with the precipitate. If too little phosphoric acid be present, the mixture containing the stannic phosphate precipitate is difficult to filter, but satisfactory conditions are ensured by adding ammonium phosphate as directed.—F. SODN.

Diphenylamine and diphenylbenzidine: Use of — for colorimetric determinations. L. Smith. Z. anal. Chem., 1917, 56, 28–42.

THE intensity of the colour obtained with diphenylamine in the colorimetric estimation of nitric acid (compare Tillmanns, this J., 1911, 44, 918), is largely influenced by shaking the tube, excessive shaking causing a diminution. To obtain reliable results, therefore, shaking should be avoided, the necessary mixing being done by moving a suitable stirrer a few times up and down in the tube, and then allowing the liquid to remain at rest for the prescribed period of one hour. It is suggested that the observed phenomenon is due to the formation of a volatile substance during the oxidation of diphenylamine, the presence of hydrogen chloride being also a determining factor. The stability of the colour is at a maximum at ordinary temperatures. The sensitiveness of the reagent depends largely on its composition, and for the determination of the following amounts of nitric anhydride per litre the annexed formulae are recommended:—0.1–3.0 mgrms.: 0.04 gm. diphenylamine, 39 c.c. water, concentrated sulphuric acid to 100 c.c.; 0.5–10.0 mgrms.: 0.01 gm. diphenylamine, 26 c.c. water, and sul-

phuric acid to 100 c.c.; 1.0–2.5 mgrms.; 0.08 gm. diphenylamine, 20.5 c.c. water, and sulphuric acid to 100 c.c. Diphenylbenzidine behaves analogously to diphenylamine as a reagent for nitric acid; its sensitiveness is somewhat greater. — G. F. M.

Arsenic in organic compounds: Estimation of —. A. J. Ewins. Chem. Soc. Trans., 1916. 109. 1355–1358.

THE methods, previously described for the estimation of arsenic in organic compounds, are either very laborious and involve complicated processes, or are only applicable to certain compounds, such as salvarsan or neosalvarsan. The Norton-Koch method (this J., 1905, 1129), the principle of which is the same as the Kjeldahl method of estimating nitrogen, has been successfully applied by the author to the estimation of arsenic in arsanic, acetylarsanic, and diethylbenzarsinic acids, salvarsan, and a number of other organic substances. 0.1–0.2 gm. of the substance is heated with 10 grms. of potassium sulphate, 0.2–0.3 gm. of starch, and 20 c.c. of concentrated sulphuric acid in a Kjeldahl flask of about 300 c.c. capacity for about 4 hours, until the liquid becomes colourless or pale yellow. The contents are cooled, made just alkaline with 10–12N caustic soda, cooled to 30–40° C., and the liquid made just acid with sulphuric acid. A saturated solution of sodium bicarbonate is added until an excess of 5–10 c.c. of this reagent is present, then 2 c.c. of a 1% solution of starch, and the arsenious acid is titrated with N/20 iodine, until a permanent deep blue colour is obtained. — B. Gas; Apparatus for the analysis of —. Aktiebolaget Ingeniörsfirma F. Egnell. Fr. Pat. 480,661. Jan. 12, 1916. Under Int. Conv. Feb. 6, 1915.

IN apparatus for determining the proportions of carbon dioxide and monoxide, oxygen, and hydrocarbons in a gaseous mixture, the gas passes in series through a measuring vessel, an absorbing solution, and finally either in series or parallel through a retort containing electrically heated finely divided metal or oxide which reduces or oxidises the gas, and a measuring vessel for the residue of gas. In a modification, additional absorption apparatus may be inserted before and/or after the retort. In another modification, the retort may be placed before the first measuring vessel and another absorption apparatus after that vessel. The residue of gas may be cooled and humidified. — W. F. F.

Owing to unforeseen delays in the receipt of the manuscript of certain sections of these Reports, it is regretted that the publication of the first volume is unavoidably postponed until March.

CROSS AND BEVAN ESSAY PRIZE OF £20 AND LATHAM RESEARCH GRANT OF £300.

The Council have pleasure in announcing that a gift of £20 has been made by Messrs. Cross and Bevan as a prize for an essay on "The Interconnection of Economic Botany and Chemical Industry."

A further sum of £300 has also been presented by their friend, Mr. T. P. Latham, of Weybridge, to be paid in three annual instalments to such one of the competing essayists as may be judged to be of conspicuous ability, as a grant towards his expenses, on the condition that he apply himself, during three years, to research of approved character on a subject cognate with that discussed in his essay.

The immediate object of the donors is to promote the study of economic botany with special reference to its bearing on chemical industry, giving the widest possible interpretation of the relationship.

They desire, under the auspices of the Society, to assist in forming public opinion in this direction and to discover and further the career of a student of promise who may wish to devote himself to work in such a field.

The Essay Prize will be open to all members of the Society who are British subjects. The Research Grant will be limited to competitors under 25 years of age at the time of sending in the essay.

Essays are to be submitted to the Council of the Society not later than the close of the year 1917. The awards will be made promptly. Neither the prize nor the first grant will be given unless the essayist or essayists shall be deemed to have real merit. The Latham Research Student will be required to submit a report at the close of each year, to satisfy the Council that he has made and is likely to make proper use of the grant.

Edinburgh Section.

Meeting held at Edinburgh, on Tuesday, January 16th, 1917.

PROF. JAMES WALKER IN THE CHAIR.

THE BROWN COAL DISTILLATION INDUSTRY OF GERMANY.

BY D. R. STEUART, F.L.C., F.R.S.E.

Brown coal is a substance intermediate in its nature between peat and ordinary coal. Formed in comparatively recent geological times, Tertiary or Cretaceous, it has not yet developed into a true coal. Peat contains 80 or 90% of water from which it parts with great reluctance; it cannot be separated by pressure. Brown coal or lignite has 20% to 60% of moisture, common coal 2% or 3%.

There is little brown coal in Britain. At Bovey Tracey in Devonshire it has been worked for 200

years but is of only local importance. There are vast fields of it in the United States of America; great fields of unknown extent in Alberta, Saskatchewan, and Manitoba, Canada; and some 1700 square miles of it in Victoria, Australia. Brown coal generally has no great covering on it, lies in beds of great thickness, and can often be worked opencast. The amount of water in it is a great drawback, and also its want of coherence when air-dried. In Manitoba, Saskatchewan, and Alberta it cannot be used for locomotive fuel on the railways on account of the dangerous sparks it throws out.

Brown coal is widely distributed through middle and north Germany and in Austria. Near Cologne it is 260 to 400 feet thick. Improved methods of mining and of preparing the products have given great importance to the industry in Germany and these methods are worthy of consideration in other parts of the world.

In the German Empire in 1905 the total coal output was 121 million tons and 30% of that was brown coal. The total output of coal in 1910 was 222 million tons. The coal production in the British Empire in 1910 was 312 million tons.

In Germany for the last half century brown coal has been subjected to low temperature distillation, and it may be of interest to give some description of the process for comparison with our Scottish shale oil industry. The products of the distillation are somewhat similar: permanent gas, spirit, lamp oil, gas oil, lubricating oil, and solid paraffin, but in Germany the oils require more chemicals in the refining, and after all the result is not so good. Dr. Scheithauer, Dr. Graefe, and others have described the German methods very fully.

This industry requires a very special brown coal and it is found only in two localities, namely, in the region of Halle on the Saale in Saxon Thuringia, and at Messel near Darmstadt. The material is quite different in the two localities, and the retorting different. The principal centre is at Halle, and works are situated between the towns of Weissenfels and Zeitz, and of Aschersleben and Eisleben. The ordinary brown coals of Germany do not contain sufficient bitumen to make retorting profitable. At first it was thought that any brown coal would do, and starting works on this supposition and without proper scientific expert advice, many ended in ruin. So a distinction arises at once between retort-coal and fuel-coal, but it often requires an expert, or chemical examination, to tell the one from the other.

The Saxon Industry.

The retort coal is found in layers situated among the fuel coal, as shown in the accompanying section of the strata in one locality (Fig. 1). There is twice as much fuel coal as retort coal.

Freshly mined retort coal forms a plastic and sometimes greasy mass, of a brownish black colour; when dry it is yellow to light brown. The fuel coal becomes black or light brown when dried. Retort coal melts on ignition and burns with a smoky flame; fuel coal does not melt. Retort coal has sp. gr. 0.9 to 1.1; fuel coal 1.2 to 1.4. The value for retorting depends on the proportion of bitumen present. The coal is of Tertiary age, Lower Oligocene, and contains 50% to 60% of water. In the Tertiary period the brown coal districts were occupied by extensive bogs with a luxuriant sub-tropical flora. Submerged in swamps the plants and trees were converted into peat as in our own peat-bogs. Sometimes large areas

were exposed to atmospheric influences for a time by droughts or alteration of water level, so that

FIG. 1.

the cellulose became partly or completely decomposed and only waxy, fatty, or resinous materials remained, and these covered up later by peat and sediments became through time the retort coal. Botanists state that the plants of that period supplied such wax or resin. The purest bitumen, called pyropissite, was at one time found throughout the coal then used, but seems to be now exhausted. It was yellow in colour or in the purest form white. The bulk of the bitumen in the coal is soluble in benzene, toluene, ether, acetone, alcohols, carbon disulphide, and carbon tetrachloride; but the amount and character of the material got in this way depends on the solvent used.

Bitumen is extracted by a solvent, or by distillation with superheated steam under vacuum, and from it montan wax is manufactured. It is a pure white or yellowish wax with a very high melting point, the crude wax having m.pt. 80° or 90° C., refined 70° C. It is manufactured by six companies with a combined output of 400 to 500 tons per annum. The coal is generally dried and then extracted with benzol. There is a wet extraction process in which alcohol and benzine are used at once on the fresh coal, the alcohol removing the water and the benzine dissolving the wax and the solution separating into two layers.

The following analyses by E. Erdmann are given by Scheithauer:—

	C.	H.	O(N) by dif.	S. Volatile.	Ash.
Pyropissite	73.12	11.63	9.43	0.10	7.72
Retort coal	64.84	7.02	13.18	0.48	7.89
Fuel coal, Waldau	62.15	6.12	22.11	0.16	8.86
Fuel coal, Greppin	58.36	4.88	23.95	1.41	11.40

The three first subjected to distillation in the natural moist state in the laboratory gave the following yields:—

	Pyropissite.	Retort-coal.	Fuel-coal.
Crude oil	32.61	18.75	8.88
Coke	10.33	20.83	28.88
Gas	7.96	10.12	12.24

The water in the materials as they came from the pit was about 50%. The sulphur is seldom above 1%. The basic substances of the ash are oxide of iron, alumina, and lime, with smaller quantities of magnesia, potash, soda, and sometimes manganese and traces of strontia. These are combined with silica, sulphuric acid, sulphurous acid, hydrogen sulphide, carbon dioxide, traces of hydrochloric acid and occasionally phosphoric acid. The ash is practically of no use as a fertiliser, but it improves the physical state of the soil.

Mining.—The coal is first proved by boring. If the cover is not thicker than the coal it is worked opencast. If, however, the coal is thick, sometimes even up to 2 of cover to 1 of coal is worked opencast, and then the cover is removed by steam navvy. With small cover it may be removed by hand. Opencast workings have haulage inclines operated by chain or rope. Most of the retort coal is worked by shafts. The depth is seldom more than 33 fathoms, although a few shafts are over 10 fathoms.

From the bottom of the shaft a double line of rails goes across the field and single lines go at right angles out to the boundary. These are for the little wagons called hutchies in Scotland. For short distances they are pushed by hand, for longer distances by endless chain or wire rope. When the thickness of the coal is great the upper part is taken out first, a layer of over 2 fathoms being removed. Spaces of 18 to 24 square yards are taken out, the timbers removed, and the cover allowed to subside. Adjoining spaces are thus worked out until the whole layer is removed. The roof is allowed time to consolidate and then another layer is removed. Sometimes 3 or 4 layers are taken out before the bottom of the coal is reached. The total bed is sometimes 40 fathoms thick, worked opencast.

Retorting in Saxony.—At first, as in this country, the retorts used were of the old iron gas-retort type. Various forms were tried. At the last they were made of oval section, 8 to 10 feet long, about 30

FIG. 2.

inches wide, and $11\frac{1}{2}$ inches deep. Thickness of metal 1 to $1\frac{1}{2}$ inches. A layer of coal 1 inch thick was shovelled in. There were 10 or 12 retorts in a bench, and they were heated by fuel coal of equal volume to the retorted coal. Distillation was completed in 8 hours and the coke raked out. Riebeck, the James Young of Saxony, started building works at Webau in 1858, and built several others afterwards. In 1858 Rolfe constructed a vertical retort, and its use became general, and with some minor improvements, is now the only type of retort used in Saxony. It gives a higher yield and a better quality of crude oil, works continuously and with less labour, and puts through five times as much per unit.

The retort is circular, of firebrick, and heated by firebrick flues around the outside (see Fig. 2). Inside the retort a hollow cylinder is made of a series of flat iron rings. The rings are bevelled and arranged above each other louvre fashion, and the coal passes down the narrow space 3 to 4 inches wide between the rings and the brick wall. The products of distillation pass through the louvres into the hollow centre of the retort and are carried off to the condensers by a pipe from near the top and another from near the bottom. The top pipe may either pass down outside the bench to join the pipe coming from the bottom, or it may pass downwards inside the retort to join the bottom pipe. A Koerting injector sucks the vapours from the retort through these pipes and passes them on to the condensers (Figs. 3 and 4).

In Scotland large amounts of steam are introduced into the shale retorts. No steam is introduced into the Saxon retorts. The raw coal

FIG. 1.

has over 50% of moisture and this supplies the steam. The coal must be crushed, or broken by hand, and lumps must not be larger than $1\frac{1}{2}$ to $2\frac{1}{2}$ inches in diameter. If too damp it is partially dried on the charging platforms of the retorts.

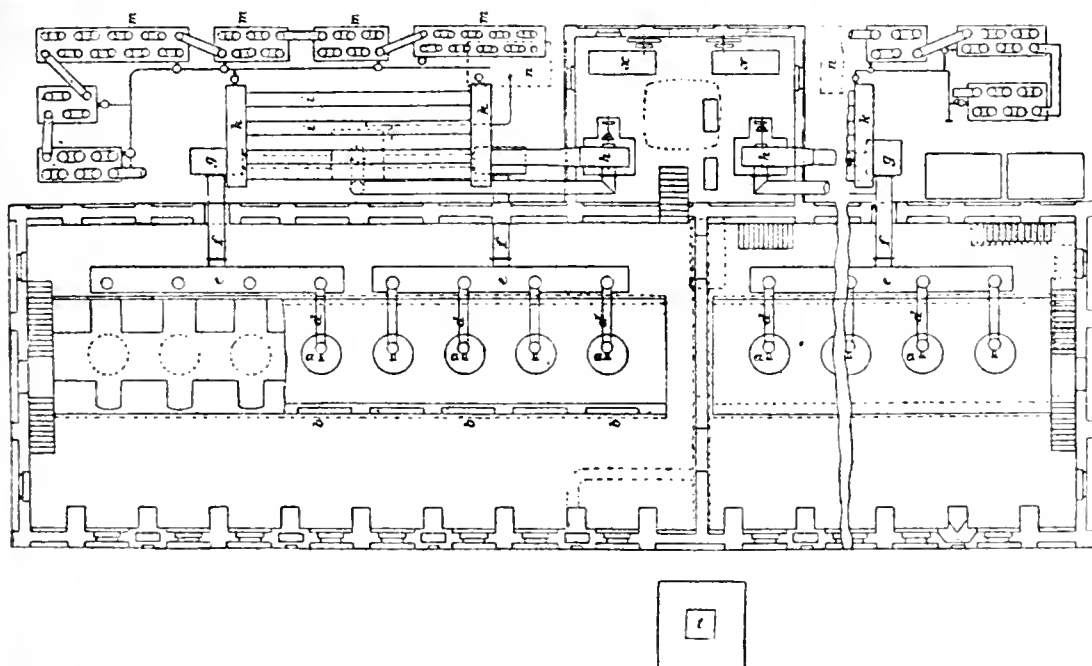

FIG. 3.

At first all the firing was done by coal. Sometimes gas firing is now used alone, but generally it is assisted by a fuel coal furnace at the side. Gas-firing, besides being a great economy, has given 20 to 30% increase of distillate. The temperature in the heating flues around the retorts increases from the top downwards from about 400° C. (752° F.) to 600° C. (1112° F.). The retort was at first 3 feet in diameter and 12 feet high, but is now 5 or 6 feet in diameter and 20 to 25 feet high.

The vapours issuing from the retort should have a temperature of 120° to 150° C. (250° to 300° F.).

The moisture content must not be more than 60%, otherwise the coal tends to stick in the retort; nor less than 30%, for then the oil vapours are decomposed by the heat, steam being necessary to protect them from decomposition. The top of the retort is closed by a heap of the coal ready to be passed down.

The residue of the distillation is a coke of some value for fuel purposes. It falls into a box below, which is shut off from the retort while the box is being emptied. This box is emptied 30 or 40 times in 24 hours. Automatic arrangements prevent the box being opened before it is shut off

from the retort. The coke is dropped into hutches and drenched with water to quench it; or immersed in and hauled through pools of water, as used to be the practice in Scotland.

The retort rings and walls get encrusted in time; after cooling down the retort, the rings are lifted by a tackle and cleaned, and the retort walls are also cleaned. This requires to be done at intervals of 5 to 12 months according to circumstances. The coal ash is basic and the firebricks used must be basic also. If acid bricks are used the ash gets encrusted as a double silicate on the brick, and when cleaning this off, part of the brick breaks off also. The bricks are segments of a circle, keyed into one another, and when building they are ground into each other for tightness. To stand the heat the bricks are best made of pure aluminium silicate. There are various recipes for mortar, of clay, finely ground sand, kaolin, and ground firebrick, mixed with molasses.

The coke after quenching contains moisture 20%, ash 15 to 25%, and the remainder is carbon. It is sold in this state. Its calorific value is 6000 to 7000 calories. Up till the middle of the "seventies" the coke was tipped on spoil heaps. Now it is burned in special but very simple stoves for cooking, for heating workshops, in metallurgy as a reducing agent for zinc, and for other purposes.

The retorts are grouped in benches of 10 to 12 in a single row, with a safety wall dividing the benches. The tops are protected by walls with felt roofing. Retorts are estimated to last a dozen years. The through-put of retort coal seems to be about 3 tons per retort per 24 hours, and less than this if the coal is rich.

The condensing is all done by air-cooling. The vapours are passed through thin-walled malleable iron pipes beginning 36 inches diameter and decreasing further on to 31, 28, 20, 16, and 12 inches, finally finishing up in 1 inch pipes. They are all horizontal until near the end when they are vertical. For a retort 5 or 6 feet in diameter a condensing surface of 960 to over 1000 square feet is allowed. Slow cooling is held to be necessary. Water cooling has been tried and rejected, although lately tried again. The suction from retort to condensers used to be by Koerting steam injectors; but now fans are much more in favour. There is no oil-scrubbing of the gas for spirit in Saxony, as there is at Messel and in Scotland.

In Saxony the water condensed along with the crude oil amounts to 40 to 50% of the retort coal, and more if Koerting injectors are used for propelling the vapours. The amount of ammonia in the water is only 0.03 to 0.07%, and it does not pay to recover it, although efforts have been made to do so. The liquor is supplied to neighbouring farmers gratis; it does not pay to convey to any distance. The great bulk of it has to be sent into the streams after some purification by aeration and filtration, or by filtering through spoil heaps. It contains besides ammonia, aldehydes, ketones, methyl alcohol, and acetonitrile, with acetic, propionic, butyric, and valeric acids, and catechol, and is faintly alkaline in reaction.

The crude oil contains hydrocarbons of various aliphatic series, and also acid and basic substances, with some aromatic compounds. The cellulose, humic acids, and bitumens of the coal produce their own products of decomposition. There is about 0.3% of nitrogen in the coal, and in the crude oil there is $\frac{1}{4}$ to $\frac{1}{2}$ % of nitrogenous bodies; 10% of the nitrogen of the coal is found in the crude oil, 12% in the condensed water, 66% in the coke, and 12% in the gas. These vary with the kind of coal and the method of distillation. The Rolle type of retort is adhered to on account of the good coke it produces.

In the Saxon field there are 12 works putting through together about one million tons of brown coal per annum, producing 60,000 tons of crude

oil and yielding over 7000 tons of solid paraffin. The crude oil yield now is about 18 gallons to the ton of coal. (Scottish production of crude oil is 273,500 tons per annum.)

The Messel industry.

Retorting methods.—The industry began in 1885. The retort coal is quite different from that of Saxony, and is distilled differently. It seems unique in its nature, being a mixture of bituminous clay and coal, and having the organic matter in combination with the mineral matter. The bitumen cannot be extracted by solvents. It has a high percentage of moisture, like brown coal, and a high percentage of ash, like shale. It is more lumpy than the Saxon brown coal, which allows steam to pass through it in the retort. It lies under not more than 13 feet of cover, and is about 480 feet thick. It fills an ancient hemispherical depression, and is in layers like an onion. There are 240 acres of surface. It is worked down 80 feet or so and will last a long time. The fossils indicate a joint animal and vegetable origin. It has the consistency and cut of Dutch cheese, is blackish green in colour, with conchoidal fracture when dry. Alternate frost and thaw make it separate into thin sheets like paper. The moisture is 45%, the ash 30%. The calorific value is low and would not pay cost of carriage for heating purposes. Dry distillation in the laboratory yields water 11%, crude oil 7.8%, coke-residue 35%, gas 6.2%. The condensed water contains volatile and fixed ammonium salts together with catechol and its homologues. The ammonia is recovered. In the fixed ammonium salts are quite a series of homologous fatty acids. The ash is rich in iron oxide.

The coal is won by opencast working and the hutches are brought to the surface by chain and let down by gravitation. The power is from small gas engines direct, or from one large gas engine in a central power-house with electromotors where required.

FIG. 5.

The crude oil is distilled from the coal in the presence of steam, and the coke is dropped into a gas-producer below and the gas used to heat the retorts. There is no marketable coke. At one time a special stove was used to reduce the moisture from 44% to 6%, the dried material was distilled in the presence of steam, and the coke dropped into the gas-producer. Thus coal was consumed in drying the retort coal, and also in raising steam from water for the coal distillation. Now the moisture of the coal is used as a steam for the retort. Vertical retorts are used of a type somewhat similar to that used in Scotland (see Ger. Pat. 200,602, May 23, 1906). The working is continuous (Fig. 5). There is a hopper on top from which the coal is let into the retort by a valve as required. More than two-thirds of the retort is of iron; the lower part is of firebrick, and this is the gas-producer, and from it the coal ash is dropped into a hutch below. In the top part of the retort the coal is dried and the steam resulting is drawn from the top by an electrically driven fan; a part is returned into the retort further down, and part caught by another fan is passed into the bottom of the gas-producer where superheated steam acts on the carbon and nitrogen to produce water-gas and ammonia. The oil is distilled at the middle of the retort and the products of distillation led off from here to the condensers. The flues around the retorts are much more spacious than the flues of the Scotch retorts. The flues are divided by partitions into three compartments, and from one compartment to the one above there is communication by a comparatively small passage. The result is that there is a surging circulation of the products of combustion in each compartment, keeping each at the required temperature, and only a quantity passes off towards the chimney in proportion to the suction. The utilisation of heat is good. The products of combustion pass to the chimney at 200 C. The vapours passing from the retort get partially cooled which causes the separation of ammoniacal liquor containing fixed ammonium salts, and some soluble organic compounds. The still hot vapours are passed on up a kind of Glover tower where all the ammonia is absorbed by dilute sulphuric acid. The ammonium sulphate solution so obtained is concentrated by the heat of the vapours, and after being centrifuged and dried the product is

Fig. 6.

ready for the market. The oil vapours pass from the Glover tower and are cooled by water condensers. The water now condensed along with the oil is free from ammonia, and to reduce the quantity of effluent it is used in tubular condensers and towers and so is much evaporated. The gas is finally led up heavy-oil towers to catch the light spirit still left in it. From 70 to 80% of the permanent gas (some 10,000 cubic feet per ton) is used for heating the retorts; the rest goes to the power station. It may be used to raise steam,

or after purification from hydrogen sulphide with iron oxide, it may go to gas engines. There is above 20% of carbon dioxide in the gas, and when this is absorbed the gas is well adapted for incandescence lighting. The ammoniacal liquor is passed down a tower-still with alkali, and the ammonia absorbed in sulphuric acid. From the spent water catechol and its homologues are recovered, and also fatty acids. The Germans extract every practicable substance from their by-products.

At one time the retort coal at Messel was graded, and yielded 1 to 14% of crude oil; now all goes together and averages about 7½% (= 19 gallons per ton).

Would a retort of this type not be suitable for distilling a rich peat? Air-dried peat might serve quite well if moist peat is too wet. Peats no doubt vary in the proportion of bitumen they

Fig. 7.

contain and they ought to be examined from this point of view. The brown coals of our Colonies should also be investigated.

Refining in Saxony. Distillation.—The crude oil is of a yellow-brown or dark brown colour, sp.gr. 0.850–0.890, usually determined at 11 C. When richer coal was obtainable the sp.gr. was sometimes as low as 0.820 to 0.850 and seldom above 0.880. The present-day crude oil is generally 0.880 to 0.900. Its sets between 20 and 30 C. The constituents boil at 80–400 C., the greatest volume between 250 and 350 C.

The refining of the crude oil is in outline the same as in Scotland. The operations consist of several distillations with fractionation, treatments with sulphuric acid and with caustic soda between the distillations, and separation of the solid paraffin from the heavier oils by cooling and pressing. The first distillation is always partly a destructive distillation, and gives a deposit of carbon and production of permanent gas.

The distillations in Scotland are done at atmospheric pressure, and in the presence of steam more or less superheated. In Saxony they are carried on sometimes at ordinary pressure, sometimes under extra pressure, sometimes under partial vacuum; sometimes with steam, often without; but under pressure it is not for "cracking." The stills are vertical cylinders with hemispherical bottoms for a charge of 140 to 550 gallons, not more; this is only one-fourth of the size of the smallest of our Scotch stills (Fig. 6). The height of the still is 5 feet and the width at top 5½ feet; the cover is domed and is made in one piece with an exit-pipe about 20 inches long. There is a

manhole in the centre of the top, 20 in. 24 in. The stills are bricked in in various ways so as to protect them from direct impact of the flame and send the products of combustion around the flues. The material is cast-iron, rarely wrought iron. Cast steel has been tried and rejected. Till comparatively recent years it was the invariable custom to work each still independently. The condensers (Figs. 7 and 8) are circular coils of piping in a vertical cylindrical water-tank. The coil is about 27 yards long, made of lead or iron, that is of gas-piping, or of cast iron semi-circular segments with flanges. The cooling surface per still is 85 to 95 sq. ft. Between the condenser and receiver there is a "U" bend and from between the condensers and this there rises a pipe to lead the permanent gas upwards

FIG. 8.

into the atmosphere or onward to a gas-holder. There are two receivers, one at each side, each of 33 gallons capacity. When partial vacuum is used it is produced by Koerting steam injector or a vacuum pump.

The crude oil is sometimes treated chemically before distillation, and, if so, slaked lime or caustic soda (1 to 1%) is added to the charge. Manganese oxide and bleaching powder have been tried to lessen the creosote and remove the sulphur; but although the creosote is reduced and the smell is improved the sulphur is left as before. A 2 or 2½ ton charge is distilled in 19 hours; the coke is removed by broad iron spades and shovels through the manhole, and the still is re-charged every 24 hours. One stoker serves 8 to 10 stills, and a stillman attends to 11 to 16 stills. The stills are generally coked, but sometimes the distillation is stopped and the residue run off to coking stills; this adds to the life of the stills. With vacuum distillation the suction is gradually increased from a slight vacuum at the beginning to 16–20 inches of mercury when the heavy oil and paraffin come over. Three-fourths of the charge is distilled off in 6 or 7 hours, the residue is cooled for 1½ hours and then run off to the coking still. The principal still gets 15 to 16 charges per week. Vacuum distillation saves fuel and has many advantages. The plant is kept fully occupied. Ten stills are charged at once in 10 minutes, hastened by the suction of the vacuum plant. The receivers are sometimes of cement, but now generally of iron.

Continuous distillation has only lately come into use. Wernecke in 1907 introduced a new type of continuous still (Fig. 9). It is of circular cross-

section, conical, broad at the top, narrow below. There is a series of flat rings fixed to the side of the still at such an angle as to form a series of gutters or channels. The oil introduced at *a* flows from channel to channel down the stairs, distilling all the time. The figure shows the heating and setting. The residue runs off by *d*. The vapour exit, *B*, at top carries off the light vapours to a condenser, while the pipe, *C*, rising from the centre of the bottom carries off the heavy vapours to another condenser. The pipe, *e*, carries a coil of plaited wire gauze with a shield, *D*, on the top. The oil vapours never touch the heated walls of the still and so do not crack, and the oil surface is twice that of the heating surface. The still only requires cleaning once in 6 or 8 weeks, and then the rings are easily lifted; there is little coking. A vacuum of at least 720 mm. is used (28 inches). The vacuum reduced the fuel consumption by 25%. There is a preliminary feed heater with a furnace for itself; and the temperature is shown by two thermometers, and ranges from 100°–210° C. There are three thermometers in the still. Towards the top the temperature is 230°–240° C., and towards the bottom 260°–280° C. The still produces an oil of high viscosity. The greater the vacuum, however, the less crystalline is the paraffin. The charge of oil is 600 kilos. (150 gallons), and 1,500,750 kilos. (380,000 gallons) is distilled in 826 hours.

The still benches are in all cases protected by walls, and roofed over with corrugated iron or felt. The stillman's platform has a fireproof partition protecting it from the fireman's platform.

The crude oil stills if distilled to dryness at ordinary pressure last 6 or 8 months; vacuum stills 6 to 8 years.

The ordinary specific gravity of Saxon crude oil is 0.870–0.880. By the first distillation it is fractionated into: 33% light oil, sp.gr. about 0.870, boiling range 100°–350° C.; 60% paraffin mass; 2% red grease, used for grease-making; 1% red product, returned to the crude oil; 2% coke; 2% permanent gas.

The light oil chemically treated and distilled produces a light oil and an intermediate oil containing soft paraffin. This light oil treated and distilled produces the marketable products benzine and solar oil. The benzine has sp.gr. 0.790 to 0.810 and flash point 25°–35° C. It has a taintly yellow colour with blue fluorescence and is used mostly for refining the paraffin. The bulk of it boils below 200° C. The solar oil, sp.gr. 0.825 to 0.835, has a light brown colour; flash point 45°–50° C. It boils below 270° C. Formerly used solely for lamps, it is now used for oil-engines.

If the crude oil has not been treated with

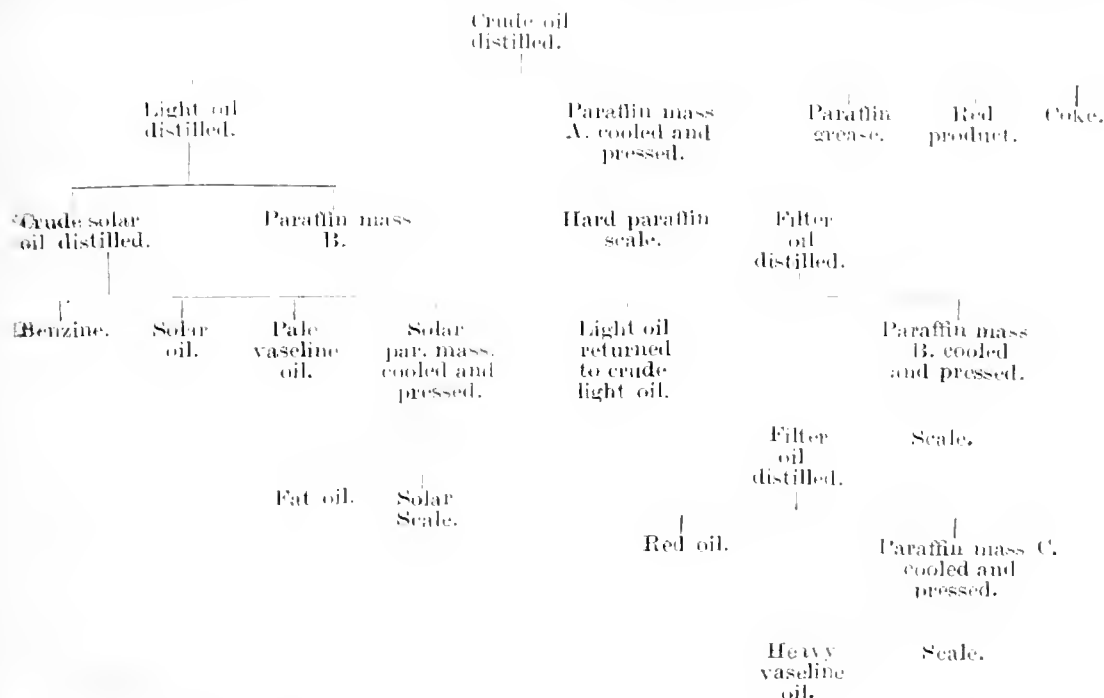

FIG. 9.

chemicals before distillation, the paraffin mass (the heavy oil containing paraffin) is now treated before cooling and pressing. The expressed oil is sometimes treated before distilling again, sometimes not. In distillation the oil is not coked, but 5% of the residue is run off without distillation, and sold as gondron. In the after distillations there are great variations in the different works and in the same works at different times, depending on the requirements of the market.

The following is a simplified diagram of one scheme of working:

The heavier oil products are:

Pale vaseline oil, a general name for cleaning oil, 0.848–0.850, having a pale yellow colour; yellow oil, 0.860–0.870, which is straw yellow; and red oil, 0.870–0.880. The yellow and red oils are mostly used for gas-making.

Dark vaseline oil, or **gas oil**, 0.880–0.890. Red-brown, used mostly for lighting railway carriages with incandescence burners; also for carburetting water-gas. It is extensively used for Diesel motors.

Heavy vaseline oil, 0.905–0.920. Dark brown, used for same purposes as dark vaseline oil, also as liquid fuel for the Navy; for the last-named purpose it is atomised by steam jet.

Fat oil, also 0.905–0.920. Red or brown. Sold unwashed; or refined for lubricating oil mixtures, when it is yellow.

Chemical treatments.—When the crude oil is treated before distillation the sulphuric acid used is of sp.gr. 1.53 or 106 Tw. In the other treatments the acid is sp.gr. 1.84 or 168° Tw. Fuming acid has been tried but does not give satisfactory results.

The caustic soda solution is made by dissolving drum soda in water, and is used of sp.gr. 1.36 to 1.38, or 73° to 76° Tw.

Some impurities in the oil are separated as tar with either sulphuric acid or caustic soda, whichever is used first, and sulphuric acid being the cheaper is in general applied first, unless there is a demand for creosote, when the soda is used first. To use the soda first has this advantage that the products of the soda reaction are more easily

washed out than the products of the acid reaction, so that secondary reactions are more easily avoided in subsequent distillations.

After the sulphuric acid treatments, settling and running off the tars, the oil is washed with water once or twice, then with recovered or weak caustic soda, and finally with strong caustic soda solution. The acid and soda washings are done in the same vessel, except for the finishing treatment. Creosote left in the oil causes the retention of solid paraffin.

The washers have capacities of 1100 to 1400

gallons. (In Scotland 30,000 to 40,000 gallons is washed at once.) Formerly the washers were of wood, now all are of lead-lined iron, the lead being 1.5 inch thick or so. The washers are always housed with sometimes a pipe to carry off the sulphur dioxide and other gases into the open air. The agitation long ago was effected by wooden paddles worked by hand; afterwards mechanical stirrers were used; in recent years it is by air-stirring. The washers are vortical cylinders with conical bottom, and the air is led down to the centre of the bottom by a lead pipe (Fig. 10). (In Scotland it is the custom to use malleable iron washers without lead lining, the strong sulphuric acid scarcely acting on the iron.) Oil containing paraffin is kept liquid for treatment by steam coil or steam jacket.

Whether the crude oil should be treated before distillation or not is a matter on which authorities differ. Treating first has certain advantages. There is less noxious gas on distillation, the coke is 50% less, and there is less permanent gas. Less heat is needed on the stills, and the stills last longer. With certain crude oils the yield of paraffin is increased by the preliminary treatment; with others it is decreased. It may be that when bitumen is present as such in the crude oil it comes down with the vitriol tar, and bitumen is capable of producing solid paraffin by destructive distillation, and is thus lost. Certain authorities hold that the retorting can be manipulated so that all the bitumen is decomposed and that if this is managed the preliminary acid treatment

does only good. (In Scotland it is found that destructive distillation of the crude oil is best; if acid is given first the total loss on refining is increased. The still-coke is valuable, and it is washed free from chemicals.)

When the paraffin mass has to be treated before cooling and pressing, it has to be very thoroughly washed with water after the soda treatment.

In treating the crude oil, to free it from water, $\frac{1}{4}\%$ of 106 Tw. acid is stirred in, or 1 to 2% of recovered acid. After this has settled and the tar run off, 3 or 4% of 168 Tw. acid is stirred in for $\frac{1}{4}$ hour. After settling for 3 or 4 hours and running off the tar, hot water is sprayed over the surface and milk of lime stirred in for $\frac{1}{4}$ hour. After settling and running off the tar the oil is ready for distillation. At this stage there is a great tendency for the oil to emulsify, and to prevent it skill and care are required.

In the subsequent treatments the lightest oils get 1–2% of acid, the heavier ones 2 to 4%, the hard paraffin mass 3 to 6%.

For the finishing treatments the acid and soda have separate washers. Only the paper oils get a finishing treatment at all, and this only in a few works. If found necessary to give a finishing treatment to the heavier oils, 1 to 3% of sulphuric acid is used, then weak caustic soda, sodium

Fig. 10.

carbonate, or sodium silicate. Sodium silicate is very useful for pale heavy oils. In refining, a total of 6 to 7% of sulphuric acid is used and 0.8 to 1.3% of caustic soda, calculated on the crude oil.

The refined oils are settled in iron tanks, holding 10 to 30 tons, until the water settles out and the oil becomes bright. For heavy oils a close steam coil is fixed at the bottom of the tank. Storage tanks, generally cylindrical, used to consist of pits of concrete or brick faced with cement; now they are generally of iron, embedded in a bricked pit, or on sand with a layer of asphalt. There is great variation in size, the largest being 770,000 gallons. Some are constructed as shown in Fig. 11, supported on a circular wall of brickwork. It has a central shaft fitted with a ladder, and having a glass window above the top of it.

All the oils used to be sent to market in barrels, and in very early times in glass carboys. Now 75%, or so is delivered by railway tank wagons.

Solid paraffin separation and refining.—Exhaustive attempts have been made on a works scale to extract the solid paraffin direct from the crude oil without distillation. The scale turned out dark and difficult to refine, and the method was abandoned. Paraffin is insoluble in alcohol, while the oil, resin, and creosote are soluble; but no practical man thinks of trying this on a works scale, although the method has been patented.

The distilled paraffin mass has been experimented on, to try to separate the paraffin by other means than cooling and crystallising, but as yet without success. Certain gases have been tried. Krey proved that the separation could not be carried out by dialysis. Centrifuging has not yet been successful.

In Saxony the paraffin mass is cooled in vessels, holding 6 to 12 gallons, with sides either vertical or tapered towards the bottom. They are exposed in cellars, first to air-cooling, then to water that has been used and is somewhat warm, then to cold water from spring or mine, so that by gradual cooling good crystals should form and grow. The cooling takes 1 to 6 days. Occasionally larger vessels of 22 gallons are used, and cooled only by air in airy apartments. This takes 10 to 15 days. The hard paraffin mass is cooled to 15° to 18° C. by natural cold in this way, and no refrigeration is used.

The soft paraffin masses are in some works crystallised in tanks of 500 to 1100 gallons capacity by the natural cold of winter, and the product is stored until winter comes and is then worked up. This requires a storage of about 1.3 the annual crude oil through-put. The cooling tanks are housed in buildings of light construction, and with walls that can be manipulated like venetian blinds, so as to let in the cold or keep out the heat as required.

In other works refrigerating machinery is used for the soft paraffin mass, which is put into small vessels, and cooled first with water, and then with cold brine. Ammonia solution machines were first adopted and the cold carried to the oil by a brine; but compression ammonia machines are now preferred as more efficient. The mass is cooled to -10° C. Refrigerating is much more efficient than natural cooling, and is carried on all the year round with many advantages. Wernecké uses cooling cells in a brine tank, and when the mass is firm it is ejected by pneumatic pressure into a conveyor to take it to the filter-presses. It is considered that for smaller works up to 5000 to 6000 tons a year natural cooling is most suitable; but for larger works refrigerating machines are certainly better. When natural cold is used and the paraffin crystallised, the oil can be drawn away from the paraffin without the use of filter-presses. Otherwise filter-presses are used first and hydraulic plate-pressing after. Plate-pressing without the filter-pressing was tried but would not do.

The chilled paraffin masses are pulped in a mechanical crusher (see Fig. 12), pumped from the receptacle below, and delivered to the filter-presses. The paraffin is scraped from the cloth of the filter-press with wooden spades. One filling of the filter-press yields about $1\frac{1}{2}$ cwt. of scale, containing still

Fig. 11.

some 26 to 30% of oil, and this is taken out with vertical plate-presses as in Scotland. The pressure is 100–150 atmos. The plate-press cloths are 32 to 38 inches square and the best are of wool on the inner side and linen outside, folded to a square of 15 to 22 inches; they are superposed in the press and covered with plates of sheet iron slightly warmed. $1\frac{1}{2}$ cwt. of scale from a filter-press yields

120 lb. of pressed scale. Referring to the diagram of operations given above:—

- "A" mass yields 15–20% of paraffin, m.pt. 50–55° C.
 "B" mass yields 10–15% of paraffin, m.pt. 40–45° C.
 "C" mass yields 10–15% of paraffin, m.pt. 38–42° C.
 Solar mass yields 15–26% of paraffin, m.pt. 35–40° C.

Attempts have been made to refine paraffin with sulphuric acid, as in ozokerite refining, also with chlorine, sodium sulphide, etc.; but all methods have given way to washing with brown coal light oil, called benzine, although it is too heavy and of too high a flash point to be included among the "spirits." Brown coal scale is always dark in colour. The sweating process used in Scotland and elsewhere does not serve the purpose; the amount of impurity is too great and the colour too persistent. Plate-pressed scale still retains 10–15% of oil. The paraffin is melted, mixed with benzine, and run off on to the surface of water. It solidifies into a homogeneous mass. The cake, 1 inch thick, is cut into squares and pressed in a horizontal hydraulic press. The presses hold 30–60 cloths, and a pressure of 200–250 atmos. is used. Two pressings are given, sometimes three, using lighter benzine each time. The presses are seldom heated with steam-pipes. The smell of benzine is removed by currents of steam passed through the melted wax, sometimes in stills, sometimes in open vessels; and if a still is used vacuum may be caused by a Koerting injector on the

FIG. 12.

condenser. The steaming is continued for 30 to 48 hours. The temperature of the steam is kept at 130° to 140° C. and must not be over 140° C. The steam must therefore not be highly superheated or at more than 4 atmos. pressure. This treatment makes hard paraffin odourless, but soft paraffin retains some smell. The colour of the wax is a faint greenish yellow. Boneblack was formerly used for a finishing treatment; latterly, char from ferrocyanide making has been employed. Clay, fullers' earth, and vegetable charcoal have also been tried. Before use the powder is dried at 100°–110° C. in ovens of various kinds derived from other industries. From 1 to 2% of char is used. No advantage is found from using more than this quantity, but it is sometimes given in two quantities. It is found inadvisable to use air in stirring. The product is thoroughly mixed for $\frac{1}{2}$ hour by mechanical or hand-operated stirrers, at a temperature of 70°–80° C. The mixture is allowed to settle and the wax filtered through paper in filter-presses. The paraffin is extracted

from the used char by benzine in apparatus that differs in every work. The char cannot be regenerated by calcination. Each works tests for itself the decolorising powder most suitable in its own case. A mixture of pure carbon and silicates is good.

Other liquids have been tried in place of benzine. Oleine, amyl alcohol, and other alcohols have been tried but found impracticable and expensive. Amyl alcohol has a strong smell and produces headache. The use of carbon disulphide involves high fire risk. Pyridine bases produce a fine white wax which is rendered inodorous by sulphuric acid of 1.26 sp.gr. (52° Tw.); this reagent is cheap enough but its penetrating disagreeable odour renders it inapplicable.

The paraffin wax varies in m.pt. from 35° to 62° C. When it melts below 50° C. it is called soft wax, above this it is called hard wax. It flashes at 160–165° C. The sp.gr. of paraffin of m.pt. 20° C. is 0.883; m.pt. 15° C., 0.908; m.pt. 58° C., 0.915. The hard wax is used principally for candles. There are five paraffin candle works in Saxony turning out 8000 tons of paraffin and composite candles per annum. The m.pt. of the candles is 125–130° F. (50–55° C.).

Soft wax, m.pt. 35–40° C., is largely used for dipping the sticks of matches; 1000 tons per annum is used for that purpose.

Messel refining. At Messel the sp.gr. of the crude oil is 0.855 to 0.860. On distillation it yields: Spirit, 1.00%; gas oil, 33.00%; and crude paraffin, 7.50%; while gas, coke, and loss in refining amount to 25.50%.

The crude oil is settled and without chemical treatment is pumped into high-level charging tanks from which the oil is run to the stills as required. The stills are much larger than in Saxony, and hold 16.00 to 1700 gallons. Partial vacuum is applied, and there are stirrers in the stills, which are worked continuously. The heavy residue is run off and coked in separate stills. There are mercury gauges to show the vacuum. The fuels used are the tars extracted from the vitriol and soda tars. The crude oil distillate is 16% light oil and 76% of a heavy fraction. The light oil is treated with 2% sulphuric acid and 3% caustic soda solution, and on distillation yields spirit, lamp oil, and gas oil. The heavy fraction receives a similar treatment and on distillation yields some light oil and the bulk as paraffin mass. The mass is air- and water-cooled to 15° C. and pressed, giving a hard paraffin. The oil filtrate is cooled down to –2° C. by cold brine from a freezing machine and pressed again, giving a soft paraffin. The oil is used for gas oil. The lamp oil is treated and has a good colour and smell, sp.gr. 0.800; but for burning in lamps it cannot compete with petroleum. The plant for cooling the paraffin occupies only one-tenth the space of a Saxon cooling plant. The vessels for the first cooling are vertical cylinders with scrapers which disturb the mass little but let new oil forward to the cold wall, and send the solid towards the centre. The oil is much more viscous than in Saxony. The second cooling of the oil filtered from the hard scale is carried out in large jacketed cooling tanks, with horizontal scrapers working at a slow speed. When chilled sufficiently the mass is pumped to the filter-presses without requiring further breaking up. The scale from the filter-presses is plate-pressed in vertical hydraulic presses. The Messel paraffin can be sweated to quality equal to American semi-refined for the market; or it may be further refined with benzine. For double refining it is first treated with small quantities of acid and soda, distilled in vacuum, and then refined as usual. The products are: spirit, sp.gr. 0.800, used extensively for petroleum engines; cleaning oil, 0.825 to 0.835; fat oil, 0.860; and lubricating oil, 0.890–0.892, used for

ght machinery. There are small quantities of other products.

Full details of Messel working are not given.

In Scotland the sulphuric acid is used twice over the refinery, first for the finishing treatment of the oils and then for the first treatment. The acid is separated from the vitriol tar with hot water, saturated with ammonia, evaporated in vacuum apparatus, and the sulphate of ammonia centrifuged. In Saxony they do not recover the ammonia, they wash out the acid as we do, but a proper use of it is still sought. Some of it is used for setting the cressote from the soda tar, and some goes to the mature manufacturers. It cannot readily be purified or concentrated.

The recovery of purified nitrogenous bases has been successfully carried out in several works. The pyridine bases were used for purification of anthracene, and for denaturing spirit to suit the German law of 1887. Now, however, the denaturing law is more stringent and this use has been given up. There is little pyridine present, the series beginning in quantity with the picolines. Lutidines are present, but bases of higher boiling point present in larger quantities have not even been isolated.

The vitriol tar neutralised with soda tar is dissolved and the residue is a glossy black solid, sold as asphalt. The gondron, the residue of the heavy oil not coked, is black and has the consistency of dough.

In the brown coal oil factories the chemists analyse the coal and select the material suitable for retorting, and see that it is properly distilled. They test the intermediate and finished products. They analyse and advise on the chemicals to be sought. The problem is always before them of improving the marketable products and at the same time cheapening the refining.

In regard to the coal testing, after careful sampling, which is always the most important part of an analysis, the moisture and ash are determined, the result of dry distillation noted, and the calorific value and percentage of bitumen determined. In determining the moisture it must be remembered that the coal readily absorbs oxygen and gives off carbon dioxide; so it is carried out in a current of inert gas or *in vacuo*. The laboratory distillation is carried out in a glass retort, fixed to a glass receiver by a cork which has also a tube to carry off the gas evolved: 20 to 30 grms. of the retort coal in its natural moist state is used. The heat is applied gradually, kept an hour at full heat, and the temperature then gradually lowered. It takes from 4 to 6 hours. The retort is weighed empty, charged, and after the distillation; and the receiver before and after use. The receiver is heated to cause a thorough separation of the oil from the water, then chilled with cold water or ice, and the cake of solid crude oil taken out, dried with filter paper, and weighed. The oil yield in the works is only 60% of the laboratory yield.

The bitumen is determined in dried coal with benzene in a Soxhlet apparatus. The bitumen extracted is a brittle solid melting at 80–85°C., and is extensively used for phonograph cylinders and stove polishes.

Crude oil contains 10 to 15% of solid paraffin, and the products of distillation the paraffin series is present from C_1 to C_{22} , or more, also olefines, acetylenes, and other hydrocarbons. In the crude oil the following substances are present according to Erdmann as quoted by Scheithauer: Paraffin series: Heptane, normal nonane, normal decane, undecane, heptadecane, octadecane, nonadecane, eicosane, heneicosane, docosane, triosane. Ethylenes: Decylene. Aromatic hydrocarbons: Benzene, toluene, *m*-xylene, mesitylene, naphthalene, chrysene, picene, and a hydrocarbon, $C_{11}H_{18}$, m.pt. 117°C., b.pt. 300–302°C. Naph-

thenes, in small quantity. Bases: Pyridine, α -picoline, β -picoline, γ -picoline, 2,6-dimethylpyridine (lutidine), 3,4-dimethylpyridine, 2,4-dimethylpyridine, 2,5-dimethylpyridine, 2,1,7-trimethylpyridine (collidine), quinoline, aniline, and a nitrile. Oxygen compounds: Homologues of acetone, phenol, *o*-cresol, *m*-cresol, *p*-cresol, guaiacol, creosol. Sulphur compounds: Carbon disulphide, thiophene.

My principal authorities for the foregoing notes are:—*Die Braunkohlenteer-Industrie*, by Dr. Ed. Graefe, 1906. *Die Braunkohlenteerprodukte und das Oelgas*, by Dr. W. Scheithauer, 1907. *Die Schmelzeere, ihre Gewinnung und Verarbeitung*, by Dr. W. Scheithauer, 1911. Of this last book there is a translation into English by Charles Sulter, "Shale Oil and Tars" (Scott, Greenwood & Son). Eleven of the illustrations in this paper are taken from the last-mentioned work, and are reproduced here by the kind permission of the publishers.

Newcastle Section.

Meeting held at Bolbee Hall, on Wednesday, February 14th, 1917.

Mrs. HENRY PELLE IN THE CHAIR.

THE CONSTITUTION OF COAL.

The members of the Section discussed the papers by Drs. Wheeler and Stopes on this subject (see this Journal, Jan. 31, 1917, Supplement pages 1 and 5).

Dr. P. PHILLIPS BEDSON said that there were so many different aspects of the chemistry of coal that it was no simple matter to determine in what way best to attack the problem of the nature of the substances which went to form the complex material. He was decidedly inclined to think that the best method of attack would be found to be based upon a systematic separation by the aid of solvents and such an examination of the several solutes as would afford more information as to their nature than could be obtained by the study of the products of their more or less destructive distillation. In the report of the Committee of the British Association, Section B, published in 1896 at the Liverpool Meeting, would be found a reference to the resinous bodies obtained from coal by the action of solvents which Muck, in his "Steinkohlenchemie," grouped as accessory constituents. Many of these resinous bodies would appear from the descriptions given by their discoverers to be mixtures. In looking through papers dealing with the subject, he (Dr. Bedson) had found one by Dr. Smythe, which was printed privately and published in 1897. That paper contained a valuable contribution to the chemistry of brown coal and illustrated a method of attacking the problem and, seeing that, of late, an interest in the chemical constitution of coal had revived, he thought it was desirable that it should be republished. The coal had been submitted to a systematic treatment with solvents and from the solutions some well-characterised substances had been obtained. The residual coal, *i.e.*, the portion not attacked by the solvents, had then been oxidised by a mixture of hydrochloric acid and potassium chlorate, yielding chlorinated products similar to those which Cross and Bevan had obtained some years previously by the action of chlorine on Wigan coal and which they recognised as similar to the chlorinated products obtained from lignified fibres. The oxidation products were very complex and their separation and isolation were

difficult. Amongst these products there would appear to be trichloroacetic acid and solids from which, by treatment with solvents such as ether, a complex $C_{22}H_{11}Cl_3O_{10}$ was isolated. As would be seen by reference to the 1896 report, similar complex products were obtained by treatment of bituminous coals. The difficulty met with in attempts to elucidate the constitution of these chlorinated products had led to the abandonment of that line of investigation. In the course of the examination of the action of solvents on coal about 1899, he had found pyridine a more satisfactory solvent than phenol or aniline, and, in his paper read before that Section in 1908, he detailed some of the results. These were avowedly incomplete but he was not without hope that, with a continuance of that method of working and with newer solvents, some further insight into the constitution of coal would be attained.

Dr. J. A. SMYTHE said that what little work he had done on the subject had convinced him of the enormous complexity of the problem. He had treated coal with various solvents and extracted some rather interesting substances, which seemed to be allied to those extracted within the last few years by Pictet, who had extracted coal on a very large scale with benzene and isolated some hydrocarbons. One of these was a C_{12} substance and Pictet had showed that that hydrocarbon absorbed oxygen from the air and became oxidised. As mentioned by Dr. Bedson, chlorination had led to the formation of very complex compounds indeed, one of the formula Dr. Bedson had quoted. In a series of the products that he had analysed, the hydrogen decreased quite regularly with the increase in chlorine. The large percentage of oxygen present was very interesting. He thought Dr. Wheeler somewhat ill-advised to introduce the term "cellulosic." It was an ugly word and implied a knowledge they did not yet possess. He regarded Dr. Stopes as more honest in the way that she made her classification as a result of an *a priori* deduction, more as a result of argument than founded upon a scientific study of the subject. He considered that these authors were attacking the subject in the right way by microscopic examination and chemical study. He had tried in the past to make transparent sections of coal and knew the extreme difficulty of getting them.

Dr. J. T. DUNN said that the amount of absolute knowledge of the constitution of coal which had yet been obtained was almost negligible. It was certainly no greater than it was in 1908 after Dr. Bedson published the results of his experiments on the exhaustion of coal by pyridine. The only new step seemed to be Dr. Wheeler's extraction of the pyridine extract by chloroform in which he seemed to have shown that that pyridine extract was composed of two separate parts. He thought the relation of the portion insoluble in pyridine to the portion soluble in pyridine but not in chloroform was a question that very much required examination. Parr and Hadley, of the University of Illinois, had done some interesting work, which seemed to have been very elaborate and careful. They had examined a great many of their local coals with the aid of phenol but, generally, the results of their phenol extractions corresponded with the results Dr. Bedson had obtained with pyridine. There was very little difference in the ultimate analyses. There were certain differences in the behaviour of the two when subjected to destructive distillation but no definite information was got and the American experimenters very wisely refrained from drawing any deductions as to the nature of the compounds from which that part of the coal was derived. The speaker thought that Dr. Wheeler had stated something to the effect that none of the hydrocarbons obtained by distillation from coal existed in the coal itself.

That was quite contrary to the result of the work of Pictet to which Dr. Smythe had referred. Pictet had distilled coal at as low a temperature as possible and had obtained some tar from which he had isolated a number of hydrocarbons running between C_8 and C_{12} . When he extracted a raw coal with benzene, he obtained from the raw coal hydrocarbons which were identical with those he had obtained from the tar, and, therefore, he assumed that they had simply distilled in his low temperature vacuum distillation. He thought that Dr. Stopes was going on the right lines in proposing to investigate microscopically not only the coal but the products of coal obtained by solution in pyridine and other solvents.

Mr. S. H. COLLINS asked as to the distribution of the nitrogen in coal.

Dr. DUNN said that Parr and Hadley had found it both in the portion soluble in phenol and in the insoluble portion.

Mr. COLLINS said that pyridine struck him as being a double-barrelled sort of extractor, in that it would extract resins as well as anything that was likely to be acidic in nature. The authorities all seemed to have the idea that humic bodies were present and anything of an alkaloid character would tend to extract these. The resin substances would affect the photographic plate and the humic substances would not. The results shown on the screen supported that idea. It would be interesting to know if these could be examined any further. Coal was a very curious substance because there were some instances in which coal made quite a good soil and other cases where it certainly made an extraordinarily bad one, and he did not quite know what it was that made the difference. The best soils produced from coal were generally from the type of coal one would not want to burn—i.e., coals with a very high percentage of ash.

Dr. BEDSON added that he did not altogether appreciate the idea that the way to get information about the nature of the various solids was to submit them to destructive or partially destructive distillation. He should rather like to see attempts which would lead to the discovery of individual substances amongst those bodies extracted by the different solvents from coal. Mr. Collins was perfectly right in his view of pyridine. He (Dr. Bedson) was very much entranced with pyridine, in the first instance, because it did so much, but it did rather too much for the purpose, and he thought the proper method of applying it would be to use as many solvents for resin as one could employ—and there were some coming on the market now with which he was making some experiments and, perhaps, at some future date in the next decade, he might be able to say something about the results. He had gone certainly on the idea that he should not apply pyridine directly to the raw coal but should treat the coal with pyridine after he had extracted as much as possible by other solvents which appeared to attack the resinic constituents. He did not know that Dr. Wheeler was altogether justified in distinguishing between resinic and cellulosic constituents. Besides the vegetable origin of coal, they had to consider the animal remains present from which, he dared say, some of the nitrogen came, and it was rather lumping things together to divide them into resinic and cellulosic constituents. That was a subject that had interested him for many years now. Whilst 20 years ago, chemists had been rather inclined to regard coal much as the ordinary consumer regarded it and, beyond that, to take very little interest in it except to use it for distillation purposes, he was glad to see that, in this country and in France and, no doubt, in Germany, in the last 20 years, a very considerable interest had developed in the nature of the compounds that went to form coal. The

outcome of that work must be very advantageous to science and lead to a considerable extension of our scientific knowledge. The subject was a vast one, but if the work were carried on systematically and the results properly collated, he felt that conclusions would be reached which would advance our knowledge of the nature of coal.

Replying to the Hon. Secretary (Mr. E. F. Hooper), Dr. BEDSON stated that, in using the pyridine, they had usually rectified it and used it with a fairly constant boiling point.

Mr. HOOPER remarked that Dr. Wheeler might obtain interesting results if he undertook the extraction of coal under reduced pressure by pyridine, so as to get the very lowest possible temperatures. He might very well extract bodies of a different character with pyridine at a low boiling point than he would under ordinary conditions.

Dr. DENN said that Parr and Hadley, dealing with phenol, had used it both in the cold and at the temperature of boiling toluene, and they had found no essential difference in the products, but they did find that the hot solvents extracted 1 or 2% more than the cold solvents.

Dr. BEDSON said that when quinoline was used, different results were obtained. They had carried out some coal extractions with pyridine at the ordinary temperature on a very considerable scale, filtering the pyridine through layers of coal two to three feet deep, and also there were some experiments with pyridine at boiling point. At the ordinary temperature, there was a difference in the nature of the products obtained.

The CHAIRMAN asked whether the resinic matter extracted by pyridine was the matter that bound the coal together when it coked.

Dr. BEDSON replied that what struck him at the very outset was that the pyridine extract of a coking coal coked readily but the residue had lost its coking powers. The pyridine extract would fill up an ordinary platinum crucible with the intumescent matter which was formed and the residue would give a sandy coke. One of the things that had always puzzled him was that cannel coals, for instance, the shales, yielded comparatively little to pyridine. He assented to the Chairman's suggestion that the resinic matter had something to do with the coking of coal. His impression was that less was extracted from a non-coking coal.

The CHAIRMAN said that he had been doing some work to see whether it was possible to ascertain whether certain pitches had greater binding powers than others.

Mr. HOOPER said that his experience in briquetting fine coal was that he could make as good a fuel briquette out of a coke-oven pitch as out of a coal-tar pitch, irrespective of the greater amount of soluble or volatile matter in the coal-tar pitch.

The CHAIRMAN said that a coke-oven pitch which had been made at a very much higher temperature had not the same binding power as a pitch that had been distilled direct, so far as electrode carbon manufacture was concerned.

Mr. HOOPER said that in fuel briquetting they had found it possible to use nearly 1% less of the by-product tar pitch than of coal-tar pitch and make as sound a block. That was admittedly against their previous ideas. Despite the fact that there was more soluble and volatile matter in gasworks pitch, the by-product pitch served as well.

Dr. BEDSON said that when he had first mentioned the matter of the action of pyridine on coals and the different behaviour of the solute and the residue from the coking point of view, Dr. Henry Louis had suggested that it might be possible to use the extract from the coking coal to make a non-coking coal into a coking coal.

New York Section.

Meeting held at Rumford Hall on Friday, January 19th, 1917.

MR. JEROME ALEXANDER IN THE CHAIR.

PRESENTATION OF THE PERKIN MEDAL TO DR. ERNST TWITCHELL.

The CHAIRMAN, in the course of his introductory remarks, gave a brief outline of the history of the Perkin Medal, and mentioned the names of previous recipients. He also called attention to some of the more important inventions made by Americans during the past fifty years.

He then called upon Professor Chandler to make the presentation of the Medal.

Prof. C. F. CHANDLER spoke as follows:—It is my privilege and very pleasant duty to present to Ernst Twitchell the eleventh impression of the Perkin medal. Dr. Twitchell was born in Cincinnati, on February 26th 1863. He graduated in 1886 from the University of Cincinnati and was then appointed chemist to the Emery Candle Co., of Cincinnati, with which firm he has been connected ever since.

Dr. Twitchell has devoted the past thirty years chiefly to the chemistry of fats. In 1891 he published his method for the determination of rosin in fatty acids of soap. The method is based on the fact, observed by him, that the fatty acids when dissolved in absolute alcohol, are readily and completely converted into ethyl esters by the action of dry hydrogen chloride. On the other hand, the rosin acids under the same treatment remain unchanged, and may be determined volumetrically with standard soda solution, or gravimetrically. Lowkowitz, in his comprehensive work on "Oils, Fats, and Waxes," remarks, "Of all the methods for determining rosin acids in the presence of fatty acids, the Twitchell method gives the best results."

Dr. Twitchell's most important contributions to industrial chemistry involve methods for the hydrolysis of oils and fats for the production of the free fatty acids and glycerin. These methods have very largely superseded the old methods such as that of Chevreul and Gay Lussac (in 1825), who saponified in open kettles with alkali. This process was improved by Milly in 1831, who substituted milk of lime for alkali, and later by conducting the saponification in closed vessels, under pressure, reduced the amount of lime required from fourteen per cent. of the fat to as low as two per cent. Then came the process of Dubrunfant, first applied practically in 1842 by Jones and Wilson, in which the fat was saponified by sulphuric acid, and the fatty acids subjected to distillation.

Wilson and Gwynne later applied the discoveries of Berthollet and Nelsens in a process in which the fat was decomposed by superheated steam and subsequent distillation, which was practised at the works of Price's Candle Co., Battersea. Finally in 1854, Tilghmann introduced his process in which the fat, emulsified in water, was forced through a coil at a temperature of 320° C. Marix found that by adding a little calcium or magnesium carbonate to the water, the temperature and pressure could be very materially reduced to as low even as 3 to 5 atmospheres.

The art of saponifying the fats had reached this stage of development when Dr. Twitchell made an entirely new departure by the application of new reagents, which by acting as catalysts, even when used in such small proportions as one to two per cent., are able completely to saponify the fats. The operation may be conducted by simply boiling the

fat with water and the proper quantity of the "saponifier." The agents first employed by Dr. Twitchell were the sulphonic acids of the fatty acids, such as sulpho-stearic acid, sulpho-oleic acid, etc. Later Dr. Twitchell found that by introducing an aromatic radical into the sulpho-acid, a much more satisfactory catalyst was obtained—a sulpho-fatty-aromatic acid. Such aromatic radicals as are furnished by benzene, phenol, and naphthalene are employed, naphthalene stearo-sulphonic acid being a favourite catalyst. These acids when converted into salts of such metals as barium, calcium, magnesium, aluminium, etc., can be produced as stable dry powders, to be used with a suitable proportion of sulphuric acid or hydrochloric acid to make them active.

The Twitchell process has made possible the large scale saponification of fats for the production of crude glycerin free from salt and of fatty acids for direct combination with soda to make soap instead of using the more expensive caustic lye on the neutral fat.

Low-grade fats, such as garbage grease, cottonseed oil foots, etc., were formerly with difficulty used in the soap or candle industry. Such material can now be readily worked up by the Twitchell process, the fatty acids being distilled to remove their colour before use. This releases a large quantity of the higher grade fats for use as food products.

The bulk of the soap used in Belgium, Holland, Germany, and Scandinavia is said to be prepared from fatty acids direct, and 75% of these acids is made by the Twitchell method. Millions of pounds of fat are saponified yearly in the United States by this process; and practically all of the larger soap factories have Twitchell plants.

All of the recent books in German and English on the soap and fat industries discuss the Twitchell process in full.

After giving a list of Dr. Twitchell's publications and patents, Prof. Chandler presented the Medal.

Dr. TWITCHELL, in acknowledging the presentation, said: The first suggestion which led to my discovery of a special catalyst for hydrolysing fats came to me in studying the so-called acidification process. This was one of the oldest methods used in candle factories for separating glycerol from fatty acids. It consisted in treating the fat at a fairly high temperature, over 100° C., with a small amount of concentrated sulphuric acid—4% or considerably less could be used; the product was then boiled with an excess of water. The result is a layer of fatty acids floating on the acid water containing the glycerol.

This reaction could not be explained by the assumption that there is a combination of sulphuric acid with the fat or fatty acid and glycerol, which decomposes during the subsequent operation of boiling with water, because there was not enough sulphuric acid to combine with all of the fat. I have seen various theories given to explain the acidification process, some quite absurd. For instance, in one text book it is stated that fats consist of minute globules surrounded by membranes and that the function of the sulphuric acid is simply to char and destroy these membranes, leaving the fat in a condition to be hydrolysed by water at 100°. Another theory I have frequently seen even in recent articles, is that compounds are formed which cause the fat to emulsify with water, and the idea evidently is that if a good enough emulsion is obtained, hydrolysis will take place even at 100°. I have seen this theory given to account for the action of my hydrolysing reagent. As a matter of fact, fats do not hydrolyse at 100°, practically speaking, with water alone, even though they may be perfectly emulsified. At higher temperatures than 100°, and under pressure, hydrolysis takes place as is illustrated in the autoclave process of separating glycerol.

In the course of practical experiments with the acidification process I found that I could reduce the amount of sulphuric acid used very considerably and yet obtain complete decomposition; but often the boiling with water had to be decidedly prolonged. It seemed clear that there was some catalytic agent which caused the reaction between the fat and the water in this process of boiling, and it would naturally occur to any one that this catalyst was probably some sulphur compound produced by the action of sulphuric acid on fat. I found that compounds of this nature could be roughly separated from the fat which contained them by treating with petroleum ether, in which they were insoluble. They could be further purified by solution in ether and extraction with water and were easily identified as sulphonic acids by their acidity, the formation of potassium sulphate on fusion with caustic potash, and other characteristics.

It occurred to me to prepare this catalyst outside the body of fat, thus avoiding the action of the sulphuric acid in forming with the fat undesirable compounds, in charring, discolouring, and partially destroying it.

As these sulphonic acids were probably produced by the action of the sulphuric acid on the oleic acid constituent of the fat, I first studied the results of the action of sulphuric acid on pure oleic acid under various conditions of temperature, quantity, etc.

The action of sulphuric acid on oleic acid at low temperatures, as was known, produces a compound of sulphuric acid, stearo-sulphuric acid, an acid sulphuric ester. This was not the catalyst that I was seeking. It very probably has all the properties of a catalyst for the hydrolysis of fats except one: it is decomposed on boiling with water, and as the hydrolysis of a fat hardly takes place at all under any circumstances at a lower temperature than 100°, it is plain that this compound would not serve my purpose.

The compounds obtained on treating oleic acid with sulphuric acid at a temperature of 100° or over are not sulphuric acid compounds but are true sulphonic acids. The principal one seemed to be derived from two molecules of oleic acid and contained one sulphonic acid group and one carboxyl group.

I have never seen this sulphonic acid described, but I believe that I had in my hands a fairly pure compound of the composition—

This was my first hydrolysing reagent or "saponifier." But as it was difficult to prepare commercially in fair yield and of any degree of purity, I dropped further investigation along this line on the accidental discovery of the fatty-aromatic sulphonic acids, described in the Journal of the American Chemical Society of January, 1900.

In this research the most important question was: What properties must a substance have to act as a catalyst to accelerate the hydrolysis of fats? My views on this subject I have partially expressed in my paper "A reagent in the chemistry of fats," published in the Journal of the American Chemical Society of February, 1906, where I say that it must be a strong acid, one dissociated strongly in water giving a considerable concentration of hydrogen ions; and then it must be soluble in both fat and water and cause the one to dissolve in the other.

The only bodies that I can at present conceive to have the desired properties are sulphonic acids containing higher fatty radicals. They have the physical character of fats or oils, yet are soluble in water forming soapy solutions, and are strong acids.

As I have said, the discovery of the fatty-aromatic sulphonic acids was made by accident. On treating a mixture of oleic acid and benzene with

an excess of sulphuric acid and pouring the mass into water, I found an oily layer floating on the acid water, which was soluble in pure water; that did not surprise me, as I supposed I had simply stearo-sulphuric acid; but when I found that after boiling for half an hour with water it still remained soluble, I concluded that I had a sulphonic acid, and the analysis of the product confirmed my conclusion. This is the compound which has been put to practical use in the separation of glycerol and fatty acids. Instead of benzene, naphthalene is used with oleic acid in the manufacture of the commercial article. This "saponifier" when added in the proportion of 0.5% or less to fat boiling with water in an open tank, will cause the separation of the glycerol.

Besides the compounds containing two stearic radicals and a sulphonic group, the first which I found to have the catalytic property, and the fatty-aromatic sulphonic acids, I have also prepared hydrolysing reagents by treating oleic acid at 200–220° C. with sulphur, or in the cold with sulphur chloride (S_2Cl_2), and then oxidising with nitric acid, potassium permanganate, bromine, or other oxidising agent. The resulting compound contained one sulphonic and one carboxyl group and its molecular weight and other properties showed it to be a sulphonic acid of the stearic radical.

Belonging to this class of substances is a compound, cetyl-sulphonic acid, described by A. Reyher two or three years ago. When I saw this description I was sure that it was also a catalyst of the same type as my reagent, although Reyher does not mention this as one of its properties. As this is a typical compound, it may be interesting to describe how it was prepared, partly following directions given in Reyher's paper. Cetyl alcohol, prepared by saponifying spermaceti with caustic potash and extracting the soap with petroleum ether, was converted into the iodide by dropping iodine into a heated mixture of the alcohol and red phosphorus. This iodide, after purification, was converted into the sulphhydrate by treating with alcoholic potassium hydrogen sulphide and the cetyl sulphhydrate converted into cetyl-sulphonic acid by oxidising with potassium permanganate, the excess of which was reduced with sodium sulphite. The cetyl sulphonates could be freed from most of the foreign matter by taking up with hot water, from which sodium cetyl sulphonate crystallised on cooling. This was dried, extracted with petroleum ether, then dissolved in water and treated with hydrochloric acid. The salted out cetyl-sulphonic acid was dissolved in ether and remained in a nearly pure state as a residue on evaporating the ether. It can be further purified by crystallising its sodium salt from dilute alcohol and there can be no doubt as to its composition. It is a simple sulphonic acid of a hydrocarbon of the paraffin series.

Reyher explains some peculiar properties of this compound in this way: the sulphonic radical tends to make it very soluble in water, while the long hydrocarbon chain has just the reverse effect. The result is that it forms colloidal solutions. Fabron, in reviewing Reyher's article, calls the cetyl-sulphonic acid, "Reyher's hydrogen soap," and that term hydrogen soap is as good a definition as I can think of to cover the whole group of compounds which catalytically induce hydrolysis of fats on the principle of my discovery. An alkaline soap plus hydrogen ions would no doubt have the same effect if it were possible to have such a combination.

Besides its use in hydrolysing fats, my catalytic agent has been applied to other less important ones. A catalytic agent which would accelerate the hydrolysis of an ester in the presence of an excess of water, would also accelerate the esterifi-

cation of a fatty acid and an alcohol on the removal of the water formed. Fatty acids can be made to combine with glycerol and other alcohols of high boiling point by simply treating a mixture of the two with a small quantity of the reagent and evaporating the water formed at 100° C.

The solubility of sulpho-fatty acids in both fat and water leads to a method of separating solid and liquid fatty acids of which I have made some application. If a small quantity of the sulphonic reagent is dissolved in melted mixed fatty acids and the mixture allowed to cool, the solid acids will crystallise out pure and the liquid acids will contain the sulpho-fatty acids, being thus rendered slightly soluble in water, and on treating with water, can be washed out from the mixture, partly in solution but mainly as an emulsion.

Patents have recently been obtained by Grigori Petroff of Russia for a reagent obtained as a by-product in refining petroleum with fuming sulphuric acid. This is a sulphonic acid of hydrocarbon radicals, probably not of the paraffin series. It is a very efficient catalyst in the hydrolysis of fats, for which purpose it is now largely used.

THE TWITCHELL PROCESS AND THE GLYCERIN TRADE.

BY A. C. LANGMUIR.

The Twitchell catalytic process (U.S. Patent 601,603, July 17, 1897) was invented at a time when catalysis was not the universal subject of attention it is to-day.

Twitchell's work has been characterised by a sound appreciation of the work of physical and organic chemists and his analytical and technical methods have been worked out, not empirically, but from theoretical premises. Thus the Twitchell method for the determination of rosin in mixtures with fatty acids, as in soap analysis, rests upon the principle of the esterification of the fatty acids when treated with dry hydrogen chloride in presence of absolute alcohol and his discovery that resin acids when so treated refused to combine with alcohol and could subsequently be separated as pure rosin. Although published in 1891 this method stands to-day as the most accurate process for the determination of rosin in presence of fatty acids.

Again in 1897 we find him bringing out a method for the separation of saturated and unsaturated fatty acids based upon the solubility of fatty acids with double bonds, such as oleic acid, in concentrated sulphuric acid at ordinary temperatures, with the formation of sulpho-fatty acids soluble in water. The saturated fatty acids such as stearic acid are unacted on. In 1914 Twitchell made use of the principle of the equal depression of the freezing point for equal molecular proportions and determined the composition of mixtures of fatty acids by the observation of the freezing point in the Beckmann apparatus. To test whether a given sample of fatty acids is identical with a fatty acid of known character he adopted the novel plan of adding a portion of the known acid and noting whether there is any change in the melting point of the mixture.

Possibly his investigation of the action of concentrated sulphuric acid on fatty acids led to his discovery of the catalytic action of these sulpho-fatty acids in bringing about the decomposition of fats by water, as little as 0.5% splitting up the fats almost completely on digestion with water.

The prevailing method for the manufacture of soap consists in the saponification of the fat by boiling with caustic soda lye. The fatty acids combine with soda as soap, which is separated by the addition of salt and comes to the surface in the molten condition. The glycerin is set free and remains dissolved in the spent lye. It is contami-

nated by the presence of the salt used to render the soap insoluble. During the concentration of the spent lye for the recovery of the glycerin a large quantity of salt is thrown out, making the evaporation somewhat difficult, although this difficulty has been largely eliminated of late years by the use of properly designed evaporators working *in vacuo*. The final crude glycerin is a saturated solution of sodium chloride and some sulphate together with sodium salts of the lower fatty acids, in glycerin and water. The glycerin averages about 80% and contains about 10% mineral salts.

The glycerin refiner distils this crude soap-lye glycerin with superheated steam *in vacuo* for the production of dynamite glycerin and chemically pure glycerol. The presence of so much salt raises the boiling point of the glycerin and reduces its vapour tension so that the output is reduced. Furthermore, the salt accumulates in the still producing finally a semi-solid mass of salt and glycerin together with tarry matter which constitutes the "foots" of the glycerin trade. It is a difficult matter to extract all the glycerin from this residue without undue loss. The treatment of the "foots" is one of the problems of the glycerin trade.

The glycerin distiller therefore prefers a crude glycerin which is free from this large admixture of salt. Up to the early nineties all the crude glycerin refined consisted of what is termed saponification or candle crude. It was the by-product of the candle factory and was produced by the breaking up of fat in autoclaves by heating under pressures of 200 lb. and more with water and a little lime. The fat was split into fatty acids and glycerin directly and the latter was a product of considerable purity, containing about 88% glycerin and less than 1.0% of mineral matter. With the greatly increased demand for glycerin for explosives, the soap makers, who formerly discarded their spent lyes, found it profitable to work them up; to-day scarcely a soap plant can be found that does not recover its glycerin as a by-product. This change in the business compelled refiners to develop methods for distilling soap lye crude glycerin and eventually the larger refiners were working mainly on soap lye rather than candle crude, although there were still a number of glycerin refiners who worked exclusively on candle crudes. Saponification crudes free from salt have always been in greater demand and have commanded a higher price per unit of glycerin. For several years before the advent of the Twitchell process it looked as if saponification glycerins would practically disappear as a raw material in glycerin refining, but with the success of this process the Twitchell saponification crudes made their appearance and are now a factor of very considerable importance.

The ideal of the glycerin refiner has thus been the production of a saponification rather than a soap lye crude by the soap manufacturer. It has also been the hope of the soap trade to obtain directly by the deglycerinising of the fat a relatively pure glycerin as a by-product and free fatty acids which could be combined with the cheap alkali, sodium carbonate, to make soap instead of the relatively expensive caustic soda. To meet this need have been developed the Twitchell process, the Krelitz lime saponification method, and the Comstein process.

The Twitchell process is characterised by its simplicity, and the low cost of the plant. Prior to Twitchell's discovery free fatty acids could only be obtained by the autoclave process, involving a heavy capital outlay for copper apparatus, which could only be used in small units and at a high temperature and pressure, making the operation expensive and somewhat dangerous. The autoclave saponification was used only in the preparation of fatty acids for candle manufacture, as the

process was too costly to be used in the production of fatty acids to be used in soap. The Twitchell process is effected in loosely closed wooden tanks by digestion with water and as little as 0.5% of the reagent and at a temperature not exceeding that of exhaust steam. The reaction may be carried out on a scale limited only by the size of the tank. The Twitchell process has made possible the saponification of fats on a huge scale for the direct production of free fatty acids and saponification glycerin. When combined with the distillation of the fatty acids for the improvement of their purity and colour, it has opened up for the soap trade the use of low grade fats such as garbage grease and cotton seed oil foots, the distilled fatty acids being combined directly with carbonate of soda to produce light coloured soaps, and the glycerin being made available for the manufacture of dynamite glycerin. In this way the Twitchell process has benefited the glycerin trade in these days of glycerin scarcity by opening up new sources of supply, which were previously unavailable.

The crude glycerin prepared by the Twitchell process comes to us from all parts of the world in normal times. There is no evidence that it is any less pure than the saponification glycerin prepared by other processes provided the fat used as a raw material is reasonably pure. Of course a crude glycerin manufactured from a low grade fat will fall behind a crude made from good yellow, but this is the fault of the fat and not of the Twitchell process.

THE TWITCHELL PROCESS IN THE SOAP AND CANDLE INDUSTRY.

BY MARTIN H. ITNER.

It is essential in the candle industry to have a satisfactory method for separating the fatty acids, as such, from fats and oils. In the soap industry such a method, although it may be considered highly desirable, is not absolutely essential, since very satisfactory methods of direct saponification by alkali with the formation of soaps have long been utilised.

In recent years there has been an ever-increasing demand for fats and oils and for glycerin, resulting in greatly increased market prices for these articles. The market for soap and candle materials is directly related to the market for fats and oils for edible purposes, and an increased demand from either source usually results in higher prices for all fatty materials. High costs of fatty materials have made the practice of economy in the soap business essential. This economy may manifest itself in several ways. We will assume at the outset that the soap manufacturer wishes to maintain the quality of his products and therefore does not wish to make any sacrifice in this direction. His economy must therefore direct itself in one of the following directions. He must be able to utilise the fats and oils which give the greatest soap-making value at the lowest cost per unit, whether these materials are of the better or of the poorer grades, and he must so utilise his raw material that his final product will be of the same high quality no matter which grade is used. This means that he must have a method for getting good results out of poor material when poor material gives him the greatest value. It is also essential that he have some method whereby he may realise the maximum yield of glycerin at a low expense for recovery. This will readily be understood when I explain that at present market prices for fats and glycerin, which are both abnormally high, the value of the glycerin which can be obtained from one pound of neutral fat is about one third of the cost of the fat. Another possible way of economising is by quicker and easier methods of manufacture.

All of these advantages have been realised in some degree by the advent of the Twitchell process. This process has given a rapid and easy method of obtaining fatty acids and glycerin from the better grades of fats so that the fatty acids are at once ready for making into better grades of soap, and the glycerin is in a condition suitable for easy refining. With care of operation the yield of glycerin may be made to approximate closely to that theoretically obtainable. When one operates on fats of poorer quality, and this may include black greases, the Twitchell process furnishes a most satisfactory method for saponifying. It renders the glycerin available even from such material and gives acids in good condition for refining by means of distillation. Such acids when carefully distilled yield a product of light colour suitable for making good soaps of light colour.

The use of fatty acids as such, has made it practicable to use soda ash very largely in the place of caustic soda. The former will combine direct with fatty acids making soap from which the glycerin has already been recovered, whereas caustic soda is necessary for the direct saponification of fats into soap, and tedious methods must be used for recovering the glycerin, and, except with the greatest care, the yields will be poor. It will thus be seen that in the use of fatty acids a saving may be effected even in the alkali employed, as soda ash is considerably cheaper than caustic soda per unit of alkali.

Fatty acids suitable for making into soaps are also suitable for making into candle material. Partial solidification on cooling will, with the aid of pressing, separate the solid from the liquid acids. The former yields commercial stearic acid, so extensively used in candle manufacture, and the liquid portion yields the oleic acid, or red oil of commerce. Red oil is used for many purposes, one of the most important being the manufacture of soaps for washing wool. The manufacture of stearic acid and red oil did not originate with the Twitchell process, but the advent of the Twitchell process gave a new and satisfactory method for the saponification of fatty materials at atmospheric pressure, with advantages over methods formerly used. Saponifications by means of the Twitchell process may be carried out on a larger scale, with less danger and with greater ease than is obtainable by other methods of acid saponification.

Twitchell's first process in which he recommended the use of sulpho-oleic acid was soon very much improved by the use of naphthalene along with the oleic acid during sulphonation. Whatever the chemical action in the formation of this reagent, it is my observation based on many experiments that satisfactory saponification will result from saponifiers made as Twitchell recommends, whereas poor results only are obtainable when separate sulphonation and subsequent mixing are tried. I may say that I was among the first to have an opportunity to become acquainted with the process, and that this acquaintance has become closer with added years. This process has been put to extensive use not only in America but also in European countries.

Twitchell later devoted himself to a method of manufacturing his reagent which would enable him to produce it in a more concentrated form. He accomplished this by methods of washing, extraction, precipitating as an insoluble salt readily convertible into an active reagent, and drying.

Twitchell and others allied with him have been busy in trying still further to perfect the process of atmospheric saponification of fats into fatty acids and glycerin, with the result that a new sulphonated reagent with increased efficiency has lately been put upon the market.

The Twitchell process has been so simple in use

that one is almost inclined to look upon it as nothing out of the ordinary. On careful thought one is forced to conclude that it is this simplicity, which has become almost commonplace, that commends it most to the many who have become familiar with it in operation.

Mr. HERMAN B. SCHMIDT followed with an appreciation of the work of Dr. Twitchell, in which he recalled the primitive conditions under which chemical work was carried out in the early days of Dr. Twitchell's career.

Nottingham Section.

Meeting held at University College, on Monday, December 11th, 1916.

DR. R. M. CAVEN IN THE CHAIR.

OUR NEED OF A NATIONAL FUEL AND POWER POLICY.

BY HENRY E. ARMSTRONG.

At a time when action and action taken without avoidable loss of time alone can save us, I am loth to come before you merely as a talker—being sick of talk, of my own feeble efforts especially: indeed, my talking on so outworn a theme will only be justified if I am successful in securing your promise of action, of action that will serve to promote reforms long overdue, the need of which is the consequence of that mental slothfulness by which we have so unfortunately been afflicted. As a nation, we are on our trial in every direction. Within the next few years, we have to show that our past lack of receptivity is not innate, but the outcome of a false and narrow system of education, lacking all the elements of true culture; without fail, we must raise up a new generation, one that is alive to its opportunities and responsibilities, fully prepared while meeting the latter to take advantage of the former. We must abandon mere book learning, deskery in schools, and take to doing things and thinking the while; there must be far less so-called teaching and some real learning: effective training must be substituted for parrot knowledge. As the Australian Prime Minister forewarns us, in his eloquent brief introduction to one of the most significant of recent books, Dr. E. J. Dillon's "Ourselves and Germany":—"We must awaken or be awakened ere it be too late. Germany," he says, "is living in the present and the future. It is a present of determined effort, of unlimited sacrifice, of colossal hope. The future for which she strives and suffers is a future incompatible with those ideals which our race cherishes and reveres. Either our philosophy, our religion and code prevail, or they fade into decay and Germany's aims remain. The choice is definite."

If Mr. Hughes be right, it is to be feared that, pending the inevitable but probably far distant struggle between East and West, we are cruelly destined to be in constant antagonism with our Teutonic neighbours. The skin-deep veneer of civilisation having been stripped from them, we are made aware that their instincts, at bottom, are more primitive than ours; being receptive, systematic, and almost superintelligent, this makes them all the more dangerous as a people—because,

in many ways they are ruthless where we are apt to be considerate. The streak of altruism which runs through our composition will be a distinct hindrance to us in the struggle of the future—inevitable because competition is the essence of progress—so that if we are to counteract its adverse influence, we must sharpen our intelligence to the utmost.

When the present conflict on the field of battle is at an end, we shall be called upon to face a more enduring and difficult struggle in the fields of industry and commerce. The race will be neither to the swift nor to the strong so much as it will be to the intelligent and the persevering.

Fuel, as the source of mechanic power, if not the chief, will obviously be one great factor in the struggle. We have long been told that our fuel supplies will suffice us for but few centuries. Should supplies be still available in Central Europe when ours are exhausted, our position must be a sorry one. If, therefore, we can look forward and desire to retard our downfall, we must seek to conserve our supplies of fuel to the utmost farthing of value. Meanwhile, it would seem that we have it in our power at least to halve our present coal bill by improving the methods of using fuel.

But little argument should be necessary to recommend so self-evident a proposition as that I have posed in my title—if it be not already accepted as proved, no further argument that might be advanced will make it acceptable.

Our policy hitherto has been one of drift—of wait and see, a self-condemnatory phrase, because those who wait to see, never having seen, never will see. The question is—are we ever to be too late in dealing with Fuel and Power Problems? If we never acquire and display the gift of insight, if we do not now realise that we must organise all our forces in dealing with such problems and subject them to comprehensive treatment, the solution cannot be otherwise than partial and unsatisfactory. "The Times," only a few days ago, printed an account of a speech by a Bavarian Prince, and in doing so provided it with the proud heading, "We are prepared for everything." Can we say that we are prepared for anything? I fear not.

The question is: Can we overcome our innate deficiencies and be practical—in other words, apply theory to its utmost limits and be seized by and act in accordance with the spirit of our times, the spirit of progress. To use eloquent words put into the mouth of Cromwell by Lowell, it is clear, that—

"New times demand new measures and new men;
The world advances and in time outgrows
The laws that in our fathers' days were best;
And doubtless after us some purer scheme
Will be shaped out by wiser men than we.
Made wiser by the steady growth of truth.

Our time is one that calls for earnest deeds.

When, several months ago, I undertook to introduce the present discussion here, I was not aware that this is the most sinful town of consequence in the kingdom—the most sinful in its Fuel and Power policy or rather in its lack of a policy worth calling one. I say this having learnt recently that several important firms in the town are spending large sums on the installation of electric power plant—because the Corporation, which has the monopoly, declines to supply electric current on terms other than those it wrings from the ordinary small user who consumes only the equivalent of a few candles a day—3½d per unit for light and 1½d. per unit for power.

What is of more consequence, you have the distinction, I believe, of being the worst served city in the kingdom. This is clearly brought out

in Table I., in which figures are given for all the towns where ten million units or more are generated per annum.

TABLE I.

Town.	Costs.	Selling price.	Total units in millions.
Aberdeen	0.58	1.28	10.46
Belfast	0.68	1.16	19.03
Birmingham	0.56	1.13	73.76
Bolton	0.64	1.11	28.74
Bristol	0.67	1.44	13.5
Coventry	0.33	0.89	20.25
Dundee	0.61	1.04	14.95
Edinburgh	0.91	1.75	17.87
Glasgow	0.56	1.07	88.83
Greenock	0.51	1.03	14.20
Halifax	0.65	1.28	11.07
Huddersfield	0.79	1.31	10.5
Hull	0.78	1.44	12.9
Leeds	0.40	1.00	44.79
Liverpool	0.59	1.5	53.07
Manchester	0.56	1.02	117.92
Nottingham	1.04	1.78	12.86
Salford	0.79	1.29	19.65
Sheffield	0.42	0.97	44.87
Stalybridge	0.29	0.66	23.6
Sunderland	0.60	1.08	15.05
West Ham	0.61	0.88	35.64
Wolverhampton	0.55	1.00	13.12

Although close to a colliery, your coal costs are higher than those of other towns in the district of far smaller output, no better nor worse situated than you are (Table II.).

TABLE II.

Town.	Coal costs.	Oil, etc.	Total costs.	Units generated.
Loughborough ..	0.28	0.03	0.78	1,300,000
Derby	0.31	0.02	0.72	8,000,000
Long Eaton	0.56	0.02	1.05	1,100,000
Burton	0.23	nil	0.65	3,500,000
Chesterfield	0.33	0.03	1.06	1,750,000
Kettering	0.34	0.04	0.87	1,890,000
Lincoln	0.26	0.02	0.75	2,300,000
Mansfield	0.28	0.07	0.81	1,600,000
Nottingham	0.59	0.06	1.04	12,860,000

You also compare most unfavourably with other towns in electrical costs and the number of units sold per head of the population (Table III.).

TABLE III.
Electrical Costs.

Town.	Works costs.	Units generated.	Average price.	Units sold per head.	Financial results.
Stalybridge	0.29	18	0.63	178	+ £4,171
Coventry	0.33	20	0.89	161	+ 22,455
Leeds	0.36	43	0.91	62	+ 12,171
Bury	0.38	10	0.69	154	+ 2,038
Sheffield	0.42	44	0.97	70	+ 25,800
Keighley	0.49	5	0.86	102	+ 1,025
Luton	0.54	8	0.91	146	+ 4,430
West Ham	0.61	35	0.86	99	— 8,552
Average	0.427	23	0.84	121.5	
Nottingham	1.04	13	1.78	27	+ £13,400
% Difference	144		110	450	

I am told that the heat lost in waste steam at the generating station would keep the town warm.

But I have no desire to pillory your town. It is entirely an accident that I happened to light on you as a crying example of the need of reform and

especially of a national policy to influence the public treatment of grave problems such as those before us.

* * * * *

Action must be taken if we are to move forward as a nation. Some few of us must apply the spur so sharply that it be felt and responded to.

The spur I wish to apply is that of a Central Fuel and Power Board. The first duty of such a board would be to take stock of our national requirements and resources and to excooperate a policy of meeting the former while utilising the latter in the most scientific and economical manner possible.

Without such a Central Board and a National Policy, it will be impossible to overcome the vested interests by which the path of progress is now blocked; also to avoid the colossal waste of money and the still worse delays that will be entailed if ignorance and the lawyers are allowed to intervene at every step. If we are to save ourselves, short and summary methods must be used, our national position being at stake.

You have coal at your doors but you make no proper use of it; you do not for one moment appreciate its value—what is in it, what can be made of it. Why is it not used scientifically or economically; do your schools allow your children ever to learn anything of consequence about it—if they did, would not housemaids and others know how to light fires; why is no organised connexion established between commerce, coal gas and electricity in your district; why are you not provided with smokeless fuel; why are you wasting so many good things which might be won from the coal you burn if it were used rationally? These are questions which the public should ask at elections—questions which they should insist on having answered by deeds not words. If a town or two took such a line of action, our country might be saved.

* * * * *

If an example be once set, it will spread like wildfire among the ignorant, particularly if the order be given to do likewise: we are learning every day that we can be obedient and do things easily when forced by circumstances.

There are two main directions in which we must move—the one being that of economy and conservation of our resources, the other that of public health and comfort; the two are coincident, in many ways.

It is well known that our methods of getting coal are in many respects inefficient. Prof. Lewis dealt with this question, as an expert, at the recent annual meeting of our Society.

But our ways of using coal are far more defective than our ways of getting it. The discussion carried on in the Press of late with regard to dye-stuffs has made the public aware of the special value of some of the products from coal but owing to the rapid improvement and wide application of the internal combustion engine and the present shortage of liquid fuel, we have been suddenly led also to appreciate the need we are in of developing our home supplies as fully as possible; large quantities of liquid fuel may be obtained especially by coking coal at relatively low temperatures and we cannot well escape the moral obligation we are under to develop this source of supply to the utmost.

It appears to be desirable, from every point of view, to submit coal to a preliminary carbonisation, as not only the liquid products are of value but the gas which is given off coincidentally is of special value and the residual coke has qualities which eventually must make it a more popular fuel than any other at our disposal.

It is unnecessary to speak at length of the value of gas as a fuel—it is daily becoming more popular with the public and is also being more and more brought into use in manufacturing operations, on account not only of the ease and certainty with which temperatures can be regulated but because of its cleanliness and the saving of labour its use entails. Those who are unacquainted with what can be done by gas should visit Wolverhampton and some of the other towns in the South Staffordshire district supplied by the Mond Gas Co. Over 160 firms are now supplied by this company and are using gas with complete success in a great variety of operations. We need only to develop the firing of boilers by gas, so that it may rank in efficiency and simplicity with coal firing, under the best conditions, to make this form of firing universally preferred—the saving of coal-transport costs and of handling ashes would be very considerable and would go far to meet the cost of producing and piping the gas; the greater ease with which variations in the load factor can be met when gas is used is also a matter of no slight importance.

There has been a continuous tendency hitherto to lower rather than to raise the quality of gas. It will be necessary to reconsider this policy, in view of the fact that the cost both to producer and consumer and also the dimensions of the necessary mains vary inversely rather than directly with the quality. The following figures given by Young in 1900 may be quoted by way of illustration.

Description of gas.	At point of Production.			At point of Distribution.		
	Calorific power B.Th.U. per 1,000 cu. ft.	Cost to produce 1,000 cu. ft.	Cost of 100,000 B.Th.U. in pence.	On-cost charges per 1,000 cu. ft.	Total cost at point of distribution.	Cost price to Consumer of 100,000 B.Th.U.
Water gas ..	300,000	d. 4	1-33	20	24	8-00
Coal gas ..	600,000	12	2-00	20	32	5-33
Cannel gas ..	900,000	24	2-66	20	44	4-88

It would obviously pay to deliver benzene vapour alone, if this were practicable. I have always myself advocated the supply of a rich rather than of a poor gas. The point is of importance, because in coking coal at a relatively low temperature, the gas produced—say from 5000 to 6000 cubic feet per ton—is of high calorific power.

Until gas heating appliances are more developed and the whole subject has been placed upon a proper scientific basis, it will be premature to come to any final conclusion with regard to the quality of supply that is most desirable; probably it will be found to vary as the possibilities in different districts and the requirements vary.

The problem which most nearly concerns the general public, at the moment, is that of coking coal so as to produce a satisfactory smokeless fuel—such a fuel cannot be much longer withheld. The gas engineer has been the main cause of delay and his primary fault is that he has almost advisedly neglected the chemical side of the industry. Being, as a rule, brought up in the works and saturated with the prejudices of past generations, he has had but one object in view—the production of the maximum volume of gas per ton of coal carbonised: the coke produced under such conditions is necessarily a hard one which burns with difficulty; unfortunately the technical journals have systematically written down all attempts to produce a soft coke suitable for general con-

sumption. All the coking plants in operation in the country have been designed either by Belgians or Germans and not a few are of foreign construction. There is no reason why we should not do such work entirely ourselves but the problems will not be solved until chemist and engineer are brought into fruitful conjunction.

In the past, attempts to produce a satisfactory smokeless fuel have been made with unfortunate results but I am satisfied that the ultimate verdict will be that the public owe much to those who have been pioneers in the cause. The late Mr. Thomas Parker, a well-known electrical engineer, one of the first in the field in that industry, was a man of ideas and ideals. He conceived the idea of producing an easily combustible smokeless fuel by carbonising coal at a low temperature and was the first who set to work to solve the problem—his labours, so far as they went, were successful but he made the mistake of operating in small iron retorts, on an impossible scale, so that the money spent in his trials was practically wasted, except as a contribution to the fund of knowledge required in such an industry. Carried forward by his enthusiasm, a number of men supported him who were quite unacquainted with the subject and naturally such men made mistakes. But gradually, taught by that great but oftentimes expensive master experience, they mended their ways and by systematic trial, under competent supervision, have gradually evolved a satisfactory process.

A plant will be in operation, if not before the year closes, at the very beginning of next. I know its details and have no doubt as to the ultimate success of the enterprise. The ovens carry a ton of coal apiece and the charge is to be drawn and renewed every eight hours, so that in a battery of 18 ovens fully 50 tons will be coked daily.

My own strong feeling is that we have to blame our senseless empirical methods—our general neglect of science and scorn of theory—rather than the extravagance of those who are held to have wasted large sums of money: in time we shall come to recognise the sacrifice that has been made and be grateful that there are some enthusiasts and idealists among us; in the absence of science, without their aid, we should have been nowhere. It will be felt to be to our national disgrace that we did not far sooner set ourselves the task of solving the problem by systematic means, at national cost.

The process of low temperature carbonisation is in no sense on its trial—only its minuter details are in course of evolution. It is useless to say that we cannot warrant the success of the system—we can. Gas making, for town use, has long been an established success, although its by-products have always been treated as of secondary importance. Many high temperature plants, in which coke is produced as primary product for use in metallurgical operations, are now established and beehive ovens are rapidly being supplanted by these everywhere. In such plants, the by-products are systematically recovered but by no means to the extent that is desirable—and yet they afford large profits. The low temperature differs from the high temperature process mainly in affording a fuel which is suitable for general domestic use—one that is required everywhere and that is bound to meet with universal favour when put upon the market in a suitable form and supplied regularly. I go so far as to assert, therefore, that within a few years the use of such fuel will be made compulsory, if only because it will be possible to abolish the smoke nuisance by using it in place of coal.

The gas given off at low temperatures, though less in volume, is of far greater calorific power than that given off in producing blast furnace coke but the richness more than compensates for the lack of volume: it will bear dilution with

2.5 volumes of producer-gas before it is reduced to a value of 300 British thermal units. It is not proposed to use any of the gas in carbonizing but to fire the ovens with producer-gas made from the small proportion of coke breeze obtained in the process and from cheap slack and washery refuse. I should say that only washed coal will be carbonized, in order to produce a smokeless fuel of standard calorific value and low average ash content.

A 200-ton coking plant such as I have in view is expected to produce daily, for outside use, 5,600,000 cubic feet of gas (300 B.Th.U. calorific value) and 124 tons of a smokeless easily-combustible coke. The amount of sulphate of ammonia obtainable will be from 20—25 lbs. per ton of coal carbonized; taking into account that made from the producer gas, the daily output of sulphate should be nearly four tons.

The gas will be scrubbed to remove benzene and similar hydrocarbons.

The one uncertain asset of the industry will be the condensable liquid products, as the use of some of these has yet to be developed; but this asset is an adjustable one, as their character may be more or less changed by secondary treatment, if not directly, by varying the conditions in the upper part of the ovens.

I am of opinion, however, taking into account the great and increasing value of liquid fuels, that the liquid products will be equal if not superior in value to those produced either in gas-making or high temperature coking plants.

The problems of coal are not to be regarded only from an economic aspect, all important though this be; moral, hygienic and political considerations must also be taken into account in determining our future policy and action.

Recent Government action in South Wales has at least called attention to the political issues and may well have advanced the discussion of the question of ultimate ownership. The question of export must also be most carefully considered—instead of glorying in the amount sent away, we must be misers to the last degree and seek to make far better use of the coal ourselves, if possible, not sell our British birthright without thought of consequence.

Some form of public control must be instituted to compel efficiency. There can be no question that our present wasteful methods of getting coal must be drastically overhauled and all waste prevented. We are clearly under an absolute moral obligation to exercise the most rigid care and economy in order that our fuel supplies may be conserved as long as possible. On this account, the utilisation of everything in or producible from coal should be a first moral charge upon our nation: it must be ordered, at no distant date, that no raw bituminous coal shall be used and that all such coal shall be first carbonised in order to abstract the volatile matters. As much of the residual coke as possible must be gasified, so as to utilise the nitrogen and recover it as ammonia. From the last point of view, coal which is not carbonized for by-products should be regarded as coke and gasified, if a remunerative amount of ammonia can be obtained from it.

Gaseous fuel is clearly foreshadowed on many grounds as the fuel of the future for industrial purposes.

Obviously, to develop a satisfactory programme, it will be necessary to consider where and for what purposes power will chiefly be required—to what extent it will be advisable to establish power producing centres at the mines, to what extent relatively coal and coke shall be the solid fuels distributed throughout the country.

The pit mouth in future should be something more than a coal dump—indeed we may confidently look forward to this often being made an

operative industrial centre of the first magnitude.

We have to foresee the electrification of some of our railways and the provision of electric power for canal use—a step of some urgency in view of the importance of cheap carriage.

Certain coals should be set aside for definite purposes—for example, Durham coal perhaps for the production of metallurgical coke. The best coking coals might well be reserved for the production of smokeless fuel and gas. Each large town might well coke as much coal as would be needed to produce the coke required locally by domestic consumers—coke being the more bulky article, the carriage of coal will probably be more economical than that of coke.

On hygienic grounds, the use of smokeless fuel is to be regarded as of primary importance and great weight must be given to this consideration in dealing with coking processes. So much has been said on smoke abatement—so little done to effect improvement—that I will not weary you by discussing it but merely say that we have but to make up our minds to take the problem in hand; we know that it can be solved if we wish to solve it.

Other points might be raised but I have said more than enough, I trust, to justify my thesis that the establishment of a National Central Fuel and Power Board, with full authority, at the earliest possible date, is a matter of Imperial consequence and must be advocated in every possible way. The first duty of the Board would be to develop and establish a national programme, while carrying forward with despatch all necessary experiments which would conduce to the rapid introduction of an improved practice.

Finally, let me repeat the proposition that coal should be made to pay for inquiries relating to coal—in other words, I would urge that all costs be met by a direct tax upon coal as it is raised from the pit.

DISCUSSION.

Mr. ROLLASON said that the theory put forward that all coals should either be gasified or carbonised with recovery of their by-products was based on imperfect knowledge of the varying physical and other properties possessed by the different seams of coal which determined their condition for gasification or carbonisation purposes. During the development of our great national industries the engineers responsible had been able to select the grade and quality of coal best suited to their requirements. The larger grades and best qualities being most in demand, commanded higher prices than the lower grades. It had been found that these lower grades could be economically used for power production in boiler furnaces, and as long as there was an ample supply prices of such fuels would remain low. By this method all coals raised were used and there was no loss of fuel which had been raised to the surface. It was by the use of such low-grade coals that large power-supply companies had been enabled to supply cheap power. To carry out the proposals made by Professor Armstrong the demand would immediately overtake the supply; consequently cheap power, on which our industries depend, would disappear. The proposals did not aim at the reduction of the cost of power, but at the conservation of coal and the prevention of smoke. Owing to the losses in the producer plant and retort when gas or coke was used for firing of boiler furnaces, there could not be any reduction in the tonnage of coal used. On the question of smoke the largest percentage arose from boiler furnaces which could be easily overcome by secondary means. The necessity for changing our methods for the generation of power in order to prevent smoke therefore ceased to exist. He

had found that by the addition of a small percentage of finely-ground amorphous sodium carbonate to all boiler slacks, the hygroscopic water (contained in the coal) was separated from the carbon, and if the air necessary for its combustion were present and the draught regulated, the whole of the carbon content of the fuel was consumed, which resulted in an economy of fuel and an absence of smoke. For gasification purposes on the lines proposed, coals low in hydrogen with a high nitrogen content were required. For carbonisation purposes, in order to produce a smokeless fuel with a low ash content, the best quality of coking coals, high in volatile matter with a low oxygen content and low in ash, was necessary. As these classes of coals were already scarce and dear, and every known seam of such coals was being worked at the present time, there would not be sufficient available to carry out the proposals of Professor Armstrong, if such were adopted.

Professor KIPPING said that even an ordinary householder could not fail to be struck with the enormous waste of fuel which went on in houses, and which had gone on since coal was burnt.

Councillor ATKEY said that he believed that some very strong and urgent measures were necessary in order to wake up the people of this country to the importance of the subject. The point of view from which he regarded it was one as affecting the latest form of motor traction in this country. To-day it was realised that even from the point of view of defence a supply of motor fuel was one of the absolute needs of warfare. Naturally the point of view from which he regarded it was one as affecting the latest form of motor traction in this country. To-day we realised that even from the point of view of defence a supply of motor fuel was one of the absolute needs of warfare. We did not regard war as the principal thing to live for, but it was evident, he thought, to most people to-day that a supply of liquid motor fuel was absolutely essential for our progress in times of peace. And that was the problem which really faced us and which gave Professor Armstrong's lecture such outstanding importance. The position at the present time, from the national point of view, was that we had to depend upon ships to bring to this country practically every gallon of liquid motor fuel that was necessary for transport purposes in this country; and when one realised, and saw, the enormous use that motor traction was to our every-day life; when one saw how it had come to be the means by which our very bread was brought to our doors, both literally and figuratively, then he thought they were bound to realise that the problem of motor traction was probably as great a one as we had to face.

He entirely agreed with the sentiments which had crept into the lecturer's paper where he had said that if we were to survive and justify our position among the nations of the world we must combine in future the theorist and the scientist with the commercial or business man who would translate his theories into practical use and benefit.

He did not venture to hope for very much from any Government, but certainly the one that had now been formed started a new era inasmuch as it had moulded into itself men who were not politicians but were business people. That certainly gave them reason to hope, and he ventured to think that lectures of this character, if properly taken to heart, and realised, would provide those business men with the necessary force that should translate the commonsense that they had heard that night into the practical policies of to-morrow.

He hoped that before they left that night it might be possible to take some definite line whereby all they had heard might be brought to

practical effect. He spoke particularly in regard to what he ventured to say was the most important industry in this country to-day, and which in time to come would be the greatest and of the utmost service to mankind. That industry required fuel that was now being wasted in the atmosphere—that was being absolutely thrown away in reckless fashion.

Mr. ULLETT said that there was no doubt that a combination of gas and electrical and coal combustion would have to be found. If the author's proposal was feasible, why should not a gas department be put down to produce coke which could be burnt in the electric light station and at the same time also produce chemicals? Was it commercially possible to put down a plant consuming something like, say, 5000 tons of coal per annum where there was a demand for steam for generating power, gas for furnaces, benzol, and a certain amount of coke? As an electrical engineer, he agreed that the electrical power station was absolutely out of date, inefficient, and costly. The power station of Nottingham was placed in the wrong position of the town, almost at the highest part of the town. Then, again, the plant was run very largely non-condensing, and consequently one-third of the steam was blowing away up the chimney to waste. The generators and engines were excellent in their way, no doubt, but absolutely out of date at the present time as far as steam consumption was concerned. The water was being bought from the water department, he supposed at the recognised rate. Could it be wondered that the cost was so much higher than in other towns; that the coal consumption was 50% more than it ought to be, and the total cost 60% more? Then, again, the plant had a capacity of 12,000 kilowatts, and was producing about half the output that other large towns were getting for the same size plant, and the electricity was sold at a far higher rate.

Mrs. ATKEY suggested that some pressure might be brought to bear upon builders to stop the installation of the present expensive and frightfully wasteful domestic kitchen stoves. When she went to the house she now lived in three years ago the kitchen stove that was then installed—her cook had told her—took three buckets of coal to get it to a proper heat. The one she had now was an American stove, which took less than half a bucket of coal; it did not need frequently replenishing, and there was very little smoke. And what would appeal to those who had to pay the bill, the cost of the installation of the stove, which was the heaviest expense, had been paid in one year by what the stove had saved in fuel, leaving the benefit of the economy for years to come.

Mr. CARR said that unless they, as citizens, used every means in their power to get action taken, the old state of *laissez faire* would be certain to continue. England was bleeding away its power by wasting fuel which would help, if conserved, to continue the supremacy of this country for centuries longer than it could continue unless they took to heart such teaching as Professor Armstrong's. Therefore he hoped that they would bring this subject before the Town Council and insist upon having the matter threshed out; insist, too, upon having the fuel which was utilised for the township, as well as that which was used in private consumption, dealt with economically and profitably.

Mr. EDGCOMBE asked whether this matter had been considered altogether from the financial standpoint? He was connected with a railway company where a lot of coal was used for stationary boilers especially and for electrical generation, and they found it always paid to get coal of the lowest grades, wasting the by-products, to get the steam rather than coke at three or four times the price. In regard to the question of the

carbonisation of fuel, the way in which Professor Armstrong might help them would be in the direction of some method of grading coals. They had tried many grades of coal and found nothing but trouble with most of them—difficulties in the producers themselves. The quality caused various troubles. The difficulty with coke was that the fire became very hard and not broken up and in that way they got high temperatures and the formation of a tremendous lot of slag. They had found in many cases a great improvement by mixing coals. Smudge coal simply slagged up the whole stoker, but by a judicious mixing of low-grade fuels they got satisfactory results in their furnaces. At one time they used to have a lot of steam coming away from steam hammers and machines of that sort, but now they had put in a pipe to convey all this to an exhaust steam turbine. They would like to know how it was possible to get hold of a proper or simple set of rules as to the best way of dealing with these fuels. At the present time he was trying to recover sulphate of ammonia, but could not get more than 35 lb. per ton. He thought it was a question of the temperature at which they gasified the coal.

Mr. PULSFORD reminded the meeting that there was already in existence—and had been in existence for many years—a Royal Commission to deal with this matter. There was also now in existence the British Association Fuel Committee for dealing particularly with this matter. He hoped that the resolution which was to be proposed would result in the inauguration of some association which would deal very vigorously with the matter. Professor J. S. S. Brame, lecturing at the Royal Naval College on December 1st, said that in 1913, when there were many labour troubles in the coal areas of the United Kingdom, of the 287,430,473 tons of coal raised the amount that was retained for home consumption was 187,000,000 tons, leaving 98,430,473 tons of coal which were exported from this country. That was more than 33½% of coal exported and upwards of 60% only consumed at home. He further stated that within the next 50 years or 100 years the situation in the collieries of this country would be such that coal would be immeasurably dearer than it was to-day. Now that brought very vividly forward a question that was really of national interest. Manufacturers could not possibly produce unless they had cheap fuel. Our industries would, undoubtedly, much more quickly than many appreciated, be very seriously handicapped. There were three great coal-producing countries—the United States of America, Germany, and our own. The United States retained for home consumption 90% of the coal got; Germany retained 75%, and the United Kingdom 67%. The reserve in the United Kingdom in relation to the coal areas is 0.14%, in Germany 0.01%, and the United States 0.13%. He urgently suggested that a tax for research should be placed upon the coal exported from this country.

Mr. WILKIE said that a magnificent piece of industrial research had been carried out in Germany with a view commercially to combining hydrogen and nitrogen for the production of ammonia. In the normal course of events, had the European war not taken place, shortly afterwards, this country would be faced with competition in natural sulphate of ammonia and its synthetic product. The research was of fundamental importance and enormous difficulties had to be overcome, but even then the combination must be carried out under such stringent conditions that it was by no means an easy operation. But in this country nature had given us the raw material—crude coal—which effected this combination for us, anyhow by heat, it gave us sulphate of ammonia. By manufacturing gas this was

saved, and coincidentally the pollution of our town atmosphere and at the same time harmful effects upon the people were prevented. England had been the greatest, or at least one of the greatest, producers of phenol, and we produced the substance and foolishly, he thought, gave all this valuable material to the Germans who were able absolutely to rule the markets of the world. Consequently they had not only bought the crude material and controlled the phenol market and the benzol market, but they could force down the price, and in other ways make the benzol market impracticable, allowing us in this country very little benzol indeed. It was incumbent upon every one to make up his mind that this chemical deficiency of ours must be remedied in the future, and he hoped engineers, colliery owners, and colliery managers would view the idea of this treatment of fuel with the greatest sympathy. No doubt these changes would cost even producers and large consumers of coal temporary inconvenience, and it would be wonderful if any legislative action which disturbed the established procedure of years did not dislocate arrangements which had accompanied previous usage, but he put forward a strong plea for everybody to help forward this work as much as they could.

Professor ARMSTRONG, replying, said that Mr. Atkey had drawn attention to the fundamental issue which was before us. It was a moral issue really—the utilisation of our coal fuel so as to get not merely heat from it directly but also the liquid materials which nowadays were really of more importance to us even than solid fuel. Liquid fuels, used in internal combustion engines, were having a great effect on the war—on under-water war and to a considerable extent also on above-land war. We *must* have such fuel and the way to get it was to take it away from coal. Mr. Bollason had left that point out of account altogether, he thought. Many things had to be found out but what he wanted to insist upon was that we had passed the experimental stage so far as the production of coke was concerned, *i.e.*, smokeless fuel. We had only got to settle details. The principle was settled. He thought it would be shown within the next few months—the next year probably—that the matter was practically settled. It was not a subject for small-scale investigation. Research in the ordinary laboratory sense was quite a secondary matter. It was large-scale practical work that was required and that was being started in Yorkshire; it would be started also directly that it had been declared a success in other districts and then there would be co-operation between the coal pit, the coking plant, the gas fire, the production of electricity and the production of various by-products—all these various industries would be brought into association as far as possible on the very best lines. He could not imagine that in the near future there would be many cases of individual use of any considerable quantity of fuel. A larger amount of work would be done by electric current, a larger amount of gas would be supplied; it would not be desirable to have relatively small-scale plants at work, which, of course, were necessarily more or less inefficient. In regard to the domestic difficulty, there was no doubt that the builder was one of the chief sinners. We had need of experimental work from that point of view also; there ought to be special regulations. The borough surveyor was not unfertile in suggestions for putting down drains and for building walls of a certain thickness; there was no reason why we should not have proper kitcheners installed in a house and important economies effected in the consumption of fuel. There were very many such problems which touched the public at every point, in which there were a large number of conflicting interests. At the present time it was essential

to develop a practical policy; therefore we should have some body of men called together, a small executive, who would bring the various opinions in this country to bear on the problems and work them out in their various details. Naturally this will be a slow process but it should bring about a practical result and a totally different condition of things from the one existing at the present moment. From that point of view, if possible, we should carry the matter forward and get the Government to make it a public question without delay; take it up as a matter of public necessity and arrange that it should be threshed out as thoroughly as possible.

Mr. RALPH BATES, President of the Nottingham Society of Engineers, spoke as representing the iron and steel industries, which were undoubtedly amongst the greatest sinners as regards the wastage of fuel. They consumed it in large quantities in blast furnaces and steel furnaces and steam boilers counted by the score. Remedies had been mentioned, and difficulties also had been dealt with by Professor Armstrong. The difficulties were largely these. First, there was the waste that was taking place in those works which had been established for anything from 50 to 100 years—plants that had been built up out of very spare capital and hardly wrought together. It was all very well for scientists to say: "You must sweep these away; you must adopt economical methods." But from the practical point of view it was a very difficult question to grapple with. But Professor Armstrong had dealt with it from the other side—it must be dealt with in large units. The manufacturer could not put in costly plant for the economy of fuel, but to deal with it from a large centre was the only solution that was practicable for the future, and undoubtedly it would be done.

THE RESOLUTION.

He then moved the following resolution:—

"That it is imperative, without delay, by public effort and legislative action, to promote the development of a comprehensive national policy to govern the use of our fuel supplies, as the sole sources of heat and power, so that they may be used with greatest effect, with utmost economy, and without creating nuisance, for the general good of the country."

Mr. PENTECOST, in seconding the resolution, said that, as a manufacturer, along with many others, he had suffered from the reluctance of the City Corporation to connect up electric power to his works. On four occasions, at any rate, he had approached the City Corporation to get the power connected up, but there had been so many conditions and difficulties and excessive financial responsibilities put before him that he had had to give up the idea. But when they got power and heat in the way Professor Armstrong had suggested, it would remove a good deal of the anxieties and troubles of ordinary manufacturers and make manufactures much cleaner and easier.

The CHAIRMAN put the resolution to the meeting and it was carried unanimously.

Sydney Section.

Meeting held at Sydney on Wednesday, 15th November, 1916.

MR. H. G. SMITH IN THE CHAIR.

COMPARATIVE TESTS WITH MANGROVE AND WATTLE BARKS.

BY F. A. COOMBS, F. ALCOCK, AND A. STELLING.

The mangrove barks are now being used in large quantities by tanners who are producing sole-

leather. These barks have a very high tannin value and very large supplies are available for the production of leather.

In a previous paper* we gave the tannin values of some Australian mangrove barks. After examining the mangrove trees in Cairns and Cooktown districts, North Queensland, we found that *Rhizophora mucronata* represents fully 75% of the trees suitable for stripping, the remainder consisting largely of *Bruguiera gymnorhiza* and *Ceriops condolleana*. For commercial reasons strippers are not likely to take the bark from the different species and keep each one in a special grade. The above three species† grow in a very mixed state and buyers can assume that bark from these districts consists of an excess of *R. mucronata* and small varying proportions *B. gymnorhiza* and *C. condolleana*. The majority of the mangrove bark from German East Africa‡ is also taken from the above three species.

We have used the commercial mangrove bark for our tanning experiments, and *B. gymnorhiza*, *R. mucronata*, and *C. condolleana* were examined by the aid of the usual qualitative tests.

The colour and precipitation tests gave results which did not differ from those described by other workers for mangrove bark. The solubility tests for mangrove tannins have not received a great deal of attention from leather chemists, and the results given for these tannins may have been obtained from one or a mixture of the genera which are described as mangroves.

The following values have been given§ for mangrove:—Ethyl acetate figure, 0 to 5; alcohol figure, 0 to 5, and gallic acid value 0.68.

These differ to a certain extent when compared with our results shown below.

	<i>C. condolleana</i> .	<i>R. mucronata</i> .	<i>B. gymnorhiza</i> .
Ethyl acetate figure	20 to 25	7	4
Alcohol figure	0	0	11, 12, 24
Gallic acid value	0.785, 0.738, 0.692, 0.657	0.600, 0.595, 0.501, 0.479	0.450, 0.385, 0.381, 0.359

Procter and his students have carried out a considerable amount of work in connection with the oxidation of tannins with permanganate and the results obtained are useful as qualitative tests for the recognition of various tannins. He gives the gallic acid value of one gm. of chestnut tannin as varying between 0.56 and 0.66 and of valonia tannin as varying between 0.55 and 0.63.

These variations are common to mangrove and apparently no constant figure can be given which represents the gallic acid value of these tannins. The gallic acid value of mangrove tannins apparently reaches the maximum with *C. condolleana* and the minimum with *B. gymnorhiza*. Procter states that the phlobaphenes or reds are probably anhydrides of their respective tannic acids, and it is a well-known fact that the catechol tannins change on exposure to heat or light from a medium to a dark red colour. This change brings about a more complicated and larger molecular aggregate; and as this aggregate increases, its solubility in water decreases, until it finally reaches the state known as insoluble reds or phlobaphenes. The tannins in wattle and mangrove barks appear to exist as variable molecular aggregates ranging from the parent body, or unit molecule, to the insoluble red; and it is probable that the oxidation values would differ for the unit molecule and the difficultly soluble reds. The tannin from *B. gymnorhiza* has a low oxidation figure and probably a high mole-

cular aggregate. Mallet bark tannins also have a low oxidation value (gallic acid value, 0.288) and the rate of penetration is slow.

Recently Bennett (this J., 1914, 1182) suggested certain changes in the I.A.L.T.C. official method for estimating tannins. He believes that the present method returns a high percentage of non-tans, and we are confronted with the problem that certain substances exist which are tannins or non-tannins according to the ratio, within certain limits, between hide-powder and tannin.

The non-tannins have a low oxidation figure and it would probably throw some light on the subject if oxidation figures were obtained for tannins and non-tannins from one sample of bark using both the official and Bennett's revised methods for estimating the tannin. Such results would show if the substances under dispute were akin to tannin or non-tannin, and we might get a better view of the value of the gallic acid figure.

The leather-forming properties of mangrove barks were tested by an experimental process described in *Collegium*.*

Two duplicate tests were carried out for comparative purposes, and wattle bark was used for the standard tannage. The mangrove bark has already been described and the wattle bark was the same as the tannins used under the name of Adelaide bark (*Acacia pycnantha*).

The hide is cut into sections of equal area and numbered as shown in the diagram. The sections are approximately 1 ft. 9 in. square and they are soaked, lined, and tanned in upright vats measuring 2 ft. × 2 ft. × 4 in. Two sections are suspended in each vat and about 32 litres of liquor is required to cover them.

The sections 1 and 5, 2 and 6, 3 and 7, and 4

and 8 are approximately constant in area, thickness (substance) from grain to flesh, and in general structure.

The first two sections, Nos. 1 and 5, are both soaked, lined, and delined in the same vat at the same time; therefore temperature, time, and constituents of all liquors are constant for these two pieces until they reach the tan liquors. Then they are separated and No. 1 goes into wattle-bark liquors and No. 5 into mangrove liquors. Under skilled control these two sections are approximately constant until they reach the tan liquors, and then if any variation occurs, it will be due to a difference either in the process of tanning or in the tanning materials. In this experimental work the tanning process has been kept approximately constant for both duplicate tests, so that if the hide sections be constant the variations can be traced to difference in the tan liquors (acidity, non-tans, etc.), or in the structure of the tannin molecule. What has been said of No. 1 and 5 applies also to the groups Nos. 2 and 6, 3 and 7, and 4 and 8, but it is hardly necessary to point out to practical men that No. 1 will differ from all others with the single exception of No. 5 section, and likewise No. 4 will differ from all except No. 8 section.

Sections 1 and 5, and 2 and 6 were used for the first test and the other two pairs were used for the second. For both, the soaking occupied two days with two changes of water; lining seven days in one fresh lime liquor; wash pits (after dehairing, etc.) two days, with two changes of water;

and deliming, one hour in lactic acid solution (2 grms. per litre).

The tanning process was continued at a constant tannin strength for both tests.

Acidity of the mangrove liquors for both tests is higher than the wattle liquors, and one might therefore expect the mangrove leather to fix more tannin. However, we are now carrying out comparative tests for the value of acid in tan liquors and hope to discuss this point at a future date. The variable ratio between tannin and specific gravity is fully demonstrated in both tannages. The wattle tannins penetrated the hide quicker than the mangrove tannins.

The figures for the tanning process show a small irregularity due to the process of extracting the tannin from the bark. We were extracting tannin from the bark at irregular intervals and some liquors had a short time for exposure to fermentation. The amount of difficultly soluble tannins was low for these tan liquors, and these conditions might adversely affect the percentage of combined tannins.

28	117.06	60.0°	15.3	62.1°	9.6

The following are results obtained by weighing each section after it was taken out of the various tan liquors. The pelt weight is taken at 100 and the percentage increase is added to that figure. It will be noted that the increase is higher with the mangrove tannage, but the increase for both tannages is lower than the amount representing combined tannins, and therefore we can assume that as the hide takes up tannin water is expelled.

Weight gained during tanning process.

Sections 1, 2, 5, and 6 were taken from the tan liquors and suspended in water for two hours, drained overnight, scoured on the grain, oiled, and then finished as sole-leather. Sections 3, 4, 7, and 8 were washed in water and allowed to dry.

Diagram of Ox-Hide.

These sections did not receive any oil. The dry rolled sections were what tanners call "firm" but not hard. The mangrove leather was a bright clean red colour. The dry unrolled mangrove-tanned sections were not inclined to a brittle grain, so that scouring is not a necessary factor in the finishing process.

The analytical results are worked out on a leather free from fat. The sum of water, total solubles, combined tannin, and hide-substance is 100%. The non-tannins are very low, suggesting that the total solubles include free tannin which was originally combined tannin. Total solubles were extracted from the leather shavings at a temperature of 45° C. The time for extraction was three hours. Previous experiments with pine and wattle barks show that the degree of tannage is low for these mangrove and wattle tests. This difference is partially explained by the fact that we used a thicker hide for this experiment. Another matter would be the age of the leather. For the pine bark experiment the leather was not analysed until ten months after it was removed from the tan liquors, but for this experiment the same work was all completed within one

month. It has been proved* that the catechol tannins, both free and combined, are gradually changing in the air-dried leather. Probably this change adversely affects the solubility of these substances and the natural result would be a lower figure for total solubles. When leather is placed in water at 45° C. it apparently releases a certain amount of combined tannin, so that, omitting bloom and reids, a final and approximately constant figure might be obtained for mangrove tannins. We carried out a second extraction for Sections 4 and 8, and the usual standard process was repeated daily for four days. The results obtained brought the degree of fannage down to 32·7 for mangrove and 31·8 for wattle; after several days the mangrove (in water 18° C.) was still giving up a little colouring matter, and it seems probable that under these conditions we could have reached 30 as a final figure for both tannages.

The stability of the combination of hide-substance and tannin, as shown by the degree of fannage, varies to a considerable extent according to the process of extraction, etc. We took four pieces out of each section, when sampling for analysis, and the samples from the two sections in each group were in the same water bath during the process of extraction; so that the results show differences between the two sections of any one group under approximately constant conditions. We have to compare results from leather shavings with results from leather ground in a mill,† and if higher total solubles were obtained from the latter then it would appear as if these tannins produce a very unstable leather. However, we recognise that we must carry out more experiments in connection with this problem of extraction.

From a commercial standpoint the leather weight returns calculated on the pelt and green-salted weights are all in favour of mangrove.

32 " "	108·6	99·2	137·7	120·7

If t_1 is the percentage of water absorbed by a leather containing a small amount of water-solubles, t_2 that absorbed by a leather with a large amount of solubles, and t_3 that absorbed by a rolled leather with a large amount of total solubles, then

$$t_1 = \frac{w}{r} 100, \quad t_2 = \frac{w-x}{r+y} 100, \quad t_3 = \frac{w-(x+m)}{r+y} 100$$

where w = weight of water absorbed

r = weight of leather,

x = water displaced by the extra amount of solubles,

y = weight of the extra amount of solubles,

m = the decrease in the volume of air spaces after the leather has been rolled.

Another factor would be an increased amount of insoluble matter such as combined tannin, bloom, and adulterants. Let t_4 be the percentage of water absorbed by a leather with a large amount of solubles and an excess of insoluble matter, then

$$t_4 = \frac{w-(x+b)}{r+y+u} 100$$

The water-absorption test was carried out by placing the unrolled sections in water for various periods as shown below. The leather weight, calculated free from water, is taken at 100, and the water absorbed is shown as a percentage on that figure. In both cases the mangrove absorbed less water than the wattle leather. The sum of the fixed tannin and total solubles is greater with the former than with the latter, and therefore there is less room for water in the mangrove leather, providing other conditions are equal for both leathers.

† Leather Industries Laboratory Book.

where

l = water displaced by excess of insoluble matter,
 u = weight of the excess of insoluble matter.

Leather, like wood, contracts or swells according to the moisture content, and this varies with the different tannages. The rate at which water penetrates the leather is related to the solubility of the substances deposited on the leather fibres. Leather adulterated with an easily soluble substance, like glucose, offers very little resistance to water penetration.

The tensile strength tests were carried out by Mr. H. T. Swain at the Mechanical Engineering Laboratory of the Sydney Technical College. Two pieces were cut from each section as shown on the

diagram. Mangrove 4A and wattle 8A are placed together for comparative purposes, as they differ only in the barks used for the tanning process. The other groups are shown below, the results being all in favour of the wattle tannage.

The moisture in the leathers is slightly higher with the wattle, and it is not possible to get the four sections with constant percentage of water when they are exposed to changeable climatic conditions. However, the difference is below

Balderston* has described a machine for testing the wear-resistance of sole-leather, and his results show that the loss by friction is at the minimum with a straight chrome and the maximum with a hemlock tannage. Now this is just the position one would expect them to occupy in a series of tests for tensile strength. Hard leather offers a low resistance to friction, the tensile strength is not high, but the water resistance is generally good.

1%, and this amount will probably be reduced in future experiments.

The leather received no special treatment for this work, and was absolutely free from oil, fat, etc., other than the natural fats in the original hide. The pieces tested were not cut out of the best part of the hide and therefore the results obtained have no value outside of this experiment.

Analyses show that these leathers differ after they are tanned, and therefore the results obtained may be influenced by this. The tensile strength of each section is at the maximum in the raw hide, where the physical condition is all that could be desired. A fibrous structure would be at its maximum tensile strength under conditions which allowed the weight to be evenly distributed between all the fibres. The other extreme would be under conditions where the whole of the weight was on a few fibres which break, and then the weight is thrown on another small portion which breaks also, and the result must be a low value for that particular test. It would not be possible to place all the weight on a few fibres until they break, if one were testing a strip of raw hide, where the elastic properties and the general structure are so finely balanced that a strain on any group of fibres causes them to stretch, and then the weight is partially taken up by other fibres, and in this way it is distributed over the whole number before any single fibre breaks. When the raw-hide or pelt is placed in tannin solutions, the physical condition is changed. It loses to a certain extent its elastic properties. The semi-liquid intercellular substances combine with tannin to form a non-elastic solid. The fibres contract and under certain conditions they may reach a brittle state.

Procter states that the tensile strength decreases with increased amounts of fixed tannin, and the same could be said of those water-solubles which dry like tannin extracts to a hard brittle state. However, the variations in fixed tannin, etc., and their influence on these results is a problem which will require special research. If all other conditions were equal we would still expect a difference in tensile strength because the various tannins could combine with the hides in equal proportions by weight, and yet the resulting leathers would differ in their physical properties. The leather with the higher tensile strength will probably offer the greater resistance to friction.

We do not claim to be working the best processes for preparing the pelt or tanning the leather, but we feel certain that this "One hide experimental process" is capable of giving results which should enable tanners to prove the value of a great number of factors such as various tanning materials, laying away in bark, acidity of liquors, strong liquors, time for tanning, etc.

DISCUSSION.

The CHAIRMAN asked what species of mangrove had been used in the experiments.

MR. A. H. DETTMANN said that leather tanned with mangrove answered well for the soles of boots, as it took up less water, and so resisted damp better than when tanned with wattle. The dark colour given by mangrove was commonly supposed to be caused by "loading," and there was a prejudice against colour.

MR. A. E. STEPHEN asked if there was any difference in the tensile strength of tanned and green hide.

MR. R. W. CHALLINOR drew attention to the great variation in total solubles from the proportion in the original liquor. He asked what had been done in testing the tensile strength after soaking at 45° C.

MR. COOMBS, in reply, said that *Rhizophora* predominated in the Queensland mangroves, but it was impracticable to keep the different kinds separate, and their experiments were made with the ordinary commercial mixed bark. The sections had been taken from the hide, and the tests made in such a way, alternately, to guard against any possible variation in the right and left halves of the hide, though he did not think there was any difference. Tensile strength was at its maximum when the hide was newly off the animal, but the hide must be tanned so as to preserve it from decay, even at the cost of loss of strength. He had made no experiments on soaking at 45° C.

CHEMICAL EXAMINATION OF THE OIL FROM THE AUSTRALIAN DUGONG.

BY R. W. CHALLINOR, F.I.C., AND A. R. PENFOLD.

The dugongs or sea cows are herbivorous mammals found inhabiting the shallow bays and

* J. Amer. Leather Chem. Assoc., 1916, 11, 429. See this J., 1916, 935.

creeks of the Red Sea, East Coast of Africa, Ceylon, Islands of the Bay of Bengal, Indo-Malayan Archipelago, and, in more or less abundance, the Queensland Coast of Australia from Moreton Bay on the South throughout the Great Barrier Reef to Torres Strait on the North, being more numerous in the waters of Wide, Hervey's, and Rodd's Bays than they are farther south, and although they are not usually observed further south than Moreton Bay, instances are on record of them having been seen off the Tweed and Richmond Rivers. The finding of bones of the dugong in the excavation of Shea's Creek, which runs into Botany Bay, by Etheridge, David, and Grimshaw (Journ. Roy. Soc. N.S.W., XXX., 158) indicates that the animals may have inhabited Australian waters much further south than they do at present.

The dugongs are usually described as ungainly creatures with small brains and very limited intelligence, hence are too easily captured or destroyed, and in consequence are now somewhat thinned in numbers.

Estimates of the length of the dugongs vary considerably, ranging from 6 to 16 ft., and even 20 ft. in exceptional cases; but the average for the Australian dugong appears to be from 8 to 10 ft.; the weight is 4—6 cwt. for ordinary specimens, and from 10 to 12 cwt. for larger animals. The average yield of oil appears to approximate to about 1 gallon per hundredweight of body-weight of dugong.

The dugongs belong to the natural order SIRENIA, genus *Halicore*, to which also belong the *Manatees*, which in some respects resemble the dugongs but do not inhabit the same waters.

The dugong fishery is carried on in Queensland at Moreton, Wide, and Hervey bays, but not very extensively, and principally for the oil, which is obtained from the blubber situated beneath the hide of the animals, and also from the tail. Other parts are also utilised to some extent. The hides are cured, the tusks sold, and the bones, which are of a fine and hard grain, and in sp. gr. and appearance approach nearly to the nature of ivory, are also utilised in various ways. The flesh is considered a relishing article of diet; roasted it has the flavour of pork and when cured the flavour of bacon, and has been exported from Queensland as dugongs bacon (R. L. Simmonds, Annual Food Products, p. 130).

The demand for the oil is somewhat limited, and according to a communication received from the Brisbane Government statistician, only 400 gallons was placed locally three years ago. It was supplied to the chemical firms in a crude state, and by them refined and placed upon the market as a medicinal product. Suppliers of oil at Traviston, Queensland, estimate the annual collection of oil at present at about 600 gallons. The price of the oil as quoted by two of the principal Sydney drug houses is 28s. and 22s. 6d. per gallon respectively.

The particular sample of oil which is the subject of this investigation was obtained directly from the fishery at Traviston, Hervey's Bay, Queensland, from one animal measuring 8 feet in length and 6 feet in girth, which gave 3 gallons of oil. The oil is obtained from the blubber by allowing it to melt in the sun's rays, and we understand that this is the usual practice at this place. It is of a pale straw tint, clear and limpid, and almost odourless, without pronounced taste and quite as palatable as olive oil. On standing, a copious white crystalline deposit separates out which at winter temperatures renders the oil of a thick creamy consistency. It was found that the solid redissolves completely at a temperature of 36° C., and remains in solution for some hours even when the temperature falls below 20° C. The white crystalline deposit, examined microscopically,

consists of innumerable wheat-sheaf-like bundles of needle crystals, somewhat like beef stearin when crystallised from ether.

The principal use to which dugong oil has been put appears to be as a medicinal oil. Dr. Hobbs, Health Officer of Moreton Bay, Queensland, about 10 years ago strongly advocated the use of this oil for wasting diseases and lung troubles, and claimed that it was not only equal to cod liver oil for this purpose but that it differed from the latter in being sweet and palatable and free from the nauseousness of cod liver oil.

In the Queensland annexe of the International Exhibition, 1872, at a dinner given by the Agent-General for Queensland, dugong oil successfully took the place of butter and lard in the menu for the preparation of the pastry and biscuits (Pharm. Journ., III., 3).

In Squire's Companion to the B.P., 1916 Ed., p. 563, it is stated, with reference to this oil as a substitute for cod liver oil, that "although recommended at one time as not being disagreeable in taste it does not now possess this character." This may apply to a sophisticated sample, but the characters of our sample do not confirm this statement.

In the experimental part of this work it is shown that two constituents which contribute to strong odour and taste in fish and marine animal oils are present only in almost negligible quantities in dugong oil, *e.g.*, the acidity, calculated as oleic acid, is only 0.15% whilst the insoluble polybromides amount only to 0.77% on the mixed fatty acids, or 0.69% on the oil.

The melting point determination of the latter shows that it is at least an octobromide and possibly a small amount of clupanodonic acid is present, although this is not suggested by the odour or taste of the oil, and moreover from a consideration of the iodine value of the liquid acids in conjunction with the amount of highly unsaturated acid indicated by the percentage of polybromide obtained, there is probably an acid present which is more unsaturated than clupanodonic acid. According to J. W. Riedel (J. Chem. Soc., 1914, 106, I., 1123) clupanodonic acid has a fishy smell and acquires after a time the odour of cod liver oil. It is a characteristic of all fish-liver and blubber oils and is the constituent by means of which these oils are at present recognised.

The complete absence of fishy odour and taste from the oil of the dugongs is undoubtedly due to the vegetable food partaken of by these marine animals, as they feed entirely upon the zostera-like marine grass "*Posidonia Australis*" and other sea weeds.

The colour reaction worked out by Tortelli and Jaffe (Annali Chim. Appl., 1914, 2, 80; see this J., 1914, 1061), which they claim is given by the oils and fats of marine animals, and by no others, when applied to dugong oil gives a negative result.

Very little chemical work appears to have been done upon dugong oil, and in those instances where constants have been determined, as far as can be ascertained, no mention is made of the source from which the sample was obtained. The examination was carried out in each of the two instances, mentioned by Lewkowitsch (Vol. 2, p. 466), apparently with the object of detecting adulteration of cod-liver oil.

The constants published by E. W. Mann (Chem. and Drug., 1903, 63, 939) and J. F. Liverseege (Analyst, 1901, 211) are included in the tabulated results of our own examination of the oil (Table I.) and it will be noticed that we differ a little as to specific gravity, free acid, and unsaponifiable matter.

Experimental. The oil was submitted to examination by the standard methods and gave the results indicated in the subjoined table. The

unsaponifiable matter was determined by the modified method of Allen and Thomson (Lewkowitsch, 5th Ed., 1, 458).

perature of the ether used to dissolve the lead salts of the liquid acids. The yields of the acids, after deducting 0.6% unsaponifiable matter (prob-

below 0.920	— n. 1.4661	-0.1°	—	5	2.5	—	0.9	Liversidge.

The slight lavo-rotation of the oil suggests that the unsaponifiable matter is probably cholesterol, more especially as cholesterol if present would find its way into the liquid acids by the usual methods of separation and render them optically active also, which is in accordance with our observations.

The presence or absence of cholesterol will be confirmed in a second communication.

The mixed fatty acids. The mixed fatty acids were separated from the oil by the usual method (Lewkowitsch, Vol. I, 110), care being taken to wash the fatty acids entirely free from mineral acid with subsequent drying by means of absorbent

ably cholesterol) from the liquid portion, together with their iodine values, are given as under:—

	Percentage found.	Iodine value.
Liquid acids	65	94.45
Solid acids	25	4.72

For the further examination of these acids, 40 grams of the mixed fatty acids were separated by the lead salt-ether method of Tortelli and Ruggeri (L'Orosi, 1900, 23, 109; see this J., 1900, 1013), the results being shown in the following table:—

TABLE II.
Solid and liquid acids.

Acids.	Refractive index.	Optical rotation (2 dm. tube).	Sp.gr.	Melting point.	Iodine value, %	Neutralisation number. (mgrms. KOH)	Mean molecular weight.
Solid	1.4390 at 60° C.	—	0.8911 60°/60° C. 0.8811 60°/15° C. 0.8867 40°/40° C.	51° C.	4.63	207.49	269.89
Liquid ..	1.4567 at 30° C.	-0°18 at 23° C.	0.8999 15°/15° C.	—	92.58	202.37	276.7

paper. On examination by the standard methods they gave the following results:—

Refractive index at 40° C.	1.4499
Specific gravity 40°/15° C.	0.8811
40°/40° C.	0.8867
Melting point	35°—36° C.
Solidifying point	33° C.
Iodine value	66.19
Neutralisation value	180.4
Mean molecular weight	310.43
Ether-insoluble polybromide	0.77%

The ether-insoluble polybromide was prepared by dissolving the mixed fatty acids in dry ether to a 10% solution, running in dry bromine drop by drop from a finely drawn-out pipette, and allowing to stand for several hours. After filtering on a tared filter-paper, the polybromide was washed well with cold ether, dried at 98°—100° C., and weighed. We have tried various modifications of the procedure as regards temperature of bromination from -10° C. to 0° C., and also the time of standing from 3 to 24 hours, but these variations had no effect on the percentage of insoluble bromide obtained (see Lewkowitsch, Vol. I, 5th Ed., 573; Eilmer and Muggenthaler's experiments dealing with the hexabromides from vegetable oils). The bromide obtained is a white powder which precipitates in a flocculent form, and turns slightly grey on drying at 100° C. On heating it darkened a little at 200° C., and decomposed at about 220° C., which indicates that it is the octobromide of elupanonic acid or the bromide of a more unsaturated acid.

Separation of solid and liquid acids. The process used was the modified Gussow-Varrentrapp method (Lewkowitsch, I., 515—7), particular attention being given to the volume and tem-

According to Lewkowitsch, oleic acid has refractive index, 1.4585 at 30° C.; sp.gr. 0.898 (15°) iodine value, 90.07, theory 92.3 for chemically pure sample; neutralisation number, 198.9, and mean mol. wt., 282.

A determination of ether-insoluble bromide from the liquid acid gave a yield of 0.97%.

The constants found for the liquid acids indicate that oleic acid is the principal constituent, together with a small amount of a highly unsaturated acid; further particulars of this will be included in a second communication on the chemistry of dugong oil, which will also deal with the soluble, insoluble, and volatile acids, and other points of interest which have arisen during this investigation.

In conclusion we wish to express our appreciation of the care taken by Messrs. Corser and Co. of Maryborough, Queensland, in securing us the fresh and authentic sample of dugong oil and for information respecting the industry at Hervey's Bay. Our thanks are also due to Messrs. Baker and Smith of the Technological Museum, Sydney, for the use of their refractometer, and free access to the library.

This investigation was carried out in the Organic Chemical Laboratory of the Sydney Technical College.

DISCUSSION.

Mr. A. A. RAMSAY asked what time had been used in the determination of the iodine value? This was usually 3 hours, but sometimes 6.

Mr. B. J. SMART asked if the fine crystalline substance obtained on cooling had been isolated, purified, and examined, and whether any examination had been made of the mixed acids?

Dr. R. K. MURPHY inquired if the low figures obtained for acidity were in any way connected with the age of the samples and whether the acidity increased with age?

Mr. N. C. NASH pointed out that the acidity of fats might be considerably modified by the method of preparation. Fats melted in the sun, which he understood was the practice in extracting the dugong oil in Queensland, gave low acid values, while those melted in a digester under pressure gave high values.

Mr. CHALLINOR, in reply, said that in determining the iodine values the time was 2 hours in all cases. The crystalline substance obtained on cooling had not yet been fully examined, but was now being investigated, as well as the mixed acids. The acidity found was the lowest that had been reported, and in their experience it did not increase at all with age.

Mr. PENFOLD added that they had made altogether 10 or 12 determinations of acidity, and were sure of the accuracy of their results. With reference to a suggestion about hydrogenation, there were plenty of other suitable materials available that could be operated on more cheaply.

Communication.

DETECTION OF HYDROCYANIC ACID.

BY DR. GEORGE W. ANDERSON.

(Paper read before a meeting of the Science Circle, Ruhlleben, on Jan. 5th, 1916.)

Free hydrocyanic acid or its alkali compounds, even when present in very small quantity, can be detected by the smell of bitter almonds. The acid is liberated at ordinary temperatures by weak acids, such as carbonic acid, hydrogen sulphide, tartaric acid, etc., and this property is utilised to separate it from mixtures. The usual procedure is to pass a stream of carbon dioxide through the solution heated to 50°–60° C.,¹ collecting the hydrocyanic acid either in water or in alkali hydroxide solution. By this method only poisonous simple and double cyanides, *e.g.*, AgCN or AgCN, KCN, are decomposed, complex compounds such as ferrocyanides and thiocyanates being unchanged under these conditions.²

In the series of experiments described below, which were carried out to ascertain the sensitiveness of the various methods for the detection of hydrocyanic acid, solutions of potassium cyanide (of 98.5% purity) were prepared ranging in strength from 0.00001% to 0.1%, *i.e.*, containing 0.00000393 to 0.0393 grm. CN in 100 c.c. For each test 10 c.c. of solution was employed, and all the reagents were examined and found to be pure.

Detection of hydrocyanic acid as silver cyanide. A precipitate of silver cyanide is formed when silver nitrate solution is added to a solution of hydrocyanic acid or an alkali cyanide in presence of nitric acid. This precipitate is easily soluble in excess of potassium cyanide or in ammonia. In a series of tests of this reaction made with cyanide solutions of different strengths, it was found that in a 0.01% solution (0.00039 grm. CN per 10 c.c.) a precipitate is formed, but with more dilute solutions only an opalescence is produced. The limit of sensitiveness is reached in a 0.0001% solution, in which case the opalescence can only be detected against a black background and in a column 12 cm. in height.

A. Link and R. Möckel³ recommend that the solution to be tested should be supersaturated with ammonia before the addition of silver nitrate and nitric acid. The author tested this modifica-

tion but obtained no better results. In fact the addition of 2 c.c. of 10% ammonia solution and a corresponding quantity of 20% nitric acid greatly reduced the sensitiveness of the reaction, owing to the solubility of silver cyanide in solutions of ammonium salts. Excess of acid must also be avoided, but excess of silver nitrate is necessary if the maximum sensitiveness of the reaction is desired.

Detection as Prussian blue. The Prussian blue reaction is very widely used for the detection of hydrocyanic acid. According to Almen⁴, two drops of a ferrous-ferrie salt solution and two drops of dilute caustic soda solution are added to 2 c.c. of the solution to be tested; after five minutes the solution is acidified with hydrochloric acid, when a blue precipitate or coloration will appear if hydrocyanic acid is present. Excess of alkali and of acid must be avoided. Some difference of opinion exists as to the advisability of boiling the solution. Link and Möckel⁵ recommend boiling, especially in the case of weak solutions, whereas Almen⁶ regards it as unnecessary. The present author has found that boiling is advantageous in that it accelerates the reaction.

This reaction was examined for sensitiveness, and it was found to fail when less than 0.000039 grm. CN was present in 10 c.c., *i.e.*, at concentrations lower than 0.001%. At this latter concentration the coloration appeared only after half to one hour.

The comparatively low sensitiveness of this reaction suggested the possibility that the conversion of cyanide to ferrocyanide was incomplete, and this was confirmed by a test with pure ferrocyanide, which it was possible to detect at dilutions corresponding to 0.000024 grm. CN.

Detection as thiocyanate. This method for the detection of hydrocyanic acid, originally proposed by Liebig, is both sensitive and reliable; it consists in converting the hydrocyanic acid into thiocyanate and applying the ferric chloride test to the latter. Link and Möckel (*loc. cit.*) describe the test as follows: To the aqueous solution of hydrocyanic acid or alkali cyanide sufficient yellow ammonium sulphide is added to impart a yellow tint. After adding a few drops of dilute caustic soda solution, the mixture is evaporated to dryness on the water bath and the residue dissolved in water with the addition of a little dilute hydrochloric acid. Addition of a few drops of ferric chloride solution produces a red coloration, which, in the case of very dilute solutions, may not appear for some time. The addition of hydrochloric acid is necessary to destroy thiosulphate which is produced during the process. The following reactions are involved:—

In a series of tests carried out according to the above directions it was found that when 0.00039 grm. CN (0.01%) or more is present in 10 c.c., a deep red colour appeared which became lighter with increasing dilution, finally showing a faint orange tint. The limit of sensitiveness is reached with a 0.0001% solution (0.0000039 grm. CN per 10 c.c.). The reaction may be conveniently carried out in a white porcelain basin.

Detection by means of picric acid. On adding to a solution of hydrocyanic acid or an alkali cyanide a cold saturated solution of picric acid together with a little caustic potash, a deep red coloration is produced, owing to the formation of potassium isopurpurate.⁷ According to Dragen-dorf⁸ the solution should be kept at 50–60° C., but the reaction also takes place at ordinary temperatures, though a half to one hour may be required before it is complete. A series of tests of

this reaction showed the sensitiveness to be limited, and moreover the same coloration may be produced by impurities in the acid and alkali or by reducing substances, *e.g.*, sugar, sulphur dioxide, etc.⁹ With a 0.1% solution of cyanide (0.0039 grm. CN in 10 c.c.) an orange colour developed after half an hour, and after twelve hours a brown-red; with a 0.01% solution an orange red colour appeared after six hours at ordinary temperature. A 0.001% solution failed to give the reaction at the ordinary temperature, but a colour developed on heating. This method, therefore, cannot be recommended.

Detection by means of guaiacol. This test, known as the Schönbein-Pagenstecher reaction, is the most sensitive for the detection of hydrocyanic acid, and is carried out, according to Link and Möckel (*loc. cit.*), as follows:—Filter paper is saturated with a 4% alcoholic solution of guaiacum resin and dried. Immediately before the test the paper is moistened with a $\frac{1}{2}$ % solution of copper sulphate. When the paper is suspended over strong hydrocyanic acid solutions it immediately becomes sky-blue. More dilute solutions are applied to the test paper, or the reagents may be used in solution. The coloration is not caused by the hydrocyanic acid itself, but is due to the oxidation of the resin by oxygen or ozone developed by the conversion of cupric cyanide into cuprous cyanide. The following equations are given by Baumann¹⁰:—

Tests as described above were carried out with test paper to a dilution of 0.0001%, but for greater dilutions the reagents were applied in solution. W. Maisel¹¹ suggests the addition of a little caustic potash to the solution to be tested, the whole being then concentrated on a water-bath. The concentrated solution is acidified with tartaric acid and the solutions of resin and copper sulphate are added. By means of this modification, as little as 0.00000039 grm. CN in 10 c.c. (0.00001% KCN) can be detected, according to the present author's tests. A 0.1% solution of potassium cyanide gave the reaction with the test paper immediately and a 0.01% solution in a few minutes. Solutions as dilute as 0.0001% gave a pale blue coloration in ten minutes, or in twenty seconds in presence of acid.

H. Kunz-Krause¹² recommends the use of an alcoholic solution of guaiacolic acid instead of the crude resin, together with a 0.1% copper sulphate solution. This modification does not appear to increase the sensitiveness of the reaction, but the coloration appears more rapidly and is a purer blue, and hence is to be recommended.

It should be borne in mind that this reaction is easily disturbed by the presence of alien substances, *e.g.*, ammonia or cigar smoke. The colour produced by cigar smoke is identical with that given by hydrocyanic acid, but ammonia produces a greenish-blue coloration.

A summary of the results obtained above is given in the subjoined table of limits of sensitiveness of the various tests:—

Test used.	Strength of KCN solution.	Amount of CN. grm. per 10 c.c.	Sensitiveness of reaction calculated as KCN.	
			According to test.	According to literature.
Silver cyanide	0.0001%	0.0000039	1 : 245,000	1 : 250,000*
	0.001%	0.000039	1 : 24,500	1 : 50,000*
Prussian blue	Ferrocyanide,			
	0.0006%	0.000021	1 : 39,000	—
Thiocyanate	0.0001%	0.0000039	1 : 245,000	1 : 4,000,000*
Picric acid	0.01%	0.00039	1 : 2450	1 : 2000†
Guaiacol	0.00001%	0.00000039	1 : 2,450,000	1 : 3,000,000*

*Link and Möckel. *Z. anal. Chem.*, 1878, 17, 455.

†Reichardt. *Chem.-Zeit.*, 1901, 25, 537.

Although the Schönbein-Pagenstecher method is the most sensitive, it can only be used as a preliminary test in conjunction with use of the other reactions, *e.g.*, the Prussian blue or silver cyanide tests, of which the latter is often preferred in forensic chemistry. This test, however, generally requires a double distillation of the original solution to be tested in order to obtain a distillate free from chlorine. The Prussian blue test will suffice for ordinary purposes, whilst the thiocyanate reaction may be useful in special cases. The picric acid reaction cannot be recommended, as already stated.

Industrial Notes.

SULPHURIC ACID MANUFACTURE BY THE CHAMBER PROCESS.

An interesting method of controlling the working of sulphuric acid chamber plant has been patented by A. M. Fairlie; brief abstracts of the claims have already been published (U.S. Pats. 1,205,723 and 1,205,724; this J., 1917, 82, 83), and a full description of the process was given by the inventor in a paper read before the Georgia Section of the American Chemical Society, and reproduced in the Jan. 27th issue of the Chemical Trade Journal.

The text of the paper is as follows:—

It is well known that the largest single item of expense in operating a sulphuric-acid chamber plant is nitrate of soda. Efforts to improve the economical operation of such a plant are naturally directed, therefore, towards the conservation, or the recovery, of the valuable nitrogen compounds. The most important of the inventions designed to effect a saving in the consumption of nitrate of soda was of course the Gay-Lussac tower. Since the use of that tower for the recovery of the oxides of nitrogen escaping from the last chamber has become universal, wherever the chamber process is in operation, many devices have been introduced to improve the efficiency of the tower. These include various styles of packing material, various ways of distributing the acid fed on the top, the use of water instead of steam in the chambers, the introduction of towers fed with cold acid between the chambers to effect greater cooling of the chamber gases, and so forth.

Even with the best of these improvements installed, the efficiency of the Gay-Lussac tower will depend largely upon the way the process is

handled—upon the proper regulation of the streams of acid in the towers, and of the steam or water in the chambers; upon the efficient cooling of the acid on the Gay-Lussac, upon the avoidance of interruptions due to break-downs; and, above all, upon the careful introduction of just that amount of nitre required for the oxidation of the sulphur dioxide admitted to the chambers per unit of time.

Let us assume that the plant has been designed and constructed intelligently—that proper materials of construction have been used; that spare pumping appliances have been provided to permit the uninterrupted flow of the streams of acid over the towers under any possible conditions; that by-pass flues or spare fans have been installed, to insure the continuous and uniform flow of gas, even in case of breakdown; that the plant, in short, has been built under the direction of a competent sulphuric-acid engineer, experienced in operation as well as in construction—let us assume further that the plant is manned by a competent crew of workmen, able to operate the appliances without interruption, and turn our attention to the regulation of the nitre in the system.

The well-known, time-tried methods of regulating the quantity of nitre introduced, or, let us say, of controlling the process are: (1) by observing, the differences between chamber temperatures at different parts of the system, learning by experience what differences yield the best recoveries in the Gay-Lussac tower, and endeavouring thereafter to maintain such desirable temperature-differences constant. (2) By observing the colour of the gases in the chambers or connecting pipes by means of windows or "sights." (3) By a combination of both of the above methods.

These methods may be satisfactory in the main, as long as the gas entering the Glover tower contains a substantially uniform percentage of sulphur dioxide, but it is questionable if, even under the best of conditions as regards uniformity of grade of burner gas, these methods are adequate to yield the most economical results. To control by these methods is to control by symptoms, whereas the rational method of control is by analysis of the gases. Certainly when the grade of burner or furnace gas is irregular, as in the case of plants manufacturing acid as a by-product of zinc or copper-smelting operations, the time-tried methods of control should be replaced by the analytical method. The temperature-difference method fails, when operating on a fluctuating burner gas, because the indications of the temperature-differences are misleading. The same change in the temperature-difference may be due to one of several causes, and as the temperature-difference does not indicate in case of trouble to which cause the trouble is due the wrong remedy may be applied. The colour method alone is altogether inadequate as a guide for controlling the chamber process. In the first place, the sight glasses are usually placed at the back end of the chamber system, whereby information about the colour of the chamber gases is obtained too late to prevent the damage which has been done; and besides, even if the sight glasses are in the front chamber, the colour there is so obscured by the white mists that few persons possess the ability to detect the differences in shade, by day and by night, which would indicate whether or not the gas mixture contained the correct amount of nitrogen oxides.

The Fairlie method of controlling the chamber process is the only analytical method known to the industry. It has been in continuous daily use at the plant of the Tennessee Copper Company, where it was invented, for the past six years, and has proved its value every day that it has been in use. It consists in determining the percentage of sulphur dioxide in the chamber gases at some point near the front end of the chamber system,

and in comparing such percentage with the percentage of sulphur dioxide in the burner gas, before admixture with nitre fumes. The comparison shows, after experience, that a certain ratio between the two sulphur dioxide percentages must be maintained in order to secure the best results in the Gay-Lussac tower. What this desirable ratio is must be determined for every possible grade of burner gas. Once determined, the desirable ratios are set down in tabular form on a card, which is framed and fastened in a convenient place for reference by the chamber operator. This operator keeps his analytical apparatus in good order at all times, and by taking frequent gas tests of the burner gas and of the front chamber gas, accurate indications as to the condition of the gas mixture, and as to the speed of oxidation of sulphur dioxide, are obtained, and obtained in time to apply the proper remedy in case anything is about to go wrong. An increase in the sulphur dioxide ratio above what is desirable indicates the need of more nitre; whereas a decrease below the desirable ratio indicates that the quantity of nitre must be reduced.

The analytical method adopted for determining the sulphur dioxide percentage in the gases is the Reich method—in its original form for the burner gas, but modified by the addition of solution of acetate of soda and acetic acid to the absorption bottle, for the chamber gas. The original unmodified Reich method is impossible for the chamber gas, because the presence of nitrogen oxides causes the starch-iodide blue colour to recur, and vitiates the results. The Reich method, as modified, will give results on chamber gas agreeing within 0.01%, and this is sufficiently accurate for the most careful control of the process. The method of testing the gases can easily be learned by a workman of usual intelligence, so that the expense of employing a chemist for the analysis of the gases is avoided.

It may be remarked in this connection that by means of the modified Reich method, as applied to chamber gases, important information may be obtained regarding the percentage of sulphur dioxide desirable in the gases entering the Gay-Lussac. Some of our old acid makers and, indeed, some of our old acid engineers, grown grey in the sulphuric acid industry, scoff at the idea of any sulphur dioxide being desirable in the Gay-Lussac tower gases. This is because the older men are not familiar with any rapid method for determining accurately the percentage of sulphur dioxide in gas mixtures containing nitrogen oxides. And because the methods of analysis which they used failed to indicate the presence of sulphur dioxide at the Gay-Lussac tower, they have formed the conclusion that none is ever present, under normal conditions. The facts, however, are these:—The nitrogen oxides are recovered most completely in the Gay-Lussac tower when the proportion of nitric oxide (NO) and nitrogen peroxide (NO₂) in the gases entering that tower are such that the combination gives nitrogen trioxide (N₂O₃) with no excess of either of the constituent gases. The presence of a small quantity of sulphur dioxide is needed in the gas mixture entering the Gay-Lussac to keep a sufficient amount of the nitrogen gases reduced to the nitric oxide form. If the quantity of sulphur dioxide present be deficient, or if there be none at all, an excess of nitrogen peroxide will be present, above what is needed to combine with nitric oxide to form nitrogen trioxide, and this excess, being only slightly soluble in the cold 60° acid with which the tower is fed, will be lost, as indicated by the red fumes escaping into the air through the exit stacks. On the other hand, if too much sulphur dioxide be present in the gas mixture entering the Gay-Lussac, an excess of nitric oxide, above the quantity needed to combine with the nitrogen peroxide to form the trioxide, will be present.

As nitric oxide likewise is only slightly soluble in cold sulphuric acid of 60° strength, this excess will be largely lost, as before, although, because the nitric oxide is a colourless gas, the loss will not be so readily detected by observation of the colour of the gases escaping from the top of the tower, as in the case of the red gas, nitrogen peroxide. For this reason it is of especial importance to have some other means of knowing when there is an excess of nitric oxide present in the gases entering the Gay-Lussac. By means of the modified Reich test it has been demonstrated that the right proportions of nitric oxide and nitrogen peroxide will be present when the percentage of sulphur dioxide entering the Gay-Lussac is between 0.07 and 0.10%, in cold weather, or between 0.09 and 0.12% in moderate or warm weather. Under moderate weather conditions any deviation in the percentage of sulphur dioxide above the high limit of 0.12% indicates an excess of nitric oxide, and any deviation below the low limit of 0.09% indicates an excess of nitrogen peroxide, so that careless handling of the process at the front end of the system will be plainly indicated by testing the gas at the entrance to the Gay-Lussac tower.

The analytical method of controlling the chamber process ought to eradicate that old advice to the chamber operator: "In case of trouble, first increase your nitre at the pots, then find out what is wrong." This advice, advocated by two such authorities as Lange and Falding, is, on the face of it, absurd. How foolish to add more nitre in case of trouble, when the thing that is wrong may be already too much nitre. The rational thing to do in case of trouble is to proceed by the indications of the analytical method. First find out what is wrong by analysis of the gases (thirty seconds of time is all that is needed), then either increase or reduce the quantity of nitre, according to indications.

The analytical method of controlling the chamber system is particularly valuable in starting up a set of chambers after a shut-down, or in starting up a new plant for the first time. It has been the experience of most chamber-plant owners that in starting up a plant a period of experimentation must elapse, varying from two weeks for an old plant to several months for a new one before the chambers settle down to regular work. The reason for this is that nobody knows, in starting up a plant, what is wrong, because the time-tried methods are useless while the process is upset. The analytical method of control, on the other hand, indicates precisely what is wrong, and indicates to what extent it is wrong, thus permitting the proper remedy to be applied, in the correct proportions. By means of the analytical method of control the immense plant of the Tennessee Copper Company has been repeatedly put into regular working condition, after a shut-down, within thirty-six hours. The new 400-ton plant of this company, started for the first time last July, and using the analytical method of control from the start, was in regular working condition forty-eight hours after the gas was first admitted to the Glover tower.

ECONOMY OF FOOD WHICH MIGHT BE EFFECTED BY THE PROHIBITION OF BREWING.

REPORT OF COMMITTEE OF THE ROYAL SOCIETY.

At the request of the President of the Board of Trade, a Committee was appointed by the Royal Society to consider the question of the food supply of the United Kingdom. One section of the report

of this Committee deals with the economy in food materials which would be rendered possible if brewing were prohibited. In 1916-17, under the "Output of Beer (Restriction) Act of 1916," a maximum of 26,000,000 barrels per annum of original gravity 1055° was allowed to be brewed. (It may be noted here that by an order of the Food Controller, the output for 1917-18 has been further reduced to 18,200,000 barrels.) The figures for consumption of brewing materials in 1916-17 were not available, but taking an average of the years 1911 to 1914, and assuming the same proportions of materials to have been used, it is calculated that the 26,000,000 barrels would require 38,200,000 bushels of malt, 59,000 bushels of malted corn, 1,090,000 cwt. of rice, grits, etc., and 2,320,000 cwt. of sugar. From these figures it is estimated that the materials contained 13,500 metric tons of nitrogen and 3,935,000,000,000 calories, whilst the products obtained are computed to have contained 12,590 tons of nitrogen and 3,267,000,000,000 calories, a loss of 6.7 and 17.0% respectively. About half the nitrogen loss is accounted for in the precipitate produced on boiling the wort and filtered off with the spent hops, and part of the loss in heat value occurs by oxidation during malting and fermentation.

It is recognised that it is not possible to utilise as human food the whole of the materials used in brewing. The sugar could be utilised, but barley would not be likely to yield more than 60% of its weight of flour, the remainder being only of indirect value as food for pigs. Direct experiment has convinced the Committee that wheat flour containing 15% of barley flour will yield a palatable loaf. It would also be possible to utilise the grits as human food. On this basis, allowing for the conversion of barley offals into pig flesh, it is estimated that the amount of human food obtainable from the whole of the brewing materials used in 1916-17 would contain 9250 metric tons of nitrogen and 2,822,000,000,000 calories, i.e., 68.5 and 71.7% respectively of the amounts in the original materials.

Dealing with the extent to which the nutritive value of the various brewery products can be realised, it is stated that brewers' grains, malt culms, and dried yeast cannot be used directly as human food, but they give their best return when converted into milk, in which case it is estimated, that 2 lb. of mixed brewers' by-products will yield 1.07 lb. of milk.

In view of the difficulty of assessing the value to the human body of the nitrogen and calories in beer, the yield of human food has been estimated, (A) allowing full calorific value for the alcohol and taking the beer at full protein value for the nitrogen; and (B) allowing no calories for alcohol and 50% of the value for protein. These calculations work out as follows:—

	(a)		(b)	
	Protein, metric tons	Million Calories.	Protein, metric tons	Million Calories.
Beer.....	17,900	2,200,000	8950	990,000
Culms, grains, and yeast	5,970	107,000	3070	107,000
Total	22,970	2,307,000	14,020	1,097,000
Percentage of original materials available	27%	59%	16.6%	27.9%

As it is certain that alcohol has some food value, the energy yield to the body lies between these two extremes. It is concluded that the loss of energy in the brewing process lies between 41% and 72%, and that the loss of protein is at least 73% (com-

pared with 29% and 32%, respectively, estimated when the materials are used as or converted into human food).

It is pointed out that if the production of beer is prohibited, the quantities of human food specified above will only be realised if the materials are used as stated, *i.e.*, barley for flour, etc. If their destination is not controlled the greater part would probably be used as food for live stock, in which case the maximum protein and calorie yields would be 17% and 15% respectively.

REGISTRATION OF BUSINESS NAMES.

A very large number of firms and persons carrying on business in the United Kingdom will be affected by the Registration of Business Names Act, 1916, which is now in force. For many years there has been a strong feeling amongst Chambers of Commerce and others that some legislation should be brought into effect which would make public the actual names of the partners of firms and businesses having designations which give no hint as to their identity; this feeling was accentuated on the outbreak of the present war, when accurate knowledge as to enemy firms was desired, and the result was the introduction of the Registration of Firms Bill, in 1911. After much amendment this Bill gave place to the present Act, which received the Royal assent on December 22nd, 1916.

The Act provides that "every firm having a place of business in the United Kingdom and carrying on business under a business name which does not consist of the true surnames of all partners who are individuals and the corporate names of all partners who are corporations without any addition other than the true Christian names of individual partners or initials of such Christian names," must register before March 22nd at offices to be set up in London, Edinburgh, or Dublin. The same applies to every individual trading under a name other than his own, and also to an individual who has changed his name or a firm of which a member has changed his name. It is not, however, necessary to register where the addition to a name merely indicates that the business is carried on in succession to a former owner, or where two or more partners have the same surname and have added to it the letter *s*, or again where the business is carried on by a trustee in bankruptcy or by a receiver or manager appointed by any court. Again, Section 2 of the Act provides that where a firm, individual, or corporation having a place of business in the United Kingdom carries on the business wholly or mainly as nominee or trustee of or for another person, or other persons, or another corporation, or acts as general agent for any foreign firm, the first-mentioned firm, individual, or corporation must be registered. The registration, which must

be made on prescribed forms, obtainable at Post Offices, and bearing a 5s. stamp, must disclose the business name, the general nature and principal place of business, the full name or names of individuals or partners, former names, nationality (and nationality of origin, if different), usual residence, and other business occupations, if any. Where a business is carried out under two or more business names, each of those business names must be stated. When any change is made in any of the particulars registered, particulars as to the nature and date of the change must be furnished.

It is further provided that where a business is carried on under a name containing the word "British" or other word which, in the opinion of the registrar, indicates that the business is under British ownership and control, and the registrar is satisfied that this is misleading, he shall refuse to register the name or shall remove the name from the register; the decision of the registrar may be appealed against to the Board of Trade, whose decision will be final.

The Act contains another important provision regarding the publication of true names, which is to the effect that, after March 22nd, every individual or firm required to be registered must mention on all catalogues, trade circulars, show-cards, and business letters, the present Christian name or names (or initials) and the present surnames, any former Christian names and surnames, the nationality if not British, and nationality of origin, of each individual or partner. The London Office of the Registrar of Business Names for England and Wales is at 39, Russell Square, London, W.C.

It should be noted that Limited Companies or Corporations do not come within the scope of this Act, excepting where they are acting as "nominee or trustee" or as "general agent" as set forth in Section 2 (see above). The following are cases in which registration will be necessary:—Henry Lewis, carrying on business as H. Lewis and Co., or as P. Lewis, or as H. Smart; H. Lewis and R. Carter, trading as Lewis, Carter and Co., or as Lewis, Smart and Co., or as The United British Chemical Works; H. Lewis (formerly Levi), carrying on business as H. Lewis; a firm in which Lewis (formerly Levi) is a partner must also register. Another case is where Lewis carries on the business of Lewis and Carter; here he must either register, or trade as Lewis or as Lewis, late Lewis and Carter. Again, if Henry and John Carter are partners, they may style themselves Carter and Carter, or Carters, but not Carter and Son or Carter Brothers without becoming liable to registration.

These few examples, and the brief description given above, will serve to show the far-reaching effects of this urgently-needed legislative measure, which should prove of great value as a safeguard to the commercial interests of this country in the industrial struggle which will follow immediately on the cessation of hostilities.

Journal and Patent Literature.

PATENT SPECIFICATIONS may be obtained by post by remitting as follows:—

English.—6d. each to the Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C.

United States.—1s. each to the Secretary of the Society, who has to furnish the U.S. Patent Office with the following data:—Patent number, date, name of patentee, and title of invention.

French.—1 fr. 05 c. each, as follows: Patents dated 1902 to 1907 inclusive, Belin et Cie., 56 Rue Feron 8, Paris (36.) Patents from 1908 to date, L'Imprimerie Nationale, 87, Rue Vieille du Temple, Paris

I.—GENERAL; PLANT; MACHINERY.

Gases; Absorption of.—W. Hempel. *Z. angew. Chem.*, 1917, 30, 6—11.

The general practice of gas washing is surveyed and particulars are given of the treatment of the flue gases from a Hoffmann brick kiln, which had

a marked destructive action on vegetation. This has been traced to the presence of silicon fluoride in these gases, which contain 0.6 grm. fluorine per cubic metre. The clay used in this works contains 0.16% fluorine. Compared with hydrochloric acid and sulphur oxides, silicon fluoride is difficult to remove from the gases, probably

because of the slowness of the reaction:— $3\text{SiF}_4 + 11\text{H}_2\text{O} + 21\text{H}_2\text{SiF}_6 + \text{Si}(\text{OH})_4$ which precedes absorption. Satisfactory results were obtained by leading the flue gases from the kiln through a cast iron pipe, 24 m. long and 50 cm. in diameter. The temperature fell from 180° to 130°—110° C. thereby, and was further reduced to 30°—40° C. in passing through a fan of special construction containing a water spray. The fan, the axis of which is of cast iron and the blades and casing wood, drove the gases under a pressure of 25 mm. water through a stoneware pipe into a so-called "filter channel." This consisted of a trench dug in the ground, 80 cm. deep and 265 metres long. It was covered in with wooden grids carrying in layers, first coarse stones, then small stones, and on top sand or earth. The flue gases had to traverse this porous filter mass before escaping into the outer air, and in so doing all acid gases and also soot were retained. The removal of the soot from the "filter channel" has to be done only once a year. Dilution of the flue gases from the kiln with air by means of numerous holes in the upper part of a chimney stack was found to be partially effective, but influenced by the direction of the wind. As a new filling material for gas washing apparatus, an artificial pumice stone is suggested (see this J., 1916, 632), which is acid-resistant. Common bottle glass is powdered and mixed with 1% of carbon. The mixture is fused, when a considerable development of gas occurs, so that the melt solidifies on pouring to a bulky, cellular product which floats on water. The filling materials in common use are all much heavier and require correspondingly greater mechanical strength in the construction of the containing apparatus. By using the material described, it is suggested that glass might be employed in the construction of gas-washing plant on the large scale.—H. J. H.

Waste heat for steam generating purposes: Utilisation of —. A. D. Pratt. *Met. and Chem. Eng.*, 1916, 15, 696—708; 1917, 16, 27—31.

The development and use of the modern waste heat boiler is considered in connection with open-hearth steel furnaces, cement kilns, furnaces for smelting and refining copper, beehive coke-ovens, and furnaces for heating and miscellaneous uses. Numerous constructional and other details are given, with data relating to various installations. In modern waste heat practice which has been developed mainly in connection with the utilisation of low-temperature gases from regenerative furnaces, an induced draught is used to produce the gas velocity necessary for a satisfactory rate of heat transfer; in certain classes of work such draught has the additional advantage of improving the operation of the primary furnace. In most cases the saving effected by the use of waste heat boilers lies mainly in the value of the power produced by the steam generated. At the present time such boilers are most largely employed with open-hearth steel furnaces, and, in this connection, have been the means of reducing the net cost of producing steel by 20–25c. (10d.—1s. 0½d.) per ton.—W. E. F. P.

Colloidal graphite in oil. Holde. See VII.

PATENTS.

Furnaces: Apparatus for feeding pulverulent fuel to —. J. E. Muhlfield, Scarsdale, and A. Z. Caracristi, Bronxville, N.Y., U.S.A. Eng. Pat. 13,007, Sept. 13, 1915.

Is apparatus for feeding pulverulent fuel such as coal, coke, lignite, or peat to furnaces for domestic, industrial, metallurgical, or transport use, the fuel is fed by a screw conveyor of increasing pitch toward the delivery end, on to radial or

helical blades carried by the conveyor shaft, and thence into the air blast nozzle. Other forms of apparatus are also described. (1) The air blast nozzle may surround the conveyor tube and may itself be surrounded by a return screw conveyor extending further forward into the mixing nozzle. Any excess of fuel is thus conveyed back and returned to the rear end of the forward conveyor. (2) The air blast is supplied from an annular surrounding chamber through jet holes in the wall of the return conveyor in advance of the forward end of the forward conveyor. (3) The air blast is so delivered as to fill only the lower half of the mixing nozzle, and the fuel is delivered on to the top of the air stream; a return conveyor is arranged below the mixing nozzle. (4) The fuel is supplied by measuring drums to the mixing chamber. (5) The fuel is fed downward from the supply hopper by vertical screw conveyors in separate tubes which extend into a diverging mixing chamber through which air is blown; the tubes are progressively shorter as the mixing chamber diverges.—W. E. F.

Furnaces fed with pulverulent fuel. K. H. W. von Porat, Stockholm, and Metala Verkstads Nya Aktiebolag, Metala Verkstad, Sweden. Eng. Pat. 103,097, Nov. 18, 1915. (Appl. No. 15,150 of 1916.)

PULVERULENT fuel is injected by the pipe, 75, into the mixing chamber, 73, where it is deflected, as shown, by the plates, 74, 82, and 81. Air for combustion is drawn in through the louvres, 79,

so as to mix with the fuel jet, which is ignited by a fire on the grate, 80, through the restricted opening, 83. The combustion gases pass to the boiler tubes through openings on each side of the central member, 76. In a modification the pipe, 75, extends through the space below the grate, 80, into the bottom of the mixing chamber where it diverges correspondingly with the walls of the chamber. In another modification the pipe, 75, projects the fuel jet first downward along the plate, 81, and then upward along the plate, 74. A single damper-controlled air opening is provided at the turning point of the fuel jet. (See also Eng. Pat. 16,298 of 1915; this J., 1916, 1251.)—W. E. F.

Furnaces: Gas-fired crucible —. R. Halkett, Glasgow. Eng. Pat. 103,232, Apr. 20, 1916. (Appl. No. 5781 of 1916.)

A GAS-FIRED crucible furnace is provided with a permanent brickwork lining, in which the gas and air supply pipe to the burners is embedded to pre-heat the fuel. The pipe is provided with outside connections to the removable burners. The crucible is supported on a block of graphite resting on a refractory lining carried by a removable base-plate, and an inclined outlet is provided for running off material in case of breakage of the

crucible. The brickwork is lined internally with a refractory composition consisting of fireclay or ball clay, 75%, alumina, 5%, sawdust, 5%, sodium silicate, 5%, and water, 10%.—W. F. F.

Furnace. A. W. Moyer. New York. U.S. Pat. 1,209,321, Dec. 19, 1916. Date of appl. Sept. 25, 1915.

A FURNACE is divided by a perforated horizontal arch, into an upper combustion and a lower heating chamber. The upper chamber is supplied with liquid or gaseous fuel under pressure and the products of combustion pass down through the perforated arch into the heating chamber below. The side walls of the lower chamber have ports for the discharge of the waste gas, but no other openings, so that they present a large surface to store up and radiate heat.—W. H. C.

Furnace-hearths: Mounting —. F. Wedge. Ardmore, Pa. U.S. Pat. 1,209,914, Dec. 26, 1916. Date of appl. Apr. 13, 1915.

AN annular furnace comprises an inner rotating cylindrical wall built up of blocks supporting annular outwardly projecting hearths, and an outer fixed concentric wall with inwardly projecting hearths alternating with the revolving hearths. The revolving hearths pass through the supporting wall and have an inner portion bearing against the inner face of the wall. The outer hearths rest on fulcrum blocks in the inner face of the supporting wall and are provided with retaining blocks above them, within the wall at a greater radius from the centre.—W. F. F.

Nitric acid vacuum pumps: Means for packing the pistons of —. S. Dreyfus, Denton. Eng. Pat. 102,527, Jan. 26, 1916. (Appl. No. 1216 of 1916.)

THE packing consists of an annulus, *a*, of vulcanised rubber, channel-shaped in cross-section, and bevelled on the exterior, which is placed between the bevelled sides of a recess formed by the two halves, *b*¹, *b*², of the piston. This recess is provided with an inflatable rubber tube, *c*, which, on being filled with air or other fluid, keeps the packing in close contact with the cylinder. The rubber is practically acid-proof.—E. H. T.

Gases: Apparatus for purifying, cooling, and mixing —. H. E. Theisen, Munich, Germany. Eng. Pat. 103,133, Jan. 6, 1916. (Appl. No. 225 of 1916.)

AN apparatus of the type described in Eng. Pat. 22,433 of 1910 (this J. 1911, 1045), in which concentric rings of beaters revolve in opposite directions, the beaters are formed like turbine blades so that the fluid is transferred from one set to the next with the maximum change of direction and the minimum of shock, and consequently with the minimum loss of energy.—W. F. F.

Gases or superheated steam: Automatic regulation of the temperature of —. P. A. W. Parkyn, London. Eng. Pat. 103,196, Feb. 16, 1916. (Appl. No. 2316 of 1916.)

A CLOSED tube containing mercury or other liquid

projects into the main through which superheated steam is passed. An inner tube opening at the bottom into the mercury is provided with a piston or float, so that a change of volume of the liquid due to a change of temperature in the main moves the piston. The piston is connected by levers to a stop valve which controls the admission of saturated steam to the main until the temperature is brought back to a predetermined value.

—W. F. F.

Slimes: Method of and apparatus for treating —.

D. Cole, Tucson, Ariz. U.S. Pats. (A) 1,205,326 and (B) 1,205,327, Nov. 21, 1916. Dates of appl. (A) Apr. 12, 1913. (B) Mar. 21, 1915.

(A) For the separation of crystalloids from slimes which tend to become flocculent, the slime mixture is diluted sufficiently to allow the crystalloid particles to settle, and passed in a slow stream through a shallow trough in which the crystalloid particles settle out before the slimy matter has time to deposit. (B) The apparatus consists of a shallow tank, allowing of a transverse flow of liquid. Slime is introduced at one side of the tank in an extended shallow stream, and several adjacent endless conveyor belts, running on pulleys, travel horizontally on the bottom of the tank, transversely to the direction of flow, the return run of the belts passing outside the tank. Adjacent belts can be made to travel at different speeds and in opposite directions, to prevent the formation of disturbing currents. A pair of superposed tanks may also be used, the belts dipping into one tank in one direction, and into the other in the reverse direction.—W. R. S.

Elutriation: Process of fractional — of simple or mixed substances. W. Aegher, Berlin. Ger. Pat. 291,908, Nov. 13, 1913.

THE substances are subjected to a mechanical elutriation process in an aqueous solution of an organic non-electrolyte which depresses the surface tension. The following substances, both colloidal and non-colloidal, exert a marked deflocculating action—egg albumin, peptone, gelatin, tragacanth, agar, rubber, glue, saponin, cyclamine, amygdaline, amyl alcohol. In general the action increases with molecular weight. The process can be applied to ochre, chalk, barytes, *blanc fixe*, lithopone, white lead, talc, graphite, clay, kaolin, and metallic powders and oxides such as are used for catalytic processes.—H. J. H.

Revivifying char: Apparatus for —. R. S. Kent, Brooklyn, N.Y. U.S. Pat. 1,207,178, Dec. 5, 1916. Date of appl. June 25, 1913.

CHAR is passed through an inclined rotary conveying drum, 2, in which is fitted a stationary furnace, 19, entirely within the drum. Heating

gases pass from the furnace through the conduit, 9, out of contact with the char, which is raised and showered within the drum by the ribs, 11. A gaseous medium may be admitted to the interior of the drum through the pipe, 28, to alter the carbon content of the char.—J. E. C.

Aerating apparatus. C. H. Nordfl, Milwaukee, Wis. U.S. Pat. 1,208,821, Dec. 19, 1916. Date of appl. Mar. 23, 1916.

A FALSE bottom, formed of slabs of wood cut

across the grain, is fitted in a tank, leaving an air chamber below. The liquid is placed in the tank above the false bottom and air is forced into the lower space and passes up through the "fibrous passages" in the wooden slabs into the liquid above.—W. H. C.

Heat of chemical action: Method and apparatus for conserving — C. S. Bradley, New York, U.S. Pat. 1,209,258, Dec. 19, 1916. Date of appl., Feb. 26, 1915.

REVERSIBLE chemical reactions which are endothermic in one direction and exothermic in the opposite direction, are conducted in a closed system so that the heat evolved in the exothermic part of the reaction is conserved and retained in the system.—W. H. C.

Retort. J. F. Wells, Seattle, Wash. U.S. Pat. 1,209,365, Dec. 19, 1916. Date of appl. May 21, 1915.

THE joint between the door and door casing of the retort is made tight by suitable elastic packing material, which will give way when exposed to excessive pressure.—W. H. C.

Radiant heat; Apparatus for utilising. C. I. Gessell, Buenos Aires, Argentine, U.S. Pat. 1,209,956, Dec. 26, 1916. Date of appl., Aug. 9, 1916.

A PORTION of the surface layer of a large expanse of water exposed to the sun's heat is isolated by a floating partition wall, which also carries suitable means for covering the surface of the isolated portion of water and preventing loss of heat. The warm surface water is conducted through a vaporising apparatus and its heat is used to vaporise a liquid. The vapour is condensed by, and gives up heat to, the cooler water from below, flowing upwards to replace the warm water.—W. H. C.

Drying and cooling substances: Apparatus for — G. H. Hess, La Grange Park, Ill. U.S. Pat. 1,210,166, Dec. 26, 1916. Date of appl., Mar. 20, 1915.

THE material to be dried is fed continuously into a vertical rack provided with inclined plates to support the material. The inner edges of the plates do not extend quite to the median line of the rack, and the distance between the inner edges of adjacent plates decreases gradually from the bottom to the top of the rack. The material is withdrawn from the rack at a controlled rate while air is passed through it.—W. F. F.

Drying room and apparatus. O. Lilly, Memphis, Tenn. U.S. Pat. 1,211,325, Jan. 2, 1917. Date of appl., May 15, 1916.

A DRYING room is provided with a perforated horizontal partition below the ceiling, and another above the floor. The drying medium is admitted above the upper partition, passes downwards over independently controlled heating pipes as it enters the drying chamber, and is finally exhausted from the space below the lower partition.—W. F. F.

Dryer; Cylindrical — with concentric inner cylinder. W. Freytag, Dortmund, Ger. Pat. 295,016, July 30, 1915.

THE material to be dried passes with a current of air first along the inner cylinder and then back along the outer annular space, through which the hot gases from a heating furnace travel. A baffle at the end of the inner cylinder prevents the entry of heating gases which travel with the material in the outer space.—H. J. H.

Solution-specific-gravity-regulating apparatus. L. Logan, Syracuse, N.Y. U.S. Pat. 1,210,180, Dec. 26, 1916. Date of appl., July 12, 1916.

THE supply of the materials which, when mixed, form the desired solution, is controlled by electrical means actuated by floats supported by a balance beam. One float is supported in a solution having the desired sp. gr. and the other in a vessel through which the other solution or a portion of it flows. Both vessels are maintained at the same temperature, and any variation in the sp. gr. of the solution causes a rise or fall of the float, and the resulting movement of the beam actuates the electrical controlling device.—W. H. C.

Catalysers: Method of making — M. Reynolds, St. Elmo, Tenn. U.S. Pat. 1,210,367, Dec. 26, 1916. Date of appl., Feb. 18, 1916.

UNREDUCED catalytic material is exposed to the action of a reducing gas, including carbon monoxide, which is non-explosive in the presence of oxygen.—W. H. C.

Decanting apparatus. J. H. Alpenfels, Denver, Colo. U.S. Pat. 1,210,392, Jan. 2, 1917. Date of appl., Feb. 5, 1916.

THE apparatus comprises a series of settling vats each provided at the bottom with an outlet for the settled solids and at the top with several outlets for the liquid, connected with a gutter formed in the upper edge of the wall of the vat. Filter screens are placed over the liquid outlets to prevent any solid matter entering the gutter.—W. H. C.

Liquids: Separating the component parts of — E. J. Sheehan, Assignor to W. S. McCay, Pasadena, Cal. U.S. Pat. 1,211,361, Jan. 2, 1917. Date of appl., Feb. 8, 1915.

LIQUIDS extracted from vegetable, animal, or mineral matter are cooled and agitated until one of the constituents solidifies. The liquid is sterilised by contact with ozone, and the solid and liquid parts separated.—W. F. F.

Boiler compound. V. J. Melsted, Winnipeg, Canada. U.S. Pat. 1,210,965, Jan. 2, 1917. Date of appl., Dec. 10, 1913.

A MIXTURE of comminuted metallic mercury, and a "separating substance," liquid at ordinary temperatures, such as petroleum.—W. F. F.

Vacuum mixing machine for substances sensitive to pressure and friction. A. Wilhelm, Benthien, Ger. Pat. 294,776, Feb. 28, 1915.

THE mixer consists of a circular covered pan, jacketed to permit of temperature regulation. Mixing is effected by an agitator which hangs from a bearing in the lid of the apparatus where a gas-tight joint is made by the use of a mercury seal. The amount of clearance between the agitator arms and the sides of the pan can be carefully regulated, thus avoiding any contact.—H. J. H.

Separation of adsorbed, colloidal, soluble, or finely divided substances from substances carrying them. Elektro-Osmose A.-G. (Graf Schwerin Ges.), Berlin. Ger. Pat. 295,043, Jan. 26, 1915. Addition to Ger. Pat. 265,628 (see Eng. Pats. 14,369 and 24,666 of 1912; this J., 1913, 241, 432).

THE passage of feebly migrating substances through the diaphragm is facilitated by stirring. The deposition on the diaphragm of layers which impede the migration is thereby hindered, and the substance can come into the sphere of action.—H. J. H.

Colloidal solutions; Production of stable—
Aktiebolaget Kolloid i Likvidation, Stockholm.
Ger. Pat. 295,161, Mar. 31, 1914. Under Int.
Conv., Dec. 18, 1913.

THE substance taken—*e.g.*, wool fat, resin, castor oil, or phosphorus—is exposed to the action of a liquid, in which it is normally insoluble, at a suitably chosen high temperature and corresponding pressure, for a sufficient time, and then rapidly cooled under normal pressure. This gives a colloidal solution stable at ordinary temperatures. A protective electrolyte may be added to produce smaller particles and accordingly greater permanence of the colloidal solution.—H. J. H.

Filtrating apparatus. C. and J. Garnatz, Berlin.
Ger. Pat. 295,221, Mar. 28, 1915.

THE lower part of the filter is a shallow inverted cone offering a large filtering surface, the upper part being dome-shaped with a wide neck. The liquid to be filtered is in an inverted bottle, the neck of which is placed in the neck of the filter; the level of the liquid in the filter is thus kept constant until the bottle is empty.—B. V. S.

Liquid filter with grids and filtering medium arranged in a closed chamber. A. Lippert, Berlin-Pankow.
Ger. Pat. 295,215, Feb. 22, 1916.

A CYLINDRICAL chamber, *a*, which can be closed at both ends, has two or more longitudinal grooves, *b*, *b'*, *c*, *c'*, from end to end, one side connecting with the inlet tube, *l*, and the other with the outlet tube, *m*. Circular filter grids, *d*, separated by

the filtering medium, are arranged in the chamber. They have flanged edges, *e*, with gaps corresponding with one set of grooves in the wall of the chamber; the gaps are so arranged with respect to the grooves that the grids communicate alternately with the inlet and the outlet grooves. Pressure can be applied so as to pack the filtering medium tight enough to prevent leakage.—B. V. S.

Roasting and like furnaces; Automatic charging devices for—A. Mond, London. From Metallbank and Metallurgische Ges., Frankfurt, Germany. Eng. Pat. 100,259, Jan. 18, 1916. (Appl. No. 788 of 1916.)

Centrifugal machines and methods. L. P. Sharples, West Chester, Pa., U.S.A. Eng. Pat. 100,342, Jan. 18, 1916. Under Int. Conv., Apr. 27, 1915. (Appl. No. 819 of 1916.)

SEE U.S. Pat. 1,207,230 of 1916; this J., 1917, 123.

Powder and other hygroscopic substances; Method and apparatus for protecting from moisture. Scovill Manufacturing Co., and R. S. Sperry, New Haven, Conn., U.S.A. Eng. Pat. 101,961, May 20, 1916. Under Int. Conv., Oct. 23, 1915. (Appl. No. 7231 of 1916.)

SEE U.S. Pat. 1,178,187 of 1916; this J., 1916, 623.

Furnaces. R. Niedergesaeess, Seattle, Wash., U.S.A. Eng. Pat. 103,228, Apr. 17, 1916. (Appl. No. 5602 of 1916.)

SEE U.S. Pat. 1,185,526 of 1916; this J., 1916, 729.

Filtrating apparatus. K. Kiefer, Cincinnati, Ohio, U.S. Pat. 1,211,917, Jan. 9, 1917. Date of appl., Apr. 8, 1913.

SEE Eng. Pat. 14,136 of 1913; this J., 1911, 632.

Means for the gradation of coal and other materials. Eng. Pat. 103,230. See II.A.

Apparatus for heating or melting and delivering resin or other material. Eng. Pat. 102,835. See XIII.

II.A.—FUEL; GAS; MINERAL OILS AND WAXES.

Board of Fuel Research; Appointment of

A BOARD of Fuel Research has been appointed by the Committee of the Privy Council for Scientific and Industrial Research, on the recommendation of their Advisory Council. Sir George Beilby, F.R.S., has consented to act as Director of the new organisation, and he will be assisted by the Hon. Sir Charles Parsons, K.C.B., F.R.S., Mr. Richard Threlfall, F.R.S., and Sir Richard Rednayne, K.C.B., Chief Inspector of Mines, as Members of the Board. It will be the work of the Board to investigate the nature, preparation, and utilisation of fuel of all kinds, both in the laboratory and where necessary on an industrial scale. Sir George Beilby, with the assistance of his Board, will be responsible for drawing up schemes of research into these problems, and when the schemes have been approved by the Advisory Council and the Committee of the Privy Council, authority will be given him to carry them into effect. By arrangement with the Governors of the Imperial College of Science and Technology, the Lord President has retained Professor W. A. Bone, F.R.S., as Consultant to the Board of Fuel Research under the Department of Scientific and Industrial Research.

Brown coal deposits in Victoria. Board of Trade J., Feb. 15, 1917.

THE existence of brown coal at Morwell, Victoria, is well-known, but it appears that until quite recently no coal has been produced in the locality for nearly twenty years. Previously, various attempts had been made to develop the field on a commercial basis, but for various reasons, success was not achieved. The need of additional sources of fuel supply has once more directed attention to the Morwell deposits. There are several outcrops in the locality, but that which is now being prepared for coal-winning is the Great Morwell seam, which outcrops in a gully at the foot of thickly-timbered hills. All the coal that has been won so far has been from an open cutting; at the present stage of development a mine does not exist, though one may be opened up later on. The State Mines Department has made preparations for exhaustive preliminary tests, in which it is hoped to show that crushed brown coal is suitable for boilers and furnaces of the open-hearth type for steel-making. Gas-making tests which have been made are stated to be encouraging. The coal has also been used for briquettes, and it is reported that in this form it can compete with black coal for steam raising.

Oil shales: The Norfolk — W. Forbes-Leslie. J. Inst. Petrol. Tech., 1916, 3, 3—35.

A RECORD of research on the Norfolk portion of the Kimmeridge outcrop. Geographical, geological, and historical details are given concerning the English shale fields. The physical characteristics of the upper and lower layers of the Norfolk shales are described in detail. In the latter the presence of resinous substances can be detected by the microscope. When crushed to 30-mesh size the sp.gr. of the Norfolk shale is 1.55. When shaken with ether the shale yields 1% of oil; carbon bisulphide extracts only 0.25%. The oil also exudes when the shale is wetted. In three specimens the volatile organic matter varied from 31.7 to 35.1, the ash from 39.8 to 46.8, and the moisture from 4 to 10%. The inorganic matter has also been determined in both the original and the spent shale. The sulphur content varies from 4.3 to 7.8%, and much of this remains in the spent shale. The yellowish-black mobile oil has sp.gr. 0.942 to 0.960. The yield is 10 gallons to the ton, together with 66 lb. of ammonium sulphate and 25,000 cubic feet of dry gas. The oil yields a considerable quantity of motor spirit, 3 to 4% of phenols, and a similar amount of benzene and toluene. A large proportion of the oil distills from the shale below 300° C. Laboratory experiments show that the sulphur in the oil can be reduced to below 3%, while it seems that some oils containing as much as 4% of sulphur can be used in internal combustion engines. Calculations based on the extent and thickness of the Dorset and Norfolk shale beds indicate very considerable additions to the oil resources of the United Kingdom.—F. C.

Petroleum and asphalt: Nature and origin of — C. Richardson. Met. and Chem. Eng., 1917, 16, 25—27. (See also this J., 1916, 244.)

THE compositions of gases from the Trinidad asphalt deposit and oil wells in the vicinity are compared with those of natural gases from various American States, and it is pointed out that in the California gases associated with highly asphaltic oils, the methane and ethane are nearly as variable as in the Trinidad gases, and that both series are characterised by a high percentage of carbon dioxide. The latter constituent is not found in gases associated with purely paraffin oils, and it is suggested that carbon dioxide may be a determining factor in the production of asphaltic hydrocarbons by contact action between the gases and the oil "sands." In cases where natural gas occurs unassociated with petroleum, it must be assumed that the gas does not remain long enough in contact with the "sands," or that the contact surfaces are unsuitable in character or extent, for condensation to be effected.—W. E. F. P.

Hydrocarbons: Pyrogenesis of — E. Lomax, A. E. Dunstan, and F. B. Thole. J. Inst. Petrol. Tech., 1916, 3, 36—120.

THE first thirty-five pages of this paper contain perhaps the most complete summary yet published of the work which has been done on the subject. Over 150 references and a chronological list of patents are appended. The processes of Hall, Rittman, Lucas, Burton, and Redwood and Dewar receive special notice. In the second part the effects of varying the temperature and pressure during cracking experiments are considered from the standpoint of thermochemistry and Le Chatelier's rule. In the majority of commercial processes the tendency is for the formation (at about 500° C.) of a mixture of paraffins and olefines, while at about 700° C. aromatic compounds are produced. The general effect of excessively high pressures is to bring about reactions at low temperatures, which otherwise

would require more drastic heating. The influence of catalysts is fully dealt with, as is also the effect of various anhydrous metallic halides. It seems probable that the particular material to be cracked has little influence on the nature of the final products. Cracked oils always contain paraffins, cycloparaffins, olefines, diolefines, and aromatic hydrocarbons, while in the gas produced hydrogen, gaseous paraffins, olefines, and diolefines, together with small amounts of the vapours of volatile liquid products occur. Erythrene appears to be almost always formed. A paraffin hydrocarbon yields on cracking an olefine and a lower paraffin. The olefine may then be similarly degraded to lower olefines and finally to ethylene. It also may isomerise, forming a cycloparaffin or naphthene, from which a side chain may be eliminated as a paraffin hydrocarbon. The olefine also yields erythrene which partly polymerises; finally hydrogen and carbon are produced from the olefine and may unite to form methane. Acetylene is produced from ethylene at about 570° C., and may give rise to aromatic hydrocarbons. Bone and Coward's theory of nascent radicals (this J., 1908, 886) is of importance in cracking operations at high temperatures since $\cdot\text{CH}_3$, $\cdot\text{CH}_2$, and $\cdot\text{CH}$ may give rise to aromatic, hydroaromatic, and paraffin hydrocarbons respectively. Finally there may be condensation of two or more molecules of a hydrocarbon with loss of hydrogen. The production of yellow resinous explosive substances when cracked oils are stored is due to the presence of diolefines, which are produced to a greater extent the higher is the temperature.—F. C.

Paraffin hydrocarbons: Stability of — G. Egloff and R. J. Moore. Met. and Chem. Eng., 1917, 16, 47—51.

AS the result of cracking at 700° C., five successive fractions of a paraffin-base petroleum, the third fraction, boiling between 200° and 250° C., and consisting mainly of paraffins ranging from $\text{C}_{12}\text{H}_{26}$ to $\text{C}_{14}\text{H}_{30}$, was found to be the least affected; while the first fraction, boiling up to 150° C. and composed of much simpler hydrocarbons, was the most changed. The general belief as to the greater stability of the simpler hydrocarbons at high temperatures is thus no longer tenable.—W. E. F. P.

Naphthenes: Action of sulphur on — under pressure. W. Friedmann. Petroleum, 1916, 9, 978—982. Z. angew. Chem., 1916, 29, Ref., 531.

FRACTIONAL distillation *in vacuo* of the product of the action of sulphur on cyclohexane under pressure gave a first fraction, considered to be cyclohexadiene, giving *m*-dinitrobenzene with a nitrating mixture, a second fraction containing thiophenol, considered to be formed from cyclohexene *via* cyclohexadiene, and a residue containing phenyl sulphide. A thiocresol was isolated from the products of the action of sulphur on methylcyclohexane under pressure. In the case of dimethylcyclohexane (octonaphthene), in addition to the formation of hydroxylenes and thioxylenol, xylene itself is produced at one stage and gives *mm*-dimethyldibenzyl. It follows that the presence of aromatic hydrocarbons in petroleum can scarcely be due to the action of sulphur on naphthenes under pressure, as no sample has yet been found to contain thiophenol or a homologous aromatic mercaptan.—F. W. A.

Absorption of gases. Hempel. See I.

Utilisation of waste heat for steam generating purposes. Pratt. See I.

Some physical properties of the two chief mineral constituents of coke-oven bricks. Fearnside. See VIII.

PATENTS.

Coal; Apparatus for extracting water from —. C. Burnett, Bath. Eng. Pat. 103,031, Mar. 3, 1916. (Appl. No. 3201 of 1916.)

COAL is supplied to the lower end of the upper plate of an inclined hollow steam-heated element, *b*. An endless conveyor, *a*, moves the coal along

the heater till it falls over the edge on to a similar lower heater, along which it is conveyed by the returning part of the conveyor. The heating elements are composed of a series of compartments connected by short conduits, *c*, which have their edges bevelled to accommodate asbestos packing plates, *b'*. The apparatus may be used in conjunction with that described in Eng. Pat. 6911 of 1915 (this J., 1916, 683).—W. F. F.

Coal and other materials; Means for the gradation of —. W. Yates, H. W. S. Martin, and Matthews and Yates, Ltd., Manchester. Eng. Pat. 103,230, Apr. 18, 1916. (Appl. No. 5669 of 1916.)

COAL falls from a hopper in a stream close to the vertical dividing wall between two similar adjacent receptacles. An aperture in the dividing wall immediately below the hopper is adjustable in size by a sliding plate, and air is drawn through the falling stream of coal and through the aperture into the adjoining receptacle. The coarser grade of coal falls into the first receptacle and the lighter portions pass through the aperture. A hinged guide-plate below the outlet of the hopper varies the distance of the stream from the dividing wall, and a curved plate on the farther side of the aperture deflects the lighter portions of coal downwards. The air current is withdrawn by a fan through a pipe opening into the top of the second receptacle, carrying with it the fine coal, which passes into a separator and is collected. The medium grade remains in the second receptacle.

—W. F. F.

Briquettes; Presses for the production of —. E. R. Sutcliffe, Leigh, and Pure Coal Briquettes, Ltd., Cardiff. Eng. Pat. 13,796, Sept. 28, 1915.

IN the operation of presses consisting of a series of cylinders in axial alinement having connected pistons, one of the pistons is balanced by the admission of motive fluid on each side. Towards the end of the forward stroke, the motive fluid in front of this piston is released to augment the pressure on the common piston rod. The movement of the piston is transmitted by hydraulic means to the main plunger of the press. In the event of an abnormal stroke due to shortage of material in the mould, communication with an accumulator is established and the requisite pressure maintained.—J. E. C.

Briquettes; Presses for the production of —. E. R. Sutcliffe, Leigh, and Pure Coal Briquettes, Ltd., Cardiff. Eng. Pat. 102,918, Sept. 28, 1915. (Appl. No. 15,601 of 1916.) (See also Eng. Pat. 20,679 of 1911; this J., 1916, 297.)

IN a vertical hydraulic press, after compression of the briquette, the main plunger is raised by means of a subsidiary superimposed hydraulic cylinder. The liquid from the upper portion of the subsidiary lifting cylinder is forced to an abutment ram cylinder which ejects the briquette from the mould. Means are provided for applying lateral pressure in the mould and for releasing this pressure to allow an upward movement of the abutment ram.—J. E. C.

Fuel; Process of burning —. E. Pohl, New York. U.S. Pat. 1,270,099, Dec. 26, 1916. Date of appl., Feb. 2, 1916.

THE vapour from an exposed surface of a liquid or solid fuel is ignited, thereby heating the fuel and increasing its rate of vaporisation. The flame is then extinguished by a cap enclosing the vapour evolved, which is burnt under pressure in a series of independent jets, the heat from which is utilised to cause continued rapid vaporisation of the fuel.—J. E. C.

Coke ovens or the like; Charging and gas-withdrawing means for —. A. Roberts, Chicago, U.S.A. Eng. Pat. 103,169, Jan. 18, 1916. (Appl. No. 815 of 1916.)

IN a coke oven, a series of charging openings are connected by side branches to a common gas-collecting main. During charging operations a substantially air-tight joint is produced by the insertion of a funnel or equivalent device, to separate the coke-oven chamber from the gas-collecting main.—J. E. C.

Coke ovens and the like, and treatment of gases therefrom. A. Roberts, Chicago, U.S.A. Eng. Pat. 103,243, Jan. 18, 1916. (Appl. No. 7034 of 1916.)

IN connection with the gas-collecting main described in the preceding abstract, a series of sprays is arranged for preliminary treatment of the gases with oil, emulsion, or the like. The sprays are preferably arranged in staggered relation to one another, and a trap or the like is fitted for the removal of excess fluid.—J. E. C.

Coke-oven construction. *Coke-oven.* G. E. Thackray, Westmonthorough, Pa. U.S. Pat. (A) 1,211,502 and (B) 1,211,503, Jan. 9, 1917. Dates of appl. (A) Oct. 28, 1913, and (B) Sept. 2, 1916.

(A) IN a horizontal coke oven with vertical heating flues, a series of regenerators extends longitudinally under each oven, the regenerators under the end portions being shorter than those under the central portion. Separate gas supplies are admitted to the sections supplied by the various regenerators. (B) The lower end of each heating flue rests upon a base block, a burner being formed in each block, and there is a recess beneath the burners on the under side of each base block. Gas is fed to these burners by distributing pipes of varying lengths, whilst air is admitted by side ports decreasing in size from the ends of the oven. The floor of the oven is formed of blocks separated from the side walls to form expansion joints.—J. E. C.

Coke-oven gases; Treatment of —. J. I. Brunn, Assignor to Rombacher Hüttenwerke, Rombach, Germany. U.S. Pat. 1,211,395, Jan. 9, 1917. Date of appl., Oct. 11, 1916.

A COMPRESSED gas for lighting, heating, and welding is produced from previously treated coke-

oven gases by passing the latter through a substance capable of absorbing carbon dioxide, then through one capable of absorbing ethylene, then liquefying the remaining gases with the exception of hydrogen and nitrogen.—J. E. C.

Gaseous mixtures; Complete combustion of —. A. C. Ionides, jun., London. Eng. Pat. 102,983, Jan. 1, 1916. (Appl. No. 129 of 1916.) (See also Eng. Pat. 15,758 of 1913; this J., 1911, 821.)

IN a multi-burner heating device the separate constituents of a self-burning gaseous mixture are fed from capacious conduits to a series of adjustable mixing devices. Means are provided in at least one of these conduits for adjusting the flow, whilst the mixing devices comprise means for creating vortices in the current of mingled fluids.—J. E. C.

Gas producer. J. A. Herrick, New Rochelle, N.Y. U.S. Pat. 1,210,171, Jan. 2, 1917. Date of appl., Sept. 26, 1913.

IN a gas producer having two rotatable sections, means for driving one of the sections and for coupling the sections together at will are provided. One section encloses the combustion zone, the other the ash zone, and a non-circular tuyere-box extends into the ash zone.—J. E. C.

Oils; Vaporising for use in high speed internal combustion engines. W. A. Hall, London. Eng. Pat. 102,388, Jan. 6, 1916. (Appl. No. 231 of 1916.)

LIQUID fuel, such as paraffin oil, is passed through a coil surrounding the exhaust pipe of the engine. This coil is housed in a chamber, packed with a fusible salt or alloy, the latent heat of solidification of which is utilised during low load periods.—J. E. C.

Petrol; Refining of—by distillation. C. A. Kühn, Williamsburg, Ont., Canada. Eng. Pat. 102,903, Aug. 10, 1916. (Appl. No. 11,306 of 1916.)

A METHOD of refining petrol by distillation consists in heating it in a tank surrounded by a water jacket, the latter being provided with means for indicating the steam pressure. Vapours from the petrol are condensed in a refrigerating chamber.—J. E. C.

Gas retorts; Charging of —. A. E. White, London. From Riter-Conley Manufacturing Co., Leedsdale, Pa., U.S.A. Eng. Pat. 103,137, Jan. 7, 1916. (Appl. No. 335 of 1916.)

Gas retorts; Machines for charging and discharging —. Apparatus for charging and discharging retorts. Riter-Conley Manufacturing Co., H. A. Carpenter, R. L. Hibbard, and A. W. Warner, Leedsdale, Pa., U.S.A. Eng. Pats. 103,138 and 103,139, Jan. 7, 1916. (Appl. Nos. 336 and 337 of 1916.)

Gas retorts; Machines for discharging and charging —. A. A. Guest, Gibbons Bros., Ltd., and J. Wigley, Lower Gornal, Staffs. Eng. Pat. 103,143, Jan. 11, 1916. (Appl. No. 132 of 1916.)

Coke-ovens or the like; Recuperators for —. A. Roberts, Chicago, U.S.A. Eng. Pat. 103,168, Jan. 18, 1916. (Appl. No. 811 of 1916.)

SEE U.S. Pats. 1,193,066 and 1,193,069 of 1916; this J., 1916, 958.

Asphalt-like masses; Process for manufacture of—and derivatives therefrom. L. Landsberg, Nuremberg, Germany. U.S. Pat. 1,211,721, Jan. 9, 1917. Date of appl., Apr. 28, 1913.

SEE Fr. Pat. 457,051 of 1913; this J., 1913, 1000.

Apparatus for feeding pulverulent fuel to furnaces. Eng. Pat. 13,067. See 1.

Furnaces fed with pulverulent fuel. Eng. Pat. 103,097. See 1.

Gas-fired crucible furnaces. Eng. Pat. 103,232. See 1.

Apparatus for purifying, cooling, and mixing gases. Eng. Pat. 103,133. See 1.

Production of ammonia [from Mond or producer gas]. Eng. Pat. 103,118. See VII.

Revivifying and utilising spent oxide. U.S. Pat. 1,211,713. See VII.

Surface mixture for pavements and other structures. U.S. Pat. 1,209,238. See IX.

IIb.—DESTRUCTIVE DISTILLATION; HEATING; LIGHTING.

PATENTS.

Fuel; Apparatus for distilling —. H. F. Wallmann, Chicago, Ill. U.S. Pat. 1,210,388, Dec. 26, 1916. Date of appl., May 9, 1912.

THE apparatus comprises a distillation conduit having two stationary side walls and two movable side walls on opposite sides which can be moved so as to agitate the fuel in the conduit. The fuel is heated in its passage through the conduit, and distillates of varying character are removed at different points by separate mains.—J. E. C.

Brown coals of all kinds; Treatment of —. P. Schroeder, Hamburg. Ger. Pat. 295,296, July 3, 1911.

THE coal, ground or not, is mixed with water and treated with superheated steam under pressure in a vessel fitted with a powerful stirrer. The mass is subsequently diluted with a large quantity of water, whereby a colloidal solution or suspension of the coal is produced, from which the insoluble impurities can be separated by filtration or the like. Sufficient mineral acid is added to the filtrate to coagulate the coal, which is then separated by filtration or the like, washed free from soluble salts, and dried; if necessary from 0.75 to 3% of alkali salts may be added before treating with acid. The yield of purified coal is 50–75%. The purified coal has a higher calorific value than the original material, and when carbonised yields from three to four times the quantity of by-products otherwise obtained.

Wicks; Indestructible —. O. Imray, London. From T. W. Glines, Waseca, Minn., U.S.A. Eng. Pat. 103,079, Aug. 11, 1916. (Appl. No. 11,370 of 1916.)

AN indestructible wick for heating and cooking stoves is made up of comparatively thin inner and outer sheets of asbestos or other non-combustible material and an interposed carbonised body portion. The latter is saturated with a solution before being carbonised so as to obtain a finely divided non-combustible mineral substance evenly distributed throughout the carbonised material.—J. E. C.

Cathode ray device. X-ray tube. W. D. Coolidge, Schenectady, N.Y., Assignor to General Electric Co. U.S. Pats. (A) 1,211,091 and (B) 1,211,092, Jan. 2, 1917. Dates of appl., (A) Sept. 8, 1913, renewed Sept. 26, 1916, (B) June 5, 1915.

(A) A RÖNTGEN ray tube is composed of an evacuated envelope, pervious to X-rays, and a stem which is provided with a tip of heat-resisting

insulating material projecting into the envelope. The tip is joined to refractory supports, carrying the anode and cathode, the latter being in the form of a flat wire spiral, disposed substantially in a plane perpendicular to an axis passing through the electrodes, and having a diameter smaller than the working face of the anode. The cathode, which is independently heated, is surrounded by a static focussing ring for focussing the cathode rays upon the anode. The envelope and electrodes are freed from ionisable gas to such an extent that the tube may be operated by an electron discharge from the cathode, independently of gas ionisation. (B) The charge-receiving face of the anode is in part surrounded by a conductive member admitting the electron discharge from the cathode, whereby an electric field is established suppressing the emanation of an electron discharge from the face of the anode.—B. N.

Apparatus for recicifying char. U.S. Pat. 1,207,178. See I.

III.—TAR AND TAR PRODUCTS.

Benzene and toluene; Electrochemical chlorination of—F. Fichter and L. Glantzstein. *Ber.* 1916, 49, 2173–2187.

THE chlorination of benzene and toluene by the electrolysis of hydrochloric acid had previously been performed under disadvantageous conditions on account of the heterogeneous nature of the electrolyte, but with a common solvent, such as glacial acetic acid, homogeneous solutions of hydrocarbon and aqueous hydrogen chloride may be electrolysed with satisfactory results by the use of a platinum anode. The progressive stages in the electrolytic chlorination of benzene may be tabulated as follows: chlorobenzene, *p*-dichlorobenzene, *symm.*-tetrachlorobenzene, hexachlorobenzene, and pentachlorophenol. It does not seem possible to prevent the formation of phenolic derivatives by oxidation, and chloranil is always present as a by-product; the use of acetic acid also complicates matters by the partial conversion of the phenols into their acetic esters, and pentachlorophenol acetate is only saponifiable with difficulty. Phenols of a lower degree of chlorination are not obtained, and pentachlorophenol is only produced after the tetrachlorobenzene stage has been reached; chloranil, on the other hand, is formed at all stages. The factors favourable to a high yield of chlorinated products are: high current density, low concentration of benzene, and high temperature; under these conditions crystals of hexachlorobenzene are formed on the walls of the clay cell at the anode and may be separated in an almost pure condition. Anodes of other material than platinum give poor results; light has little influence. The electrolytic chlorination of toluene is far more complicated because substitution takes place both in the ring and in the side-chain; the influence of light gives the reaction an undesirable direction, and the electrolysis should be carried out in the dark. The stages may be formulated approximately as follows:—*o*- and *p*-chlorotoluene, 2,1-dichlorotoluene, 2,4,5-trichlorotoluene, pentachlorotoluene and 2,4,5-trichlorobenzylidene chloride, pentachlorobenzyl chloride, and 2,4,5-trichloro-3,6-dihydroxybenzylidene chloride, and hexachlorobenzene. As in the case of benzene, the degree of chlorination is determined mainly by the current density, but substitution in the side chain does not begin until the nucleus has taken up 3 atoms of chlorine and presents a certain degree of resistance to further chlorination. It would appear that the chlorination of the nucleus is effected primarily by the nascent

atomic chlorine liberated electrolytically and that accumulations of molecular chlorine are responsible for the attack on the side chain.—J. F. B.

p-Cresyl carbonate: Nitration of—A. F. Holleman and J. M. A. Hoeflake. *Rec. Trav. Chim. Pays-Bas*, 1917, 36, 271–280.

THE authors have investigated the nitration of *p*-cresyl carbonate, which was found by Meister, Lucius, u. Brünig to yield the *m*-nitro-derivative, instead of a mixture of ortho and para derivatives, as was to be expected. By comparing the proportions of *o*-, *m*-, and *p*-derivatives formed when phenyl carbonate, toluene, and *p*-cresyl carbonate are nitrated, it was found that, although the free hydroxyl group has a far greater influence than the methyl group in determining the position taken up by a new substituent, if the hydrogen of the hydroxyl group is replaced, as in *p*-cresyl carbonate, its directing influence disappears, and the influence of the methyl group preponderates.—F. Sp.

Ketones: Action of alcoholic caustic potash on—
IV. *Action of alcoholic caustic potash on halogenated aminobenzophenone.* P. J. Montagne. *Rec. Trav. Chim. Pays-Bas*, 1917, 36, 258–270.

IN studying the reduction of benzophenones to benzhydriols by boiling them for two days with alcoholic caustic potash, it was found that 3-aminobenzophenone is not completely reduced, proving that the single amino group inhibits the reaction. If halogens are introduced in the meta position, the inhibitory influence of the amino group is destroyed, so that the following compounds are completely reduced:—4-chloro-3-aminobenzophenone, 4-bromo-3-aminobenzophenone, 4-chloro-3-aminobenzophenone, 4-bromo-3-aminobenzophenone, 4,1'-dichloro-3-aminobenzophenone, 4,1'-dibromo-3-aminobenzophenone. Of these compounds, 4-chloro-3-aminobenzophenone and 4,1'-dichloro-3-aminobenzophenone lose only a little halogen during the reactions, the others losing more. The corresponding benzhydriols also lose halogen if boiled with alcoholic caustic potash, 1-chloro-3-aminobenzhydriol losing the least, and 1-bromo-3-aminobenzhydriol the most.—F. Sp.

Pyrogenesis of hydrocarbons. Lomax and others. See IIA.

PATENTS.

Pitch: Process for preparing hard commercial—R. P. Perry, Montclair, and E. F. Stewart, Woodliffe, N.J., Assignors to Barrett Manufacturing Co., New York. U.S. Pat. 1,210,697, Dec. 26, 1916. Date of appl., Feb. 16, 1916.

HARD pitch is obtained in small particles by introducing water and molten pitch independently into a vessel in which they are subjected to independent centrifugal action. The pitch is caused to take an upwardly curved path, and to pass through the centrifuged water, with which it is subsequently mixed.—F. Sp.

Mono-alkylated aromatic amines (N-alkylaryl amines); Manufacture of—G. T. Morgan. London. Eng. Pat. 102,831, Jan. 12, 1916. (Appl. No. 514 of 1916.)

N-ALKYLARYLAMINES are prepared from aniline or naphthylamines or their homologues or simple substitution products (other than nitro-compounds), by treating the amine with an aliphatic aldehyde in the presence of a reducing agent in a medium not possessing a strongly acid character. The anhydroadaldehyde-amine or Schiff base produced from the amine and aldehyde is simultaneously reduced to the alkyl aromatic amine. *Example*:—60 parts of aniline and 66 parts of 10% formaldehyde are added slowly and con-

currently to 300 parts of 31% caustic soda solution (sp. gr. 1.37) containing 90 parts of zinc dust in suspension. The addition of the reagents should take about two hours, and the mixture should be well stirred and kept at 90° C. The heating and stirring are continued for 6 hours longer, during which 40 parts of 10% formaldehyde is slowly added. When the percentage of methylaniline has reached a maximum, the mixture is steam distilled and the methylaniline obtained from the distillate in any of the usual ways.

—F. Sp.

Sulphonic acid of an aromatic hydrocarbon: Method of separating— from sulphuric acid, and of converting the sulphonic acid into a salt. L. M. Dennis, Ithaca, N.Y. U.S. Pat. 1,211,923, Jan. 9, 1917. Date of appl. July 14, 1916.

A MIXTURE of a sulphonic acid of an aromatic hydrocarbon and sulphuric acid is treated with a solvent, e.g., benzene, which only dissolves the sulphonic acid, and the solution is subsequently treated with a suitable compound to form the salt.

—F. W. A.

Sulphonation of hydrocarbons. D. Tyrer, Stockton. U.S. Pat. 1,210,725, Jan. 2, 1917. Date of appl. May 22, 1916.

HYDROCARBONS boiling below 200° C., e.g., benzene, are sulphonated by passing them in the form of vapour through strong sulphuric acid, which is heated gradually from 100° to 185° C., until the hydrocarbon vapour ceases to be absorbed.

—F. Sp.

Phenol: Manufacture of—. D. Tyrer, Stockton. U.S. Pat. 1,210,726, Jan. 2, 1917. Date of appl. May 22, 1916.

(A) CALCIUM benzenemonosulphonate is treated with sodium sulphate, forming calcium sulphate and sodium benzenemonosulphonate, and the latter is fused with caustic soda. (B) A mixture of calcium carbonate and calcium sulphite is treated with sodium bisulphate, forming sodium sulphate, sulphur dioxide, and carbon dioxide. (C) The gases from (B) are passed into a solution of the melt from (A), liberating phenol and forming sodium sulphite and sodium carbonate, which are treated with lime, forming caustic soda, and a mixture of calcium carbonate and calcium sulphite.

—F. Sp.

Phenols: Process of producing—. A. S. Ramage, Assignor to Bestaph Engineering Co., Detroit, Mich. U.S. Pat. 1,208,833, Dec. 19, 1916. Date of appl. Apr. 20, 1916.

PHENOLS are produced from high boiling tar acids by spraying a material containing them, by means of a jet of hydrogen, into a chamber containing a catalyst, e.g., nickel, at 600°–650° C., and condensing the phenols produced.—F. Sp.

Sulphonating hydrocarbons. D. Tyrer, Stockton. Eng. Pat. 103,204, Jan. 12 and Mar. 1, 1916. (Appl. Nos. 3091 and 3078 of 1916.)

SEE U.S. Pat. 1,201,725 of 1916; preceding.

IV.—COLOURING MATTERS AND DYES.

Cutch production in Burma.

THE demand in the United States for crude dyes is being met, in part, by increased shipments of cutch from Burma. In 1915, 1,234,140 lb. of cutch was exported, in contrast with 237,140 lb. in 1914.

In the manufacture of cutch no scientific process is employed, the industry being carried on exclusively by natives. It is obtained from the

Acacia catechu the trees being felled while green, the bark taken off, and the timber chopped up and boiled in large cauldrons. The resultant liquid is drained off and solidifies as it cools. In the better qualities of cutch only the heart-wood of the tree is utilised. Cutch is brought to the market in several forms, the three principal ones being: (1) Tablets—small rectangular blocks weighing from 1 lb. to 2 lb.; (2) blocks—more or less square blocks weighing from 28 lb. to 56 lb.; (3) baskets—a soft cutch of a thick consistency. Tablet cutch is the best quality and basket cutch the lowest. Block and basket cutch usually contain more impurities than tablet cutch, but in recent years a larger business has been done in basket quality than in the other two, probably because basket is the cheapest of the three. On arrival in Rangoon the cutch is packed in wooden cases (usually containing 1 cwt. net) and is then ready for export.

Cutch trees are found throughout the whole of Burma, but the question of transportation makes cutch-boiling unprofitable in many districts. Licences for cutch manufacture are granted annually by the Government, and the industry is more or less of a stand-by to the population in seasons of bad harvests. The Burmese Government increases or reduces the number of licences as necessity indicates. The principal producing districts in Burma are Prome, Thayetmyo, Myingyan, Minbu, Pegu, Yamethin, and Pyin-mana.

Cutch is used largely as a dye, but in addition to this it is employed in some countries for tanning and as a preservative. In Burma it is used to preserve fishing nets and sails.

Sulphide dyestuffs: Chemistry of the—. F. M. Rowe. J. Soc. Dyers and Col., 1917, 33, 9–17.

A SUMMARY of published work on the probable thiazine constitution of certain sulphide dyestuffs is followed by a discussion of the possible existence of other sulphur-containing rings in sulphide dyestuffs. It appears probable that the blue and black sulphide dyestuffs are thioldiphenylamine derivatives related to the Methylene Blue type, whereas those of the yellow and brown classes are thiazole derivatives more analogous to dehydrothiolumidine or Primuline base. Only those compounds of a Methylene Blue type, e.g., Immedial Pure Blue and Immedial Indone, have been obtained in a sufficiently pure condition for analysis, and as the dyestuffs approach the real sulphide dyestuff type the possibility of crystallisation decreases. There is not sufficient data regarding the breaking-down of the molecule of sulphide dyestuffs to enable any reliable general conclusions to be drawn, and the synthesis of sulphide dyestuffs is limited to the simpler members of the series. Reference is made to the work of Vidal, Bernthsen, Gnehm and his collaborators, Green, Meyenberg, and Wichelhaus in investigating the mechanism of sulphide dyestuff formation. In discussing Vidal's formulae representing the condensation of thioldiphenylamine derivatives to form blue dyestuffs and subsequent elimination of ammonia to form black dyestuffs, it is emphasised that they do not take into consideration whether the dyestuffs are quinonoid compounds, nor is it evident why the dyestuffs contain only four benzene rings; still less do they explain the solubility or insolubility of the dyestuffs in alkalis or acids respectively. Structures other than those of a thiazine type have been advanced for sulphide dyestuffs in addition to Vidal's tetraphenylthiazine structure; certain dyestuffs derived from azines may contain one or two phenazine rings combined with the thiazine rings. In black-brown sulphide dyestuffs made from certain diphenylamine derivatives, the thiazine ring may be united to the

thiazole ring. The formation of thianthrene rings, alone or united with thiazine rings—bodies derived from diphenylenedisulphide—is not yet proved, but the formation of a thiopyrone ring in the dyestuff from diaminodiphenylmethane, and in the dyestuffs derived from Fluorescein is highly probable. The presence of the thio-benzidine ring, alone or united with the thiazole ring, in yellow sulphide dyestuffs prepared with addition of benzidine is also probable. The piazthiole ring is considered by Ris to be present in the black sulphide dyestuff obtained by the action of sulphur dioxide on *o-p*-diaminodiphenylamine, and the same worker assumes the presence of the acritiole ring in the yellow sulphide dyestuffs derived from *m*-toluylendiamine and phthalic acid; the evidence advanced is not considered convincing by the present author, as the analytical results would be better explained by the presence of the thiazine ring. The thiazole ring is considered to be present in the brown sulphide dyestuffs obtained from Primuline.

The solubility of sulphide dyestuffs in sodium sulphide is generally considered to be due to the presence of free mercaptan groups: other groups, such as COOH, SO₂H, OH, are suitable for imparting solubility in alkali, but in presence of such groups alone the colour is not fixed on the fibre on dyeing from an alkaline bath, whereas this is the case with the mercaptan group, owing to the formation of an insoluble disulphide on oxidation. Friedländer has disproved the view of Vidal that the solubility of the sulphide dyestuffs is due to their phenolic character and that mercaptan groups influence the shade of the dyestuffs. The experimental evidence of the thiozone theory advanced by Erdmann is considered to be very slight. The polysulphide theory of Mohlau, elaborated by Schultze and Beyschlag is discussed. —F. W. A.

Dyestuffs of the Methylene Blue group. III. Limited action of fatty amines on phenazthionium salts. F. Kehrmann. Ber., 1916, 49, 2831—2838.

IN previous communications (this J., 1916, 353, 732) it has been shown that not only aromatic but also fatty amines, notably dimethylamine, react with phenazthionium perchloride to give alkyl-substituted thionines. This reaction may be limited to the introduction of one amine residue, and methods are given for the preparation of thiazine (3-aminophenazthionium), and its dimethyl and diethyl compounds by the action of ammonia, dimethyl- and diethyl-amine respectively. The absorption spectra follow those normally expected.—F. W. A.

Anthraquinone-1-diazonium halides. A. Schaarschmidt. Ber., 1916, 49, 2678—2681.

THE diazonium salts of the anthraquinone series are characterised by their comparatively great stability, many of them undergoing at 100°C. scarcely any decomposition. Anthraquinone-1-diazonium chloride was prepared by diazotising a suspension of 1-aminoanthraquinone in concentrated hydrochloric acid at 30°—10° C., dissolving the precipitated substance in boiling water, and slowly adding saturated brine, when the compound separated in glittering leaflets. Still more stable is 4-chloroanthraquinone-1-diazonium chloride which on account of its solubility in water was isolated by diazotising in acetic acid solution with amyl nitrite, and precipitating from the filtered solution by addition of ether. In the same way anthraquinone-1,4-bis-diazonium chloride was prepared and purified by precipitation from hot aqueous solution with brine. The anthraquinone-2-diazonium salts were prepared by similar methods but are less stable.—G. F. M.

α -Styryl-benziminazoles and their related azo-dyestuffs. O. Kym and S. Jurkowski. Ber., 1916, 49, 2681—2697.

THE introduction of the styryl or substituted styryl group for the phenyl group in the α -phenylaminobenziminazoles produces a considerable deepening in the colour and strengthening of the affinity for cotton in the corresponding azo-dyestuffs. These styryl derivatives were prepared by treatment of diaminomoyl- α -phenylenediamines with alkali, or better by condensation of α -methylbenziminazole with benzaldehyde or its substitution products. The affinity for cotton is already in evidence in the styryl-*m*-nitro- and *m*-amino-benziminazoles, which give pale yellow shades, whilst α -(*p*-nitro-styryl)-*m*-nitrobenziminazole and the corresponding diamino-derivative give pale orange dyeings on cotton. The azo-dyestuffs formed from the mono- and diamino-styrylbenziminazole bases by diazotising and coupling with β -naphtholdisulphonic acid R give deep reddish violet shades on cotton, compared with light violet or lilac shades given with the phenylbenziminazole azo-dyestuffs. In addition to the condensation products of α -methylbenziminazole with benzaldehyde, similar compounds with ketones were prepared. Isatin gave in this way a red condensation product of normal composition, whilst with phenanthraquinone a green substance was obtained, the analysis of which indicated that the reaction had taken an abnormal course. (See also Ger. Pat. 288,490 of 1914; this J., 1916, 355.)—G. F. M.

Nitrocarbocyclic compounds: Action of sulphuric acid on certain —. I. Action on nitrobenzene. M. L. Crossley and C. B. Ogilvie. J. Amer. Chem. Soc., 1917, 39, 117—122.

A MIXTURE of 161 grms. of nitrobenzene with 144 grms. of sulphuric acid, heated slowly to 195° C. in a 2-litre flask under a reflux condenser, produced a vigorous reaction controlled with difficulty. The product yielded 83 grms. of unchanged nitrobenzene, 52 grms. of a black amorphous solid resembling melanin, and 12 grms. of *p*-amino-phenol-*o*-sulphonic acid. The black substance was completely soluble in sodium hydroxide solutions, partially soluble in strong sulphuric acid, and slightly soluble in nitrobenzene, pyridine, quinoline, trimethylamine, and aqueous ammonia, yielding brown or purplish solutions. Similar but not identical black substances are formed when sulphuric acid and nitrobenzene are heated together with anthraquinone, β -aminoanthraquinone, or anthracene. In all cases the black products can be reduced to form vat dyes which dye cotton. The product from nitrobenzene and anthraquinone, like that from the former alone, dyes cotton a steely grey. That from nitrobenzene and β -aminoanthraquinone gives a brown vat oxidising on cotton to a heliotrope, whilst that from anthracene is less readily reduced than the others and dyes cotton brown. These dyes are not fast to boiling alkalis. The reaction appears to be general for nitrocarbocyclic compounds. —J. H. L.

Thioxanthone- and benzophenonesulphone series: Studies in the —. F. Ullmann and O. van Glenck. Ber., 1916, 49, 2487—2514.

IT has been established that the introduction of hydroxy groups into the thioxanthone molecule gives rise to mordant dyestuffs: in the present work a study has been made of derivatives in which auxochrome groups are situated in the *ortho* position relatively to the chromophoric carbonyl group, in order to compare this series with the similarly constituted anthraquinone- and benzophenonesulphone series. The starting point was the product of the condensation of

thiosalicic acid with *p*-chlorotoluene: the crude product behaved on recrystallisation as a pure substance, with sharp melting point, but its further condensation reactions showed it to be a mixture of 60% of the 1-chloro-1-methylthioxanthone with 10% of the 1-methyl-1-chloroisomeride: on fractional distillation under 4 mm. pressure the 1-chloro derivative was concentrated in the residue. This 1-chloro-1-methylthioxanthone condenses with anthranilic acid on prolonged heating with copper acetate and potassium carbonate in amyl alcoholic solution, with elimination of hydrogen chloride, yielding 4-methylthioxanthonyl-1-anthranilic acid, which on elimination of water gives the corresponding yellow acridone; a similar condensation is effected with thiosalicic acid, leading to methylthioxanthone. When the chloro derivative is fused with copper, chlorine is eliminated, giving a dithioxanthonyl derivative. Its behaviour with hydrazine hydrate, yielding the internal anhydride of the hydrazine derivative, confirms the constitution of this chloro compound, showing that the chlorine must be in *ortho* position to the carbonyl. By condensing thiosalicic acid with other toluene derivatives, members of the thioxanthone series were prepared containing amino and methoxy groups; 6-chloro-1-methyl-3-methoxybenzene yields a single condensation product with the chlorine in *ortho* position to the carbonyl; the aniline derivative of this is decidedly redder in shade than the corresponding derivative of methylthioxanthone; its sulphonic acid dyes wool orange. Members of the benzophenonesulphone series were prepared by the oxidation of the chloromethylthioxanthones, preferably with hydrogen peroxide, or else with potassium persulphate in presence of strong sulphuric acid. The acridone derivative prepared from the condensation product of 1-chloro-1-methylbenzophenonesulphone has a fine red colour; it is reducible as a vat dyestuff but only dyes cotton a pale yellow in this manner. The sulphone obtained by oxidising methylthioxanthone is also reduced by alkaline hydrosulphite, but is not a dyestuff.—J. F. B.

Pyrrrole black. A. Angeli and L. Alessandri. *Gazz. Chim. Ital.*, 1916, 46, 279—282, 283—300.

On oxidising pyrrole in an acetic acid solution, chilled with ice, by means of hydrogen peroxide, it yields a product with the properties of succinimide, together with a black compound for which the name of "pyrrole black" is suggested. This substance is insoluble in most solvents, but is sparingly soluble in pyridine. It is very similar to the melanins of animal pigments both in composition (C, 60.01; H, 4.87; N, 15.91%) and in properties, and, like them, is soluble in solutions of alkalis and ammonia. The mother liquors from which the black substance has been separated yield other oxidation products, including a yellowish white substance, which melts at 161°C., and has a tendency to form compounds of a blue colour. —C. A. M.

Colour and degree of dispersion of particles in coloured solutions: Relation between—. W. Harrison. *J. Soc. Dyers and Col.*, 1917, 33, 7—9.

From the similarity in the colour-changes of a number of colloidal solutions, Wo. Ostwald (*Kolloid Beihefte*, 1911, 2, 409) concluded that in all cases of colloidal solutions the colour would change in the direction of yellow, red, and blue, as the size of the particles increased, provided chemical changes in the dispersed substances did not occur. The author (*Koll. Zeits.*, 1912, 10, 45; *J. Manch. Sch. Techn.*, 1913, 6, 205) showed that a colloidal solution of Alizarin changed from yellow to violet on adding caustic soda, while the size of the particles decreased. Later Ostwald (*Koll.*

Zeits., 1912, 10, 97, 132) stated that this rule applied to most dyestuffs, even in case chemical action takes place, e.g., Night Blue was changed by acids from blue to green and yellow with gradual increase in the size of the particles. Repeating Ostwald's experiment with pure Night Blue and also with Victoria Blue B, Nile Blue, Acid Violet 7B, and Formyl Violet 81B, the author found that a very small amount of acid precipitated the dye from solution without change in colour; subsequent additions dissolved this precipitate and produced a change in colour through green to yellow. It is shown that the cause of the change in colour of dyestuffs is quite separate from the cause of precipitation, although the two phenomena may occur at the same time, in some cases in accordance with Ostwald's rule. Maxwell Garnett (*Phil. Trans.*, 1905, 205, 283) concluded that the mean distances between adjacent molecules was an important factor in causing the colour, and showed that in metallic films a change in colour was accompanied by a change in the density of the metal; it is therefore probable that change in colour is due to change in the molecular arrangement, and not merely to change in the size of the aggregate, although they may occur together.

PATENTS.

o-(Hydroxy azo dyestuffs; Manufacture of direct ——. O. Imray, London. From Soc. Chem. Ind. in Basle, Switzerland. Eng. Pat. 102,881, May 13, 1916. (Appl. No. 6872 of 1916.)

DIRECT *o*-hydroxyazo dyestuffs are obtained by coupling the tetrazo-compound of an *o*-aminophenol derivative of the type:

(where X is a diphenyl linking or a CH_2 , NH.CO.NH , or CO group) with 2 mols. of 2-amino-5-naphthol-7-sulphonic acid or a derivative thereof, or with 1 mol. of this acid and 1 mol. of any other dyestuff component, or with 2 mols. of any dyestuff component. (Reference is directed, in pursuance of Sect. 7, Sub-sect. 4, of the Patents and Designs Act, 1907, to Eng. Pats. 11,795 of 1889, 15,386 of 1892, and 20,216 and 30,284 of 1910; this J., 1890, 172; 1893, 754; 1911, 678, 1006.)

—F. W. A.

[Azo] dyestuffs; Manufacture of direct cotton ——. O. Imray, London. From Soc. Chem. Ind. in Basle, Switzerland. Eng. Pat. 103,251, June 12, 1916. (Appl. No. 8292 of 1916.)

DIRECT cotton dyestuffs are obtained by combining tetrazo-*p*-diphenyl or a derivative with 1 mol. of an acidyl-1-8-aminonaphtholsulphonic acid and 1 mol. of an acidyl- or aryl-2,5,7-aminonaphtholsulphonic acid, or with 2 mols. of an acidyl-2,5,7-aminonaphtholsulphonic acid, the combinations with benzoyl-1-8-aminonaphthol-5-sulphonic acid and with phenyl-2,5,7-aminonaphtholsulphonic acid (Eng. Pat. 4609 of 1901; this J., 1902, 337) being excluded. After-treatment with copper salts changes the tint of dyeings produced with these dyestuffs towards blue-violet to red-violet, and improves the fastness, especially towards light.—F. W. A.

Trisazo dyes. R. Haugwitz, Assignor to Akt.-Ges. f. Anilinfabr., Berlin. U.S. Pat. 1,209,151, Dec. 19, 1916. Date of appl., July 24, 1916.

TRISAZO dyes of the following general constitution are claimed:

in which R^1 , R^2 , and R^3 are radicals of the benzene series. The trisazo dye from 1,1-phenylenediamine-azo-3-amino-1-methoxy-1-methylbenzene, 1,8-dihydroxynaphthalene-3,6-disulphonic acid, and 1,3-phenylenediamine is specially claimed: it dyes cotton violet tints which become black on treatment with 1-nitrodiazobenzene.—F. W. A.

Sulphur dyestuffs; Manufacture of —. Akt.-Ges. f. Anilinfabr., Berlin. Ger. Pat. 295,251, Jan. 22, 1914.

DYESTUFFS fast to washing and scouring are obtained by the action of sulphur on a mixture of amino-, diamine-, nitroamino-, nitrohydroxy-, and aminohydroxy-compounds with C-alkylated diamines of the benzene and naphthalene series, e.g., *m*- or *p*-tolylenediamine, xylylenediamine or their N-aryl derivatives, or with the corresponding nitroamino-compounds.—F. W. A.

Vat dyestuffs and process of making same —. B. Homolka, Frankfurt. Assignor to Farb. vorm. Meister, Lucius, und Brünig, Höchst, Germany. U.S. Pat. 1,209,163, Dec. 19, 1916. Date of appl., July 30, 1915.

VAT dyestuffs are obtained by heating *para*-quinones with arylaminoacetic acids in a suitable solvent. The product—

is specially claimed: it forms a brown crystalline powder (m. pt. 232° C. with decomposition), insoluble in water, dilute acids, and alkalis, practically insoluble in alcohol, ether, and benzene, soluble with an orange-yellow colour in boiling xylene and glacial acetic acid, and with a red colour in concentrated sulphuric acid, and yielding a colourless vat with alkaline hydrosulphite from which it gives yellow tints on animal fibres.—F. W. A.

Seleno-phthalins and their halogen derivatives; Manufacture of —. Farb. vorm. Meister, Lucius, und Brünig. Ger. Pat. 295,253, Dec. 8, 1911. Addition to Ger. Pat. 290,549 and 291,883 (this J., 1916, 595, 922).

IN place of the phthalins specified in the previous patents, their O-acetyl compounds or O-acetyl compounds of phthalins are used in indifferent solvents. The products are different from those obtained by the action of selenium on fluoresceins in aqueous alkaline solution according to Ger. Pat. 279,549 (this J., 1915, 271).—F. W. A.

Vat dyestuffs or initial products of same; Manufacture of —. M. P. Schmidt, Assignor to Kalle and Co., Biebrich, Germany. U.S. Pat. 1,209,212, Dec. 19, 1916. Date of appl., Apr. 28, 1916.

VAT dyestuffs or initial products are obtained by heating arylamino derivatives of halogenised benzoquinones with a metal powder in presence of a suitable solvent or diluent. The products obtained from dichloroanilidobenzoquinones and copper powder give with alkaline reducing agents a vat from which wool is dyed yellowish-brown tints.—F. W. A.

Logwood dyes; Purifying —. I. Kitsee, Assignor to Dye Patents Co. of the United States, Philadelphia, Pa. U.S. Pat. 1,210,918, Jan. 2, 1917. Date of appl., Nov. 5, 1915.

LOGWOOD dyes are purified by subjecting them to the chemical action of a sulphur oxide, e.g., sulphurous acid.—F. W. A.

Indoxyl and derivatives; Method of making —. L. E. H. Cone, Assignor to The Dow Chemical Co., Midland, Michigan. U.S. Pat. 1,211,413, Jan. 9, 1917. Date of appl., June 21, 1916.

INDOXYL and its derivatives are obtained by heating a phenylglycine derivative with a mixture of caustic alkali, e.g., caustic potash or a mixture of caustic soda and potash, alkaline-earth oxide, e.g., lime, and metallic sodium; or the phenylglycine may be added to the molten mixture; the fused product is passed into water.—F. W. A.

Sulphur dyestuffs; Manufacture of —. Farb.-fabr. vorm. F. Bayer und Co., Ger. Pat. 295,101, Oct. 18, 1914. Addition to Ger. Pat. 293,101 (this J., 1916, 922).

INSTEAD of the ethylated amines of the benzene, diphenyl, or naphthalene series specified in the main patent, their sulphonic or carboxylic acids are used.—F. W. A.

Ortho(hydr)oxazo dyestuffs; Substantive - - and process of making same —. E. Anderwert, H. Fritzsche, and H. Schobel, Assignors to Soc. of Chem. Ind. in Basle, Switzerland. U.S. Pat. 1,210,751, Jan. 2, 1917. Date of appl., Oct. 8, 1915.

SEE Eng. Pat. 102,881 of 1916; preceding.

V.—FIBRES; TEXTILES; CELLULOSE; PAPER.

Cotton fabrics; Some effects of the action of ultra-violet light on —. C. Dorcé and J. W. W. Dyer. J. Soc. Dyers and Col., 1917, 33, 17—19.

SINGLE-PLY cotton fabric, specially scoured and bleached for use in the manufacture of airship envelopes, was exposed continuously at 30°—35° C. to the light from a Cooper-Hewitt mercury vapour lamp placed centrally about one foot above the fabric, which was spread flat on a sheet of 3-ply wood. The upper surface of the fabric became biscuit yellow in colour, which shaded off from the centre, and was not affected by dilute caustic soda, in which the exposed fabric possessed a high solubility; the exposed material also possessed high cupric-reducing power and capacity for absorbing basic dyestuffs (Methylene Blue), and gave a comparatively large yield of furfural. Ultra-violet light in presence of air and moisture may not improbably act in two ways: by some specific physical action causing disintegration of the cellulose, and by the probable development of ozone—known to convert celluloses into acidic, alkali-soluble products having the properties of oxycelluloses. Comparison of the exposed fabric and a hydrocellulose, prepared by the action of dilute sulphuric acid on cotton, showed considerable differences, whereas the properties of the exposed material closely resembled those of oxycellulose. The strength in the affected portions of the exposed fabric had entirely gone; the appearance of transverse cracks with occasional swollen places similar to the effects produced by excessive action of alkali, were noted. The affected part was much more absorbent and wetted out more readily than the unaffected part of the fabric.—F. W. A.

PATENTS.

Linen yarns and fabrics; Process of scouring —. J. B. Marshall, Ltd., and S. H. Higgins, Perth. Eng. Pat. 102,892, July 17, 1916. (Appl. No. 9990 of 1916.)

THE raw goods are treated with volatile solvents to extract oils and waxy matters before scouring; by this treatment the process of boiling with lime may be omitted and the goods scoured with soda

only. (Reference is directed, in pursuance of Sect. 7, Sub-sect. 4, of the Patents and Designs Act, 1907, to Eng. Pats. 1052 of 1871, 15,012 of 1892, 16,889 and 23,964 of 1895, 18,720 of 1901, 10,951 of 1908, and 28,291 of 1913; this J., 1892, 928; 1901, 1011; 1905, 798; 1909, 211; 1911, 1153.)
—J. F. B.

Flax plants: Process for treating — J. Brodin, Sioux Falls, S.D., Assignor to L. E. Baker, Baker, Mont. U.S. Pat. 1,209,516, Dec. 19, 1916. Date of appl., Aug. 21, 1916.

IN the case of flax plants grown for seed, the heads are removed from the stalks at maturity at such a point that rain may penetrate the tubular stalks, which are still left standing exposed to the action of the weather, until a natural rotting has taken place and the fibre is loosened. The stalks are then cut and harvested, and the fibre removed by hackling.—J. F. B.

Animal filaments, fibres, or threads: Process of finishing — H. R. Anders, Perth Amboy, N.J., Assignor to The Roessler and Hasselcher Chemical Co., New York. U.S. Pat. 1,210,391, Jan. 2, 1917. Date of appl., Dec. 10, 1914.

ANIMAL fibres, filaments, threads, or hair, e.g., human hair, are shaped into any desired form, which is then made permanent by treating the material in the wet state with formaldehyde.
—J. F. B.

Paper and process of making same. Glazed paper and coating composition therefor. N. Statham, Boonton, N.J., Assignor to Industrial Chemical Co., New York. U.S. Pats. (A) 1,209,221 and (B) 1,209,222, Dec. 19, 1916. Date of appl., Apr. 26, 1916.

(A) PAPER of high bulk is made by incorporating uniformly throughout its mass over 20% of light precipitated chalk as a loading material, the weight of which in the dry state does not exceed about 18 lb. per cub. ft. and the presence of which in the finished paper does not substantially increase the weight of a sheet of standard thickness. (B) Glazed paper is prepared with a coating composed of an organic sizing material, such as an alkaline solution of casein, and an inorganic pigment consisting largely of light precipitated chalk as above.
—J. F. B.

[*Paper:*] *Process and apparatus for drying* — E. P. Butts, Springfield, Mass. U.S. Pat. 1,212,014, Jan. 9, 1917. Date of appl., Sep. 11, 1915.

IN a paper-making machine, the web of paper passes over a series of drying drums supplied with a heating medium, and then over a pair of parallel rollers spaced apart. The rollers are connected with a source of electrical energy so that a current passes through the moist paper substance. The current, according to the variation in the conductivity of the paper, also controls an electromagnetic device for operating the valve which admits the heating medium to the drums. The temperature of the drying drums is thus automatically maintained constant.—W. F. F.

VI.—BLEACHING; DYEING; PRINTING; FINISHING.

Sizes and finishes: Analysis of some — M. C. Lamb and A. Harvey, J. Soc. Dyers and Col., 1917, 33, 19—21.

ANALYSES have been made of a large number of animal and vegetable products used in the sizing and finishing of various textile fabrics, leather, etc., and certain standards are suggested. Egg and blood albumin should be completely soluble in 1%

caustic soda and should dissolve readily in water at 45 C.; albumin is liable to adulteration with gelatin (readily detected by means of 1—2% tannic acid), and zinc salts are often added to solutions to increase the viscosity and act as antiseptics. *Carrageen* (*Irish moss*), employed as a thickening agent, should contain 1.4—2.5% N. *Alginate*, obtained by extracting *laminaria* with caustic alkali, and adding alginate acid to the extract, is employed as a substitute for Irish moss; it should contain 1—6% of alginate anhydride. *Gum tragacanth* of good quality gives saponification values from 100—180, water 18—22%, and mineral ash 2.5—3.0%; Indian gum tragacanth gives an acid, transparent mucilage, whereas the genuine gum gives a neutral opaque mucilage (viscous in 1% solution) and a blue coloration with iodine not given by the Indian gum; a higher percentage of volatile acid on hydrolysis than 1.8—2.4% indicates adulteration with the Indian or other gums. *Gum acacia* (*gum arabic*) varies from white and soluble (African) to dark and insoluble (Indian), the usual adulterant being dextrin; it gives a precipitate with basic lead acetate solution not given by gum tragacanth; the acidity is 2.5—3% of free arabic acid. *Gum tragacanth* is extracted from the locust bean as a substitute for gum tragacanth. *Casein* is analysed for moisture, fat (0.2—0.6%), and nitrogen.
—F. W. A.

PATENTS.

Stoving and bleaching flannel: Apparatus for — T. Woolfenden, Rochdale, Eng. Pat. 103,093, Oct. 9, 1916. (Appl. No. 11,317 of 1916.)

AN apparatus for stoving and bleaching flannel with sulphur fumes consists of a closed wooden chamber with apertures in the ends for the introduction and withdrawal of the flannel, and containing a number of rollers over which the flannel passes in a zig-zag path. A hood provided with a fan is placed above the chamber to collect escaping fumes.—F. W. A.

Mercerising yarn: Machines for — B. E. D. Kilburn, London, From Sulzer Frères Soc. Anon., Winterthur, Switzerland. Eng. Pat. 102,891, July 5, 1916. (Appl. No. 9177 of 1916.)

IN a machine for mercerising yarn in skeins or hanks, the rollers receiving the yarn are supported by an oscillating member with which they are swung into and out of their working positions, the distance between their axes being reduced as they are taken out of the working position so that the skeins or hanks may be readily removed and replaced. During the introduction of the rollers into their bearings, one roller may be pressed against a pressure roller, the gear of the rollers being at the same time automatically coupled for the purpose of rotating them, and the direction of rotation of the one roller being such that it is assisted into its bearings by the action of the pressure roller.—F. W. A.

Weighting of silk: Process for the — Gebr. Schmid, Basle, Switzerland. Ger. Pat. 295,272, Apr. 27, 1916. Addition to Ger. Pat. 291,009 (this J., 1916, 596).

BY using tin chloride in place of the zinc chloride or zinc chloride-tin chloride baths claimed in the main patent, the elasticity of the silk is not damaged to such a great extent.—F. W. A.

Dyeing machines. H. W. McL. Christie, Glasgow, and W. Farquhar, Alexandria, N.B. Eng. Pat. 103,239, May 5, 1916. (Appl. No. 6462 of 1916.)

IN dyeing machines of the type in which poles to receive the hanks are arranged above and/or in dye-vats and rotated during the dyeing operation, to avoid the necessity of removing the poles and

thus facilitate the placing in position and removal of goods, the poles driven from one end are so supported and articulated by means of hinge or universal joints to the driving means that the other ends may be tilted upwards without the poles being disconnected from the driving gear. Guides are provided to prevent the poles from being displaced sideways while being tilted.

—F. W. A.

Batik work; Method of producing special effects in —. A. E. Diener, Fürstenberg, Germany. U.S. Pat. 1,210,279, Dec. 26, 1916. Date of appl. Dec. 29, 1914.

To produce special effects in batik work, the fabric is prepared by treating with a dye containing a wax-repelling substance, e.g., water, in the form of a design, afterwards applying to the fabric wax or the like, and finally breaking the wax and dyeing in the usual way.—F. W. A.

Dyeings fast to washing; Production of —. Farbenfabr. vorm. F. Bayer und Co., Ger. Pat. 295,072, Oct. 18, 1914.

RED, violet, to blue dyeings, fast to washing, are obtained by treating on the fibre with formaldehyde the dyestuffs obtained by coupling tetrazotised diamines with one molecule of an aminonaphtholsulphonic acid or a derivative thereof, and one molecule of an amino-substituted derivative of 2,5,7-aminonaphtholsulphonic acid containing a free amino-group.—F. W. A.

Dyeings and prints; Production of fast — by chroming. Stolle und Kopke, Rumburg, Bohemia. Ger. Pat. 295,354, July 8, 1915.

IMPROVED effects are obtained by using in place of pure chromates mixtures of chromates with suitable per-salts, e.g., persulphates or perborates.—F. W. A.

Lustre of silk in hanks and woven goods; Process for increasing the —. W. Reidemeister, Berlin. Ger. Pat. 295,070, July 21, 1914.

SILK in a stretched condition is treated with highly concentrated fatty acids or their anhydrides or mixtures thereof, with addition of glycerin, then washed and dried; or the silk may be treated with these substances and subsequently stretched. Formic acid of 60–70% concentration or even weaker produces a good lustre, but other acids or their anhydrides or mixtures thereof are not so effective.—F. W. A.

Dyeing; Impts. in —. W. Somerville, Auburn, Victoria, Australia. Eng. Pat. 18,059, Dec. 28, 1915. Under Int. Conv., Dec. 31, 1914.

SEE U.S. Pat. 1,193,838 of 1916; this J., 1916, 960.

VII.—ACIDS; ALKALIS; SALTS; NON-METALLIC ELEMENTS.

Hydrogen halogen acids; Action of light on the formation and decomposition of the —. A. Cohn and K. Stuckardt. Z. physik. Chem., 1916, 91, 722–744; J. Chem. Soc., 1917, 412, ii., 5–6.

THE authors have investigated the action of light on the gaseous systems hydrogen iodide, hydrogen bromide, hydrogen chloride, and their components. The reactions have been effected by means of a mercury lamp in both quartz and uviolet glass apparatus. In all three cases equilibrium has been reached from both sides. In quartz apparatus the decomposition proceeds to the extent of 92.3% in the case of hydrogen iodide, and this is reached in ten minutes; the formation

proceeds to 7.6%. In both uviolet glass and ordinary glass there is a decomposition of 100% and no formation in the case of hydrogen iodide. With hydrogen bromide there is 100% decomposition in quartz, 20% in uviolet glass, and no decomposition in glass. The amount of formation of hydrogen bromide is zero in quartz, 80% in uviolet glass, and 100% in glass. In the case of hydrogen chloride there is 0.42% decomposition and 99.58% formation in quartz and 100% formation with no decomposition in uviolet glass and ordinary glass. In the case of hydrogen bromide the reaction is complete in four hours and with hydrogen chloride in less than five minutes. The use of the three types of apparatus shows the effect of the different spectral regions; in quartz, light down to 220 μ is active, in uviolet glass to 251 μ , and in Jena glass down to 300 μ .

Supply of sulphate of ammonia; Appointment of Committee on —.

THE Food Controller announces that, with the concurrence of the Agricultural Departments of Great Britain and Ireland, he has approved of an arrangement whereby, as from 12th February, sulphate of ammonia is to be sold at the price of £16 per ton, 24½% basis, in makers' bags, net cash, delivered at the consumer's station in any part of the United Kingdom. The price to consumers who take delivery at the producers' works for conveyance otherwise than by railway remains at £15 10s. per ton. In the event of purchasers experiencing difficulty in obtaining supplies locally, they should apply to the Secretary, Sulphate of Ammonia Advisory Committee, 84, Horseferry Road, London, S.W.

The Food Controller has appointed, with the concurrence of the Agricultural Departments of Great Britain and Ireland, the following Committee of Manufacturers of Sulphate of Ammonia to advise him with regard to questions affecting its production and distribution, and to give effect to an approved scheme for regulating the distribution of supplies to farmers in all parts of the United Kingdom:—Chairman, Mr. D. Milne Watson, of the Gas Light and Coke Co.; Mr. Wm. Fraser, of the Pumphreyston Oil Co., Ltd.; Mr. E. J. George, of the Consett Iron Co., Ltd.; Mr. W. R. Hann, of the Powell Duffryn Steam Coal Co., Ltd.; Mr. N. N. Holden, of Messrs. Hardman and Holden, Ltd.; Mr. A. K. McCosh, of Messrs. Wm. Baird and Co., Ltd.; Alderman F. S. Phillips, of the Salford Corporation Gas Department; and Mr. A. Stanley, of Messrs. Simon-Carves, Ltd. The Secretary of the Committee is Mr. F. C. O. Speyer.

Rare-earths; Observations on the —. E. W. Engle and C. W. Balke. J. Amer. Chem. Soc., 1917, 39, 53–68.

THE authors have investigated some separation methods which might be suitable for the isolation of the various individual rare-earths, more particularly those of the yttrium group, and for the preparation of dysprosium material of sufficient purity for the determination of the atomic weight of that element. It was found that the bromate method of separating the rare earths of the yttrium group (this J., 1908, 518) is efficient for concentrating erbium, yttrium, and dysprosium material. A comparative study of the permanganate method (Gibbs, Amer. Chem. J., 1893, 15, 546) and the sulphuric acid volumetric method (Holden and James, J. Amer. Chem. Soc., 1914, 36, 638) for control analyses, showed that they give practically the same results in earth mixtures having bromates with a solubility near that of yttrium bromate. Dysprosium material of very high purity was obtained by fractional crystallisation of the rare earth bromates, followed by

fractional crystallisation of the ethylsulphates. The mean of five consecutive determinations gave the value 164.228 for the atomic weight of dysprosium, which is considerably higher than the one now in the International table. The specific gravity of dysprosium oxide was found to be 7.81. J. B. C. K.

Chemical reactions in isoamyl alcohol solutions.
H. A. Curtis and R. M. Burns, J. Amer. Chem. Soc., 1917, 39, 33—38.

THE authors have studied the reactions between anhydrous inorganic salts dissolved in dry isoamyl alcohol, precautions being taken to exclude moisture. The following are some of the results obtained:—*Cobalt chloride* dissolves readily in isoamyl alcohol to form a deep blue solution. Hydrogen sulphide partially precipitates the cobalt as a black cobalt sulphide. This settles readily leaving a blue supernatant liquid. Ammonia produces a pale rose-red precipitate containing cobalt, ammonia, and chlorine. After drying in the air, the compound has the composition: $\text{CoCl}_2 \cdot 3\text{NH}_3$. *Mercuric iodide* is slightly soluble in cold isoamyl alcohol, but dissolves readily in the hot alcohol. Hydrogen sulphide produces an orange-yellow precipitate. Ammonia has no effect on the cold isoamyl alcoholic solution, which contains but little dissolved iodide, but if ammonia be passed into the hot concentrated solution a lemon-yellow precipitate is obtained. *Mercuric chloride* dissolves in isoamyl alcohol to form a colourless solution. Hydrogen sulphide produces a yellow precipitate which becomes brown and finally black if the stream of hydrogen sulphide be long continued. Ammonia produces a white precipitate containing mercury, chlorine, and ammonia in the ratio of approximately $2\text{Hg} : 6\text{Cl} : 3\text{NH}_3$. *Copper chloride* dissolves in isoamyl alcohol to form a dark green solution. Warming the solution changes the colour to a brownish green, the solution becoming almost opaque. Hydrogen sulphide precipitates black copper sulphide, the reaction being quantitative. Addition of calcium bromide solution causes the copper chloride solution to become deep brown in colour. Copper bromide dissolves in isoamyl alcohol to form a solution which has the same deep brown colour. Ammonia precipitates from the chloride solution at first a green compound, but this changes to a blue compound if the ammonia stream be continued for a few minutes. The blue compound is not stable in the air but liberates ammonia and changes into the green compound. This green compound, dried in the air, has the composition, $\text{CuCl}_2 \cdot 2\text{NH}_3$. The reactions with *cobalt nitrate*, *zinc chloride*, *cadmium iodide*, *ferric chloride*, *selenium dioxide*, and *ammonium thiocyanate* were also studied. *Methyl orange* dissolves sparingly in isoamyl alcohol to form a yellow solution. If ten c.c. of this solution be shaken with an equal volume of $\text{N}/2$ aqueous hydrochloric acid, both the water layer and the alcohol layer become pink. If, however, the concentration of the acid used be $\text{N}/8$, the water layer will become pink, but the alcohol layer will remain yellow.—J. B. C. K.

Kelp: Occurrence of free carbon monoxide in—
S. C. Langdon, J. Amer. Chem. Soc., 1917, 39, 149—156.

THE gas in the floaters of the giant kelp of the Pacific coast (*Neoreocystis luteoventris*) was found to contain amounts of carbon monoxide ranging from 0 to 12%; carbon dioxide was only occasionally present, and then in very small amounts (maximum 1.2%).—J. H. L.

Graphite: Colloidal—in oil. D. Holde, Deutsche Bunsen Ges., Dec., 1916, Chem.-Zeit., 1917, 41, 32—33.

THE efficiency of colloidal graphite lubricants depends on the purity of the graphite, the proportion of this element present, and the stability of the colloidal state on standing. A method devised by Freundlich (this J., 1916, 590) for estimating the graphite consists in the addition of benzene and a suitable electrolyte to cause flocculation. After standing 6 to 7 hours, the graphite can be filtered off. A more rapid method devised by the author consists in adding benzene to the mixture, and without further standing, filtering through a Gooch crucible packed with a finely divided powder such as fullers' earth. The filter is then washed with carbon tetrachloride or chloroform, so as to remove soluble impurities separated from the oil. The stability of the suspensions varies with the viscosity and nature of the oils, and can be measured by allowing a column of the mixture to stand for a prolonged interval, and determining the amount of separation by observing the loss of opacity in the top layer, or by analysis. The settling can be accelerated by diluting with an oil of low viscosity.—J. N. P.

Melting zirconia, and production of ware therefrom.

PATENTS.

Sulphuric acid; Apparatus for concentrating—
T. Kilroy, Bayonne, N.J. U.S. Pat. 1,211,594, Jan. 9, 1917. Date of appl., Aug. 18, 1915.

A DESCENDING, finely divided stream of sulphuric acid meets an ascending stream of hot flue gases. The operation is conducted in a tower or a series of towers each composed of metallic sections with a packing of refractory material, and having a removable lead pan at the bottom and distributing apparatus at the top. The acid is fed in at the top of the tower at one end of the series, being pumped from the bottom of one tower to the top of the next, and the hot flue gases enter at the bottom of the tower at the other end of the series and pass along a connecting pipe from the top of one tower to the bottom of the next. The lead pan at the bottom of the tower, where the flue gases enter, is heated.—B. V. S.

Acetic acid: Method of purifying—A. Gorhan, Liesing, Austria-Hungary. U.S. Pat. 1,210,792, Jan. 2, 1917. Date of appl., May 21, 1915.

FORMIC acid and empyreumatic substances are removed from acetic acid by distilling a mixture of equal parts of the crude acid and 70% sulphuric acid. Acetic acid distils over from this mixture at a temperature above the decomposition point of formic acid, but below that of acetic acid.

—B. V. S.

Nitrogen compounds: Process for the manufacture of—Norsk Hydro-Elektrisk Kvaestofaktieselskab, Christiania, Norway. Eng. Pat. 100,099, Feb. 8, 1916. Under Int. Conv., Feb. 23, 1915. (Appl. No. 1884 of 1916.)

NITROGEN compounds are produced by the oxidation of nitrogen in an electric arc furnace and subsequent absorption of the resultant nitrous gases, the oxidation and absorption being effected in a closed system in which the gases are circulated under pressure. The circulating gases are maintained at their original volume and pressure by supplying a compressed gas mixture of suitable composition and quantity, at a certain point. To prevent accumulation of impurities, a portion of the residual gases leaving the absorption system may be withdrawn previous to the introduction of fresh compressed gas. The gas withdrawn is relatively rich in argon, etc., and may be utilised

for the manufacture of argon. The gaseous mixture most favourable to the reaction is $O_2 : N_2 = 1 : 1$.
—T. H. B.

Gaseous reactions with the aid of air rich in oxygen; Process for carrying out —. Norsk Hydro-Elektrisk Kvaestofaktieselskab. Fr. Pat. 480,205, Nov. 12, 1915. Under Int. Conv., Nov. 28, 1914.

IN gaseous reactions in a closed system, such as the fixation of atmospheric nitrogen, the necessity of using an airtight system is avoided by working under diminished pressure, and compensating for the increase of volume due to leakage by withdrawing a part of the gases after removal of the products of reaction. The gas withdrawn from the system, being relatively rich in oxygen, is purified, and then used for producing oxygen to be added to the air supplied to the system to make up for the loss of oxygen in the reaction. The method of withdrawing a portion of the circulating gases may also be applied to closed systems working under pressure (see preceding abstract).

Ammonia; Production of —. F. Perry, Tipton, Staffs. Eng. Pat. 103,118, Jan. 12, 1916. (Appl. No. 538 of 1916.)

AMMONIA is produced by passing Mond or producer gas through iron pipes heated to 650° to 700° C.; or a mixture of either gas with steam may be passed through a furnace of iron or refractory material containing coke or similar carbonaceous material at 650° to 700° C. After removal of the ammonia by means of sulphuric acid, the residual gas may be subjected to the same treatment until the whole or greater part of the available nitrogen is removed.—B. V. S.

Condenser for ammonia. L. Bloek, Mamaroneck, N.Y. U.S. Pat. 1,210,142, Dec. 26, 1916. Date of appl., Dec. 2, 1912.

THE condenser consists of a vertical series of double, concentric pipes connected at the ends to form a continuous coil, the ammonia passing upwards in the inner tube and cooled water downwards in the outer tube. A check valve prevents the backward passage of the gas, and means are provided to carry along condensed liquid with the uncondensed gas, and to pass uncondensed gas from the top of the coil back to the bottom.—B. V. S.

Base-exchanging silicates; Manufacture of —. H. Kriegsheim, Assignor to The Permutit Co., New York. U.S. Pat. 1,208,797, Dec. 19, 1916. Date of appl., Mar. 21, 1916.

A BASE-EXCHANGING material is obtained as a precipitate by mixing an alkaline solution of alumina with the solution obtained by leaching an alkaline melt containing silica and alumina.
—B. V. S.

Magnesium chloride and the like; Method of making —. E. O. Barstow, Assignor to The Dow Chemical Co., Midland, Mich. U.S. Pats. (A) 1,209,245 and (B) 1,209,246, Dec. 19, 1916. Dates of appl., Mar. 13 and Apr. 17, 1916.

(A) BRINE containing sodium, calcium, and magnesium chlorides is treated with magnesium sulphite in sufficient amount to react with the calcium chloride present, precipitating calcium sulphite, and leaving a solution of sodium and magnesium chlorides which are separated by crystallisation. The magnesium sulphite is prepared from magnesium hydroxide obtained by treating a quantity of the brine with lime. (B) Magnesium hydroxide is mixed with the brine and sulphur dioxide passed through to form magnesium chloride and a precipitate of calcium sulphite.—T. H. B.

Uranium oxide; Process for the manufacture of —. H. A. Seil, Assignor to Standard Chemical Co., Pittsburgh, Pa. U.S. Pat. 1,210,714, Jan. 2, 1917. Date of appl., Apr. 20, 1916.

By heating a mixture of alkali uranate and sulphuric acid to drive off excess acid, a mixture of alkali sulphate and uranium oxide is produced from which the latter is obtained by washing away the sulphate with water.—B. V. S.

Spent oxide; Revivifying and utilising —. E. B. King, Oak Park, and E. C. Wescott, Sacramento, Assignors to Pacific Gas and Electric Co., San Francisco, Cal. U.S. Pat. 1,211,713, Jan. 9, 1917. Date of appl., May 27, 1916.

SPENT oxide from gas-works is treated with unslaked lime and hot water or steam, and a soluble compound of lime and sulphur extracted.—B. V. S.

Oxygen from atmospheric air; Furnaces for production of —. H. G. Ross, Merton Abbey, Surrey, and W. S. Edwards, Bridport, Dorset. Eng. Pat. 18,221, Dec. 31, 1915.

AIR and steam are allowed alternately to react with a suitable chemical reagent in heated horizontal tubes or chambers in a furnace, the oxygen being withdrawn from the air by the reagent and given off on treatment with steam. The furnace tubes are provided with an inner pipe for admission of air and steam, this pipe being perforated throughout its length, in such a manner that the air or steam passes into intimate contact with the reagent. Three tiers of furnace tubes are preferably employed, and each tier receives in succession a current of steam while the remaining two tiers are supplied with air; thus the reagent in two tiers absorbs oxygen while oxygen is being given off in the third tier.—T. H. B.

Argon; Apparatus and process for concentrating —. G. R. Fonda, Schenectady, N.Y., Assignor to General Electric Co. U.S. Pat. 1,211,125, Jan. 2, 1917. Date of appl., Oct. 12, 1915.

A LIQUID containing about 94% oxygen and 4% argon, obtained by the fractionation of liquid air, is subjected to further fractionation on the counter-current principle in a special rectifying column, argon being concentrated at the top of the column and oxygen at the bottom.—B. V. S.

Carbonic acid compounds of ammonia; Manufacture of —. C. Bosch, Assignor to Badische Anilin u. Soda Fabr., Ludwigshafen, Germany. U.S. Pat. 1,211,393, Jan. 9, 1917. Date of appl., Apr. 8, 1915.

SEE Eng. Pat. 8763 of 1915; this J., 1915, 904.

Catalyser [for oxidation of ammonia to nitrogen oxides]. C. Bosch, A. Mittasch, and C. Beck, Assignors to Badische Anilin u. Soda Fabr., Ludwigshafen, Germany. U.S. Pat. 1,211,394, Jan. 9, 1917. Date of appl., Apr. 8, 1915.

SEE Eng. Pat. 13,848 of 1914; this J., 1915, 799.

Antimonates; Production of —. P. Eyer, Halberstadt, Assignor to R. Koepp und Co., Oestrich, Germany. U.S. Pat. 1,211,564, Jan. 9, 1917. Date of appl., July 21, 1915.

SEE Eng. Pat. 11,083 of 1915; this J., 1916, 839.

Cuprous oxide; Process for production of — electrolytically. B. Hunt, Glasgow. U.S. Pat. 1,212,062, Jan. 9, 1917. Date of appl., Oct. 7, 1916.

SEE Eng. Pat. 14,310 of 1915; this J., 1916, 1156.

Aluminium nitride; Process of producing—O. Serpek, Assignor to Soc. Gén. des Nitrures, Paris, U.S. Pat. 1,212,119, Jan. 9, 1917. Date of appl., Apr. 14, 1915.

VIII.—GLASS; CERAMICS.

Society of Glass Technology.

AT a meeting of this Society, held on Jan. 18th last, Mr. W. F. J. Wood, President, in the chair, the Rules and Constitution of the Society were passed. The Society is to consist of three classes of members, viz., collective members, i.e., firms engaged in the manufacture, distribution, or use of glass (annual subscription, £3 3s.); ordinary members, i.e., persons (not being either representatives of collective members or student members) who are interested in glass technology (sub., £1 1s.); and student members, i.e., registered students who are attending a course or courses of technical instruction in the United Kingdom (sub., 2s. 6d.). Applications for membership should be sent to the Secretary, Society of Glass Technology, The University, Sheffield.

Papers on British glass sands were read by Dr. P. G. H. Boswell and Mr. C. J. Peddle, abstracts of which are given below.

British glass sands; their location and characteristics. P. G. H. Boswell. Soc. Glass Tech., Jan. 18, 1917.

THE analysis of British sands has proved their value. The analysis of sand can be carried out in three ways—(1) chemical, (2) mechanical, (3) mineral. *Chemical analysis* proves the value of a sand by determining its silica content, which must be high, and its iron content, which must be low. In the past, sands with higher iron oxide content than 0.02%, were regarded as useless for the best types of glass, but recent work has shown a higher iron content to be permissible, and so British sands can be used for good glass. *Mechanical analysis* determines the grading of the sand, the best for glass being that with the largest percentage of grains of diameter 0.25 to 0.5 mm. *Mineral analysis* is important in the laboratory for controlling consignments of sands, and also gives an indication of impurities to be expected.

The relative value of crushed rock was discussed, and it was shown that, after crushing, screening and washing were necessary to remove the larger grains and the fine material. By means of a geological map the position of English sand deposits and their situation relative to the centres of the glass industry was illustrated. The paper closed with a consideration of the transport question, and the need for development of the canal system together with a cheapening of railway rates.

British glass sands; the substitution of foreign sands by British sands for high grade glass making. C. J. Peddle. Soc. Glass Tech., Jan. 18, 1917.

THE author summarised the essentials of a good glass sand from the manufacturer's point of view, and showed that it must contain a high percentage of silica and a low percentage of impurity, particularly iron oxide. It must be evenly graded, and the grains should be angular. In addition, a sand should always be true to sample, and consignments should not vary, nor should there be any treatment necessary at the hands of the manufacturer. All these essentials are fulfilled by Fontainebleau sand, but not all by any British sand as at present supplied. That some British sands compare favourably with Fontainebleau, both as regards purity and grading, has been established by the author, whose results in general are in agreement with those of Dr. Boswell. In addition, a long series of melts also support this view, and on this account the statements of Dr. Rosenhain as to the non-availability of British sands for good glass are to be criticised. Excellent results are obtainable with British sands which have been properly treated, and numerous specimens of glasses made from British sands were exhibited side by side with the sands. Several of these glasses could not be distinguished from similar melts made with Fontainebleau sand, being just as brilliant and colourless. The question of treatment was then discussed, and the necessity for washing and grading was demonstrated. The need of proper scientific treatment of British sands and the necessity of putting them into the manufacturer's hands ready for immediate use was emphasised, and it was pointed out that unless this treatment was forthcoming, together with attention to mode of delivery, British sands could not hope to compete favourably with Fontainebleau sand.

Glass; Production of blue, green, black, and gold colours on—L. Springer. Keram. Rundschau, 1916, 24, 211–212. Z. angew. Chem., 1916, 29, Ref., 526.

THE author concludes that so far as present knowledge goes, satisfactory colours can be burnt on to glass only by the use of compounds of copper and silver, and possibly gold and platinum. A black is produced by burning on copper compounds in the ordinary way with a subsequent burning under reducing conditions. A third burning under ordinary conditions gives a red colour. The first burn with copper compounds gives a green. A yellow, burnt on in the usual way, is converted into a bright golden colour by a second burn under reducing conditions. Blues cannot be produced by burning cobalt compounds on to glass. Compounds of other elements also gave negative results.—H. J. H.

Coke-oven bricks; Some physical properties of the two chief mineral constituents of—W. G. Fearnside. Coke-oven Managers' Assoc., Jan. 27, 1917. Gas. J., 1917, 137, 253–254.

COKE-OVEN bricks are manufactured from fireclay alone or a mixture of fireclay and crushed siliceous rock. The refractory properties need not be as highly developed as in bricks for steel furnaces, whilst the durability is dependent on the physical stability of the body and the chemical inertness of the mineral constituents in the presence of certain fluxes at temperatures between 800°C. and 1100°C. From the results of chemical examination, etc., it is generally agreed that the base of fireclay is similar to the kaolinite of china clay. The value of a fireclay would be appraised by comparing its analysis with that of the mineral kaolinite with 39.5% Al_2O_3 , 46.5% SiO_2 , and

about 14% H_2O . any other bases, especially alkalis, being detrimental to the quality of the material. Mellor (this J., 1911, 804; 1913, 195; 1916, 1218) has shown that on heating kaolin, entangled water is given off at temperatures just above 100°C . but the combined water does not come away till 500°C . is passed, the heat absorption during this dissociation retarding the rise of temperature considerably. The temperature then rises steadily to 800°C . at which temperature there is an exothermic reaction, with a more rapid increase in temperature. Beyond 1200°C . a new chemical rearrangement of molecules occurs, and what Mellor regards as a mixture of $\text{Al}_2\text{O}_3 + 2\text{SiO}_2$ recombines as $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2 + \text{SiO}_2$, and the mineral sillimanite begins to crystallise. According to Mellor the heating curves of fireclay are similar to those of kaolin. When air-dried fireclay is heated it expands a little whilst water is given off, but then contracts continuously right up to the higher temperatures. The contraction at lower temperatures is correlated with loss of water, giving rise to increased porosity. Above 900°C . the density is further increased, probably due to the fluxing of silica and feldspathic minerals. As the temperature rises more fluxing occurs until the mass may be described as vitrified. Contraction and other vitrification effects can only be controlled by fixing the rate of rise of temperature above the lower limit of fluxing temperature. When bricks consisting of clay or kaolinite burnt to the point of vitrification are examined microscopically, the bonding material appears to consist of glass. Next to kaolinite, quartz is the most abundant mineral in the fireclays of this country. When quartz is heated it expands up to 870°C ., and above this temperature, if time be allowed, and the environment be suitable, it breaks down, expanding abruptly and considerably, and passing into a substance similar to tridymite, a mineral of a density less than 2.33, compared with the 2.66 of quartz. At higher temperatures, up to 1470°C ., the tridymite changes to cristobalite of a density about 2.27. Any pair of chemically related substances heated to the melting point of one of them react to form new compounds or to some extent dissolve each in the other, forming an eutectic of lower melting point than either. Pure kaolin does not melt as a single substance, but heated to 500°C . gives up its water, and at about 1200°C . the dehydrated residue changes into a mixture of sillimanite and probably tridymite, which on further heating passes into cristobalite. This mixture on cooling forms an eutectic, with a melting point, as determined by Rankin, of 1600°C . From this it appears quite evident that kaolin and quartz cannot flux each other and may be mixed in any proportion with little loss of refractory properties.—J. E. C.

Zirconia; Melting — and production of ware therefrom. E. Podszus. Z. angew. Chem., 1917, 30, 17—19. (See also this J., 1917, 85.)

RAW zirconia is an unsatisfactory material for the production of refractory articles as they crack readily and soon fall to pieces. If a bond is used to prevent this, the refractoriness of the articles is seriously impaired. The author has found that zirconia which has been heated to above 2000°C ., and especially fused zirconia, is free from this objection and is excellent for the manufacture of refractory ware. The use of a carbon resistance furnace or of an ordinary electric arc for fusing the zirconia is unsatisfactory on account of the formation of carbide. The best results are obtained by embedding a carbon electrode in coarsely ground calcined zirconia, heating the latter with the arc formed from a second carbon electrode and thus partially melting the zirconia with

formation of some carbide. The latter then acts as an electrode and the zirconia fuses and continues to do so when the upper carbon electrode is slowly withdrawn. After a time, the arc becomes quiet and the fusion proceeds rapidly. Arcs 30 cm. long, accompanied by a molten mass of zirconia 15 cm. in diameter, have repeatedly been obtained in half an hour with a current of 50 amps. at 220 volts, the resulting blocks of zirconia being pure, and white, with a yellowish sheen in parts, due to traces of iron. The fused zirconia is ground for 100 hours or more in a steel ball mill and any iron taken up from the latter is removed by treating the powder with acid. The zirconia is moulded or pressed into articles, with or without the addition of an organic bond. By reducing a part of the zirconia to the colloidal form it is possible to render the whole material plastic and to manufacture articles from it by "slip-casting" in plaster moulds in the same manner as porcelain. Crucibles made by this process are as fine as those made of porcelain. Attempts to cast articles from molten zirconia have, hitherto, been unsuccessful. The articles are burned at 2300°C — 2400°C . until they cease to contract; if properly burned they should "ring" clearly when struck. The burning temperature may be reduced to 2100°C . by adding a little boric or phosphoric acid to the zirconia before making it into articles, but this is not recommended. The oven used is constructed chiefly of fused zirconia; it is cylindrical in shape, with internal dimensions of 20 cm. by 30 cm., and is of the injector type. The fuel is either town's gas, petroleum, or acetylene supplied with a blast of air and, later, with oxygen. The author's furnace has been in use for 200 hours without requiring any repairs. A uniform yet very high temperature and an oxidising atmosphere can be obtained without difficulty, so that ovens of this type may be useful for testing the fusibility of refractory materials up to 3000°C . The shrinkage of the articles during drying and burning varies with the size of the particles of zirconia. If a finely ground material is used, the total shrinkage is about 20%. Fused zirconia resembles fused quartz in some respects, but when cooled rapidly it forms an opaque mass of minute crystals and not a clear glass. The crushing strength of cold fused zirconia is many times that of cold quartz, so that it is exceedingly difficult to grind. Such zirconia has a high thermal endurance and is not affected when heated to redness and then plunged into cold water. A large block may be heated irregularly by an oxy-hydrogen blowpipe without showing any signs of spalling. A block of fused zirconia maintained at 2200°C . for 30 hours showed no signs of disintegration when cold. Hence, fused zirconia appears to be a refractory material of extraordinary value. It has a hardness between quartz and corundum, a specific gravity of 5.89, a porosity below 1%, and a melting point—determined with a Lummer-Kurlbaum pyrometer—between 2950° and 3000°C ., but 0.5% of impurity reduces this by 100° .—A. B. S.

Absorption of gases. Hempel. See 1.

PATENTS.

Glass; Non-scatterable — and the process of making it. A. Roosevelt. Assignor to Glass Founders' Corporation, New York. U.S. Pat. 1,201,987, Jan. 2, 1917. Date of appl. June 3, 1915.

A SOLUTION of gelatin and one of cellulose material are applied successively to a sheet of glass, at least one of the solutions containing a solvent of both the gelatin and cellulose material, such as formic acid.—A. B. S.

Firebricks: Plastic composition for making — E. V. Wagner, Scranton, Pa., Assignor to Wagner Firebrick Co., Helena, Mont. U.S. Pat. 1,209,784, Dec. 26, 1916. Date of appl., Aug. 5, 1916.

The firebricks are made of a mixture of coal ashes 100 lb., alumina 2 lb., and water 2–2½ galls.

—A. B. S.

Tiles: Composition for — P. C. Boying, Philadelphia, Pa. U.S. Pat. 1,240,756, Jan. 2, 1917. Date of appl., July 19, 1915.

A mixture of ground, burned clay, calcined magnesite, and magnesium chloride solution is made into a paste, dried to a moist powder, and compressed in moulds to form tiles.—A. B. S.

Grog in dust form: Production of — as shortening material. M. Bertram, Neustädte, Ger. Pat. 295,290, Apr. 13, 1916. Addition to Ger. Pat. 288,721 (this J., 1916, 424).

THE process described in the original patent, when applied to the more fusible clays, may give rise to fritting or even melting if the development of heat by combustion of admixed material is excessive. If the mixtures be distilled in closed vessels before burning in a kiln, even the most fusible clays give a satisfactory product.—H. J. H.

Glass surfaces: Joining together — A. Hilger, Ltd., F. Twyman, R. G. Parker, and A. J. Dalladay, London, Eng. Pat. 103,233, Apr. 20, 1916. (Appl. No. 5839 of 1916.)

SEE U.S. Pat. 1,206,177 of 1916; this J., 1917, 85.

Process of fractional elutriation of simple or mixed substances. Ger. Pat. 291,908. See 1.

IX.—BUILDING MATERIALS.

Concrete specimens: Tests of — in sea water at Boston Navy Yard. R. E. Bakenhus, Proc. Amer. Soc. Civ. Eng., 1916, 42, 1571–1601.

TWENTY-FOUR specimens of concrete, made from cement, sand, and stone (broken trap rock), each 16 ft. long and 16 in. square, were hung suspended from a pier and immersed in sea water for 7 years in order to determine the action of the water on wet and dry concretes of various proportions, made of materials from various sources. The results seem to show that the specimens richer in cement were the most durable. Thus, the 1:1:2 mixture was superior to the 1:2½:4½, and the 1:2½:4½ was in turn superior to the 1:3:6. The wet mixtures were superior to the dry mixtures. The effects of magnesia or alumina in varying proportions were not very marked, and followed no apparent law, although the two most durable specimens were those lowest in alumina content. Extra care in mixing produced decidedly beneficial results. Hydrated lime was of no benefit, but rather a detriment. The addition of Sylvester wash was harmful. In this case, 3 lb. of alum was added to each bag of cement used and the materials were mixed dry. Instead of then mixing them with plain water, Sylvester wash was substituted. This consists of 1¼ lb. soap dissolved in 12½ galls. of water. The addition of 1½ lb. of clay to each bag of cement had a slightly beneficial result. The deterioration was most marked at mid-tide, little deterioration being observable with non-immersed and continuously immersed specimens. The experiments are too limited to warrant drawing more definite conclusions.—A. B. S.

Absorption of gases. Hempel. See 1.

Utilisation of waste heat for steam generating purposes. Pratt. See 1.

PATENTS.

Paving: Process for treating fibrous material for manufacture of compositions suitable for — J. E. Clark, Toronto, Canada. Eng. Pat. 102,826, Jan. 7, 1916. (Appl. No. 313 of 1916.)

STRAW, corn-stalks, sugar cane, wood chips, or other coarse fibrous material (but not wood pulp or dust) is boiled with water. The juices and excess of water are removed by passing the material between rollers, and the product is then immersed in a bath of asphalt, bitumen, or other binder, heated to 200°–400° F. (93° to 204° C.). The product is withdrawn mechanically, rolled or otherwise compressed, and allowed to harden under the action of the sun. It is resilient, dustless, sanitary, waterproof, and non-slipping.

—A. B. S.

Cement and by-products: Process of making — [from felspar, etc.]. E. C. Eckel and A. C. Spencer, Washington, D.C. U.S. Pats. (A) 1,209,135, (B) 1,209,219, and (C) 1,209,220, Dec. 19, 1916. Dates of appl., Jan. 4, 1911, June 6, 1910, and May 18, 1912.

CEMENT is made by heating a comminuted mixture of (A) potash felspar, or a potash silicate of the (B) glauconite, or (C) nephelite or mica type with calcareous materials (e.g., limestone) to a temperature sufficient to vaporise the potash and then to form cement clinker, but not to cause fusion. The potash is recovered in the flue-dust.—A. B. S.

Pavements and other structures: Surfacing mixture for — F. H. Welsh, Richmond, Cal. U.S. Pat. 1,209,238, Dec. 19, 1916. Date of appl., Feb. 21, 1916.

AN asphaltic surfacing composition is made by mixing steam-distilled, crude petroleum asphalt with 20% of a product obtained by heating crude petroleum with air under pressure without removing its volatile constituents.—A. B. S.

Furnace lining. G. S. Davison, Assignor to A. S. Davison Co., Pittsburgh, Pa. U.S. Pat. 1,210,431, Jan. 2, 1917. Date of appl., July 7, 1916.

A FURNACE lining is made of a mass of granular, basic refractory material, the pores in the particles of which are impregnated with a small amount of silicious and ferruginous material, such as basic slag. The faces of the particles are substantially free from such silicious material.—A. B. S.

Wood: Process of artificially seasoning — M. Kleinstück, Dresden, Germany. U.S. Pat. 1,210,491, Jan. 2, 1917. Date of appl., Mar. 19, 1914.

WOOD is treated with a gaseous primary oxidation product of an alcohol, e.g., an aldehyde, and a catalytic agent, such as a volatile amine, so as to transform the tannins, albumins, and carbohydrates into high-molecular compounds.—A. B. S.

Portland cement and similar products: Apparatus for the manufacture of — W. H. Mason, Easton, Pa. U.S. Pat. 1,210,510, Jan. 2, 1917. Date of appl., May 21, 1914.

AN unground mixture of cement-forming materials is calcined in one section of a rotary kiln and is passed through a grinding section and then through a second burning section where it is converted into clinker. The three sections of the kiln are in a straight line with a continuous closed passage through them, but each can be rotated separately.—A. B. S.

Roofing and waterproofing materials; Manufacture of flexible bituminous—. C. N. Forrest, Rahway, N.J., Assignor to R. L. Fowler and M. S. Darrow, Perth Amboy, and E. B. Rosevear, Boonton, N.J. U.S. Pat. 1,211,837, Jan. 9, 1917. Date of appl., Feb. 26, 1916.

A HIGHLY absorbent, flexible sheet composed of fibres of cotton or wool and leather scrap felted together and saturated with a bituminous material.—A. B. S.

Artificial slates; Production of— from cement and asbestos. E. Imer-Schneider, Geneva, Switzerland. Ger. Pat. 295,268, Feb. 23, 1916. Under Int. Conv., Feb. 16, 1916.

ASBESTOS is mixed with vegetable fibres previously treated with cold dilute alkali to preserve their binding properties towards the cement. Such fibres may replace at least two-thirds of the asbestos otherwise necessary.—H. J. II.

X.—METALS; METALLURGY, INCLUDING ELECTRO-METALLURGY.

Cast-iron: with special reference to engine cylinders. J. E. Hurst. Manchester Assoc. Eng., Dec., 1916. Engineering, 1917, 103, 40—41, 51—54, 75—76.

THE worn surface of cast-iron cylinders and pistons of steam and internal combustion engines is covered with small pits or holes. Microscopic examination shows the harder constituents, such as cementite and the phosphide eutectic, standing in relief. This is brought about by the polishing action of detached material suspended in the film of lubricating oil; eventually these projections become detached and cause gradual disintegration of the cylinder. After a cylinder has been in use for a time, especially if the metal is high in manganese, it is known to work more satisfactorily, and this is found to coincide with a peculiar glazed appearance of its inner surface. Microscopic examination reveals that in many cases the original coarse-grained structure has become much more finely granular, while hardness has increased. This is attributed to the absorption of carbon from the lubricant, or detached graphite, or both, by the surface of the cylinder, under influence of the high temperature, with formation of hardenite. Experience has shown that the most satisfactory bearing-metal alloys consist of at least two constituents of very different physical properties, one embedded in the other, and cast-iron probably owes its peculiar anti-frictional properties to a similar structure: the harder constituents serve as a support for the greater part of the load, while the depressions produced by the wearing away of the softer constituents serve as distributing reservoirs of the lubricant. The determination of hardness by Brinell's method gives no satisfactory guide as to the resistance to wear of cast-iron cylinders, the true wear depending upon the resistance to deformation of the individual component grains. As regards the effect of machining on the resulting surface, the quality of the finish is known to improve as the cutting speed decreases. In spite of the slow rate of machining cylinders and liners, due to the great accuracy required, small cracks and holes are liable to form; the more recent method of internal grinding is therefore preferable. The growth, or permanent increase in volume, of cast-iron when heated for several hours to 650°—750° C., which is due to the absorption of furnace gases along the graphite plates with oxidation of the silicon and iron, has been observed in the piston tops of internal combustion engines.—W. R. S.

Iron; Influence of cobalt, nickel, and copper on the atmospheric corrosion of pure commercial—. H. T. Kalmus and K. B. Blake. Amer. Inst. Chem. Eng., Jan., 1917. J. Ind. Eng. Chem., 1917, 9, 123—136.

As measured by the loss in weight per unit of surface exposed, after removing the rust by means of ammonium citrate solution, the atmospheric corrosion of pure iron was retarded by copper, nickel, and cobalt which, in the present investigation, were alloyed separately with the iron in proportions ranging between 0.25 and 3%. On exposure, all the alloys became coated with a protecting layer of oxides by which the rate of corrosion was subsequently decreased. The cobalt and nickel alloys, generally, suffered 50—25% less corrosion than pure iron; and the relative corrosions of the 3% and 0.5% alloys were as 3:4. The oxide coating on the cobalt alloys was darker and more dense and tenacious than those on the corresponding nickel and copper alloys, but, over the period of investigation, appeared to be no more advantageous than the latter. Alloys containing 0.25—0.75% Cu were more resistant than pure iron to atmospheric corrosion. In all cases the amount of corrosion varied with the carbon content of the alloy.—W. E. F. P.

Steels; Corrosion and electrical properties of—. R. Hadfield and E. Newbery. Proc. Roy. Soc., 1917, A 93, 56—67.

IN order that a metal may dissolve in an acid, the sum of the single potential of the metal and the overvoltage must be less than the single potential of the hydrogen electrode. The first value is the potential (usually negative) acquired by the metal through contact with its surrounding medium. The overvoltage is the potential required to overcome the resistance offered, in varying degrees, by all metal surfaces to the liberation of gas. The potential of the hydrogen electrode refers to an electrolyte of the same composition as the medium surrounding the metal. Measurements were made with different samples of steels, including silicon-, chromium-, nickel-, and tungsten-steels. Determinations were made of the single potential differences of prepared samples of the metals in dilute acid solutions, of the overvoltage by the back E.M.F. method, and of the rate of corrosion in acid and when exposed to the atmosphere. The corrodibility as determined by the sum of the single potential and the overvoltage gave results parallel to those measured by the rate of solution in acid. The degree of atmospheric corrosion with different alloys was, however, more closely in agreement with the values obtained by the electrical method than with those given by measurement of the rate of solution in acid. This is attributed mainly to the fact that corrosion, like overvoltage, is determined largely by the nature of the surface, which necessarily undergoes great changes during solution of the metal in acid. Since the electrical measurements are capable of being made with precision, and of distinguishing between the two determining factors, this method offers certain advantages over the acid test for determining corrodibility. It should also be possible to ascertain in this way how far the addition of certain elements can be made with the object of raising the overvoltage, and of others with the object of lowering the negative potential in order to attain the ideal of a rustless steel.—J. N. P.

Steel springs; Investigation of the brittleness produced in— by electroplating. M. De K. Thompson and C. N. Richardson. Met. and Chem. Eng., 1917, 16, 83—84.

THE brittleness produced in spring steel, by using the latter as cathode in a hot cyanide bath,

was found to be more pronounced with sodium cyanide than with sodium cuprocyanide, and not to occur when the spring was used as anode, or suspended in the solution without the passage of electricity, or when the steel was previously annealed. The brittleness was not due to the liberation of hydrogen on the metal, or characterised by any change in carbon content or crystalline structure; it was produced whether the steel was coiled or not. Brass and bronze were not similarly affected.—W. E. F. P.

Gold ore; Flotation experiments on a Transvaal —.
F. Wartenweiler. J. Chem., Met., and Min. Soc., S. Africa, 1916, 17, 87—90.

PYRITIC gold ore containing arsenic, from Barberton, crushed to -150-mesh and cyanided, gave a maximum extraction of 45%; amalgamation proved a failure. Roasting followed by cyaniding gave 82.5% recovery, but the high working costs militated against roasting. Concentration on a Deister table, with subsequent cyaniding of the concentrate, yielded 70% recovery. Laboratory flotation tests were successful under the following conditions: The ore, crushed to pass a 90-mesh screen, was mixed with water in the ratio of 1:5, lime being added to produce an alkalinity of not more than 0.005% CaO. The pulp was agitated for 15 min. with a mixture of wood creosote and paraffin oil. The middling and tailing were easily cyanided direct, the recovery being 22.4%. The concentrate was roasted, then amalgamated and cyanided, with an extraction of 65.0%. Allowing for volatilisation losses on a commercial scale, the total extraction on this ore would be 84%. W.R.S.

Countercurrent decantation [in the cyanide process].
L. B. Eames. Amer. Inst. Min. Eng., Feb., 1917. Met. and Chem. Eng., 1917, 16, 91—99.

THE chief factors affecting countercurrent decantation—namely, grade of ore, ratio of solution precipitated to ore treated, thickness at which the pulp can be discharged, cost of chemicals, rapidity of dissolving the gold and position in the circuit at which solution takes place, and efficiency of precipitation—are considered, and the effects of variations in the first three shown by means of curves based on the assumption that 75% of the gold is dissolved during grinding and the remainder during agitation. Various mechanical devices for pumping and thickening the pulp and measuring the volume of solution precipitated are also discussed, and a brief description is given of the decantation plant of the Hollinger Co. At this plant, during the 12 weeks ending on April 21, 1916, 85,854 tons of ore was treated by the countercurrent system at a total cost for decantation of 0.0209c. (0.01015d.) per ton, this figure being about 40% of the cost of filtering with leaf filters at about the same daily tonnage. The extraction and recovery of gold over this period compared very favourably with that obtained from filter plants and, as in the latter case, a reasonably accurate forecast could be made of results obtainable under specified conditions.—W. E. F. P.

Platinum; Microchemical estimation of small quantities of — in presence of gold and silver.
M. Van Breukelen. Rec. Trav. Chim. Pays-Bas, 1917, 36, 285—288.

The following method is recommended for the recognition and determination of small amounts of platinum in ingots of gold and silver. A sample of the alloy in the form of foil is freed from silver by heating it with sulphuric acid. If it originally contains less than four parts of silver to one part of gold, a sufficient amount of silver free from

platinum must be added to bring the proportion up to this value. After removal of the silver, the gold and platinum are dissolved in *aqua regia*, and the solution is evaporated to dryness. All the nitric acid is removed by evaporation with a little hydrochloric acid, and the auric chloride is converted into insoluble aurous chloride by heating for 15—30 minutes at 170°—190° C. To the residue is added 2 drops of N/3 hydrochloric acid, and a spot of the solution is placed on a cover-glass with a trace of solid potassium chloride. The drop is examined under a magnification of about 110 diameters, and, if platinum is present, yellow octahedra of potassium chloroplatinate are seen to form. By continuing to add 2 drops of hydrochloric acid to the residue and repeating the procedure, the number of drops is found at which the octahedra cease to form, owing to their solubility in the dilute acid. By determining this number for alloys of known platinum content, the method can be applied to determine platinum quantitatively when present in small amounts in gold and silver alloys.—F. Sp.

[Copper smelting.] Ore treatment at the Falcon Mine (Rhodesia). H. R. Adam. J. Chem., Met., and Min. Soc., S. Africa, 1916, 17, 91—96.

THE Falcon mine, which has been producing for two years, treats 11,000—15,000 tons of sulphide and 5000 tons of oxide ore per month; the output is given as 600,000 lb. of blister copper, 3000 oz. of gold, and 6000 oz. of silver. The sulphide ore (Cu 2½%, Au 6 dwt. per ton) is crushed to 2½ in. diameter and hand-picked on a belt conveyor, yielding 9% of picked smelting ore. The rest is crushed to ½ in. size and concentrated by vanning; the tailings, ground in tube-mills, are passed over vanners followed by blanket tables. The final tailing is classified into underflow which returns to the tube mill, and overflow which is thickened and concentrated by flotation in a plant of the Minerals Separation type. The oxidised ore is stamped, vanned, the tailings re-ground in a tube-mill and passed over vanners and blanket tables. The total extraction by concentration is 80% of the gold and 90% of the copper. The mill concentrate is sintered in 12 blast-roasting pots, each of which holds 8 tons, a charge requiring about 8 hours' treatment. The two blast-furnaces have a cross-section of 120 × 46 in. at tuyere-level and a capacity of 300 tons per 24 hours. The fuel is a mixture of coke and coal. The matte (32—35% Cu) is blown in upright converters of 15 tons capacity per 24 hours. The blister copper carries 10 oz. of gold and 20 oz. of silver per ton; the smelting recovery is 96% of the gold and 90% of the copper. The flues from the sintering and smelting plants lead into two settling chambers from which a 900 ft.-flue extends to the stack.

—W. R. S.

Copper refining; Current efficiency in —. L. Addicks. Met. and Chem. Eng., 1917, 16, 23—25.

Loss of current efficiency in copper refining by the multiple system is caused by (1) current leakage to the ground, through the electrolyte, or between the electrodes; (2) reactions involving deposition of impurities, "gassing," or change in valency of the copper; and (3) cathode shrinkage due to re-solution of deposited copper by sulphuric acid (sulphatising) or ferric salts, or to the mechanical separation of nodules, etc., from the deposit. Complete disregard of conditions may result in an efficiency of only 60%, and poor work in 85%; while 92% may be obtained by well balanced operating, and 99% by working for efficiency without regard to expense.—W. E. F. P.

Copper; Vaporisation of — in wirebar furnaces.
A. Butts. Met. and Chem. Eng., 1917, 16, 85—86.

IN the operation of a 200-ton reverberatory furnace equipped with waste heat boilers and economisers, 79.6 kilos. of copper was found to pass from the furnace into the flue apparatus during the melting of each charge, and it appeared probable that the whole of this loss was due to vaporisation of the metal. The maximum possible loss of copper by evaporation was calculated as 466 kilos. per charge, the vapour tension of the metal at the working temperature ($1120^{\circ}\text{C}.$) being about 0.28 mm. and the volume of gas passing through the furnace 440,000 cub. m. (at N.T.P.) per charge. The percentage saturation of the furnace gases with copper vapour was thus about 17% in the actual melting operation, assuming the loss to be due entirely to vaporisation. The copper vapour began to condense at $1005^{\circ}\text{C}.$ (about 55° above the temperature at the entrance to the waste heat boiler), and was collected, largely as copper sulphate, in the dusts obtained from the boiler, economiser, and stack. These dusts contained 28, 18, and 15% Cu. of which about 60, 85, and 90%, respectively, was soluble in water.—W. E. F. P.

Babbitt metal and alloys of tin, antimony, lead, and copper; Analysis of —. E. W. Hagmaier. Met. and Chem. Eng., 1917, 16, 84—85.

Antimony. 1 grm. of the sample (filings) is heated with 10 c.c. of water and 25 c.c. of sulphuric acid until no black particles remain. The cooled solution is then diluted with 100 c.c. of water and 10 c.c. of hydrochloric acid, boiled for 10 mins. to expel sulphurous fumes, and titrated with potassium permanganate after being cooled and further diluted with 100 c.c. of water. *Tin.* 0.5 grm. is dissolved in hydrochloric acid (with potassium chlorate if necessary) and the tin determined by titration with $N/10$ iodine solution after reduction with soft iron and hydrochloric acid. *Lead.* Solution is effected by dilute nitric acid in the presence of a large excess of tartaric acid. Sulphuric acid is then added and the solution boiled sufficiently to expel all nitric fumes but without charring the tartaric acid; after which the lead sulphate is filtered off, dissolved in ammonium acetate solution, and the lead reprecipitated and weighed as chromate. *Copper.* Solution is effected as in the preceding case and the filtrate from the lead sulphate is further acidified with hydrochloric acid and heated with pure aluminium. The precipitated copper is filtered off and redissolved in dilute nitric acid for determination by the electrolytic or iodide method.—W. E. F. P.

American mercury industry. Bull. U.S. Geol. Survey, U.S. Commerce Reports, No. 298, Dec. 20, 1916.

THE American mercury industry continued to be of more than usual interest throughout 1915, owing to the large consumption of the metal in the manufacture of war supplies and the generally prevailing high prices resulting from the great demand. Owing to foreign embargoes on the exportation of metals, domestic producers largely controlled the market in the United States, although several shipments were received from Italy (made, it is reported, under contracts drawn prior to the disturbed conditions abroad). Prices for the metal became so high in February and March, 1916, that certain foreign Governments permitted the shipment of some mercury, and thus, to a small but important extent, competition in the home market between domestic and foreign

supplies was re-established, and prices fell from \$300 per flask in February, 1916, to \$75 in August, 1916. In the fiscal year ending June 30, 1916, the United States imported for consumption 554,792 pounds of mercury, valued at \$595,007, and exported 232,763 pounds, valued at \$274,086. Although, owing to the efforts of producers to make capacity output, some stocks have doubtless accumulated, the price of mercury abroad will probably justify exports from this country, and cause reduction of stocks if the domestic quotations run much below \$70. The mercury mines and prospects of the United States were under active development in 1915. Additions to reduction plants were made at old mines and retorts were put in operation at promising prospects. Including small prospects, there were 39 producers of mercury in the United States in 1915, against 30 in 1914 and 24 in 1913. Thirty-two of the producers in 1915 were in California, 4 in Nevada, and 1 producer each in Arizona, Oregon, and Texas. The output was 21,033 flasks of 75 pounds each, against 16,548 flasks in 1914 and 20,213 flasks in 1913. At the average sales price reported by the producers of \$86.86 per flask for 1915 the output was valued at \$1,826,912, against \$1,680 in 1914 (average per flask, \$19.05) and \$813,171 in 1913 (average per flask, \$40.23). Compared with 1914 the yield for 1915 showed an increase of 27 per cent. in quantity and 125 per cent. in value.

A full statement of the world's output cannot be expected during the progress of the war in Europe. The production of Spain and of Italy has been increasing since the outbreak of the war. The famous Santa Barbara deposits of Huancavelica, Peru, have passed into new hands and may be re-opened. The production of mercury from low-grade ores at Punitaqui, Chile, is reported. Deposits of cinnabar have been noted in Mexico, but no reports of recent operations have come to hand. The Terlingua field, of Brewster County, Tex., is said to extend for a considerable distance into Mexico, with promise of workable ore bodies similar to those on the Texas side of the border.

Tungsten; Electrolytic behaviour of —. W. E. Koerner. Amer. Electrochem. Soc., Sept., 1916. Met. and Chem. Eng., 1917, 16, 40—47.

THE single potentials of tungsten in $N/1$ solutions of acids, alkalis, and normal salts were calculated from E.M.F. measurements and found to be lowest in alkalis and highest in neutral salts. For the alkaline solutions the order of increasing potential was KCN, KOH or NaOH, NH_4OH (the potential in KOH or NaOH corresponding to that of thallium in a solution of thallium chloride of $N/1$ Tl ion concentration); for the acid solutions, H_2SO_4 , HCl, HNO_3 (the value in the last corresponding to that of copper in a solution of cupric chloride of $N/1$ Cu ion concentration); and for the neutral salts, KNO_3 , KF, KBr, KCl, K_2SO_4 , KI. The electrochemical equivalent of tungsten was found to be 0.3173 mgrm. per coulomb, a value corresponding closely with the theoretical. Tungsten occurs as cation in acid and anion in alkaline solutions. Tungstic acid is hydrolysed, and dissolved as $\text{W}(\text{OH})_6$ by mineral acids, being most soluble in nitric and least in hydrochloric acid; $\text{W}(\text{OH})_6$ in water is an electrolyte and not a colloid. Tungsten dissolves anodically, and becomes passive, in aqueous and non-aqueous solutions of alkalis, acids, and salts. In aqueous solutions of acids and salts passivity occurs at low current densities, and the active state is maintained only at very low current densities; but in aqueous solutions of alkalis, in a solution of hydrogen chloride in absolute alcohol, in hydroxylamine, and in methyl-, ethyl-, and propyl-ammonium hydr-

oxides, passivity occurs only at very high current densities. The passivity of tungsten is due to adherent films of hydrated tungsten oxides which may be readily dissolved and the passivity destroyed. The films appearing on the anode vary in colour from brown, through blue to yellow, and the degree of passivity varies with the colour of the film. In experiments on the use of tungsten in storage cells, the potential difference between the brown oxide (positive) and the blue oxide (negative) was found to be +0.75 volt.—W. E. F. P.

Ruthenium; Action of oxygen on —. A. Guthrie, G. A. Leuchs, H. Wiessmann, and O. Maisch. Z. anorg. Chem., 1916, 96, 182—206. J. Chem. Soc., 1917, 112, ii., 38. (Compare Guthrie and Ransohoff, Z. anorg. Chem., 1905, 45, 243.)

FINELY powdered ruthenium oxidises rapidly when heated in oxygen, the maximum absorption of oxygen corresponding very closely with the formula RuO_2 . The value actually obtained is very slightly lower, owing to volatilisation. It is independent of temperature between 700° and 1000° C., although the rate of oxidation varies considerably. The formation of the volatile tetroxide begins at 600° C., and then increases rapidly, being 4000 times as great at 1200° as at 700° C. Crystals of the dioxide are observed in the sublimate. Metallic ruthenium is rendered more compact by heating at 800° C. Previous heating at a high temperature in hydrogen reduces the velocity of oxidation.

Utilisation of waste heat for steam generating purposes. Pratt. See 1.

PATENTS.

[Steel] rails; Treating —. E. F. Kenney, Westmont Borough, Pa. U.S. Pat. 1,205,998, Nov. 28, 1916. Date of appl., Mar. 20, 1916.

THE rails are finished at a temperature of 1400°—2000° F. (740°—1090° C.), quenched in a vertical or slightly inclined position so as to cool them to a temperature not less than 400° F. (205° C.), again heated to above 800° F. (425° C.) but not higher than their recalcrescent temperature, and straightened before they have cooled to less than 600° F. (315° C.).—W. R. S.

[Iron and steel.] Rust-proofing metal; Process for —. W. H. Allen, Assignor to Parker Rust Proof Co. of America, Detroit, Mich. U.S. Pat. 1,206,075, Nov. 28, 1916. Date of appl., Aug. 21, 1915.

ARTICLES of iron or steel are rendered rust-proof by immersing them in a saturated phosphoric acid solution of manganese phosphate until hydrogen ceases to be evolved.—W. R. S.

Furnace [for treating steel]. F. J. Ardner, Detroit, Mich. U.S. Pat. 1,206,077, Nov. 28, 1916. Date of appl., Feb. 3, 1916.

A FURNACE for treating steel comprises an annular conduit of refractory material, the bottom of which is formed by a rotating table consisting of connected metallic segments having channelled flanges at their edges, and covered with refractory material. Refractory projections are disposed in the channel of the flanges so as to retain the refractory material upon the table.—W. R. S.

Steel; High-speed —. J. M. Flannery, Assignor to Standard Chemical Co., Pittsburgh, Pa. U.S. Pats. (A) 1,210,625, (B) 1,210,626, (C) 1,210,627, Jan. 2, 1917. Dates of appl. (A and B) Feb. 19, 1916, (C) Sept. 7, 1916.

(A) URANIUM, in the proportion 0.05 to 5%, is

added as sole toughening agent to the steel. (B) Uranium is added to replace part of the tungsten in tungsten steel, so as to give approximately 8% tungsten and 3% uranium. (C) Uranium is added to molybdenum steel to give approximately 3 to 10% of molybdenum and 3% uranium.—B. N.

Metal insulated against electrolysis and corrosion; Manufacture of rigid pieces of —. P. M. Stewart, New York. Eng. Pat. 18,947, Dec. 28, 1915.

THE metal is cleaned, then heated, a layer of bituminous composition is applied to the heated surface, and, whilst the bitumen is soft, a layer of fibrous insulating material, such as asbestos paper, is pressed into firm contact with it. (Reference is directed, in pursuance of Sect. 7, Sub-sect. 4, of the Patents and Designs Act, 1907, to Eng. Pat. 27,101 of 1911.)—B. N.

Cobalt-silver alloy; Electrolytic deposition of —. P. Marino, London. Eng. Pat. 102,828, Jan. 7, 1916. (Appl. No. 346 of 1916.)

THE electrolyte is prepared from aqueous solutions of a salt or oxide of each of the metals, such as cobalt acetate and silver nitrate, each of these being added to separate solutions of sodium thiosulphate or bisulphite; the two solutions are then mixed in relative proportions corresponding to the composition of the alloy to be deposited.—B. N.

Anodes for electroplating. G. Jones, Birmingham. Eng. Pat. 102,897, July 29, 1916. (Appl. No. 10,745 of 1916.) Addition to Eng. Pat. 17,328, Dec. 10, 1915 (this J., 1916, 895).

SHEETS of perforated celluloid are secured to wood separating pieces, or to a wood frame, by insulated or protected screws, rivets, or the like, so as to form the container for the nickel or cobalt pellets. Conductors of a similar metal are connected to the bottom contact strip, upon which the anode metal rests, and the strip is secured between the pieces of the frame.—B. N.

Plating metals [iron and steel with nickel]; Process for —. C. W. Parker, Assignor to Parker Rust Proof Co. of America, Detroit, Mich. U.S. Pat. 1,211,218, Jan. 2, 1917. Date of appl., July 31, 1916.

IRON and steel articles are immersed in a solution of phosphoric acid mixed with manganese oxide, and then cleaned mechanically, the articles being afterwards suspended in a nickel-plating bath containing nickel sulphate.—B. N.

Pyrometers for metallurgical and like operations. F. C. Fairholme, W. R. Barclay, and G. E. M. Stone, Sheffield. Eng. Pat. 103,048, Apr. 3, 1916. (Appl. No. 4855 of 1916.)

THE pyrometer consists of (a) a vertical outer tube, the lower end of which is made of silica and the upper end of metal. The metal portion is surrounded by a second tube which slides over it and can be adjusted to any required position by means of slots and set-screws, (b) a vertical rod, fitting loosely inside the tube, the lower part being made of silica or other refractory material and the upper part of metal. The lower end of this rod rests on a piece of fusible metal at the bottom of the tube; its upper end passes through a hole in the cap covering the top of the tube and is pivoted to a lever of the first order which acts as a pointer. The free end of the pyrometer is immersed in the contents of the crucible, or other material of which the temperature is to be

ascertained; as soon as the temperature of the latter is sufficiently high, the metal at the bottom of the pyrometer fuses, the rod resting on it falls, and the free end of the pointer rises. The pyrometer is then withdrawn, the end of the pointer is depressed by hand and kept down by a spring catch so that the lower end of the vertical rod may be kept clear of the fusible metal until the latter has again solidified. The fusible metal used is selected in accordance with the temperature to be indicated. In the manufacture of crucible steel, it may consist of an alloy similar to that being manufactured, but rather less fusible, so as to indicate the pouring temperature and not the melting point of the product to be tested.

—A. B. S.

Sintering-machines; Ignition furnace for —. F. W. Yost, New York, and B. G. Klugh, Cleveland, Ohio, Assignors to American Ore Reclamation Co., New York. U.S. Pat. 1,206,397, Nov. 28, 1916. Date of appl., March 11, 1915.

THE furnace has a combustion chamber and supply connections leading to different sources of fluid fuel which may be used independently or in admixture. A transverse fuel-distributing chamber provided with burner orifices at its base is situated above the combustion chamber.—W. R. S.

Tungsten; Method of producing malleable —. A. Helfgott, Uj-Pest, Hungary, Assignor to General Electric Co., New York. U.S. Pat. 1,206,704, Nov. 28, 1916. Date of appl., July 16, 1913.

FINELY pulverised tungsten, which has been heated in a reducing atmosphere to free it from oxide while maintaining its fineness unimpaired, is mixed with coarsely granular tungsten and the mixture pressed into a coherent mass which is subsequently sintered.—W. R. S.

Aluminium; Flux for soldering —. C. F. Kriews, Assignor to F. C. Kriews, Cleveland, Ohio. U.S. Pats. (A) 1,208,798 and (B) 1,208,799. Dec. 19, 1916. Dates of appl., Feb. 10 and Apr. 21, 1916.

(A) A GLYCERIDE of a fatty acid, e.g., olive oil, or (B) a fatty acid such as oleic, palmitic, or stearic, obtained from animal fats, is used as a flux for soldering aluminium.—W. F. F.

Electric welding; Method of and apparatus for —. F. H. Neff, Assignor to The Electric Railway Improvement Co., Cleveland, Ohio. U.S. Pat. 1,209,871, Dec. 26, 1916. Date of appl., June 15, 1915.

A RAIL is homogeneously united to a smaller metal bond, having a lower fusing point and greater conductivity for heat, by holding the two in contact, and heating the bond directly by pressing an electrode, composed of a number of electrically separated resistance elements, against it. An electric current is passed in recurring cycles successively through different pairs of the resistance elements and the bond arranged in series, whereby the bond and the contacting surface of the rail are brought to a welding temperature.—B. N.

[Ores and] *matte; Process and apparatus for converting [smelting]* —. S. R. Garr, Garfield, Utah, Assignor to American Smelting and Refining Co. U.S. Pat. 1,209,282, Dec. 19, 1916. Date of appl., Oct. 21, 1915.

A CONVERTER for the treatment of ore or matte is provided with a cooled conduit extending through the upper part of its wall, through which silica

is blown into the closed space above the material and allowed to settle uniformly on the surface.—W. F. F.

Ores; Method of recovering valuable constituents of —. H. G. C. Thofelm, Pittsburgh, Pa. U.S. Pat. 1,210,724, Jan. 2, 1917. Date of appl., Mar. 3, 1915.

AN electrical field is maintained between electrodes in a mixture of comminuted ore and water, and a compressed gaseous mixture of nitrogen pentoxide and air is injected into the field in such a manner as to cause a circulation and agitation of the liquid through the reaction zone between the gas and water.—W. F. F.

Precious metals; Process for separating — from their ores. W. H. Aghan, Burke's Flat, Victoria, Australia. U.S. Pat. 1,210,880, Jan. 2, 1917. Date of appl., Dec. 9, 1914.

THE ore is neutralised with lime and then treated with a solution of sulphuric acid, corrosive sublimate, and common salt, with or without potassium cyanide. Other reagents capable of modifying the action of the bath are excluded.—W. F. F.

Cementing or case-hardening material. R. B. Corey, Edgewood Park, Pa. U.S. Pat. 1,211,093, Jan. 2, 1917. Date of appl., Mar. 29, 1916.

CARBONACEOUS material is mixed with 10% of its weight of magnesium oxide, or a mixture or compound reducible by heat to the oxide, such as a mixture of magnesium oxide and carbonate.—B. N.

Preparing metal for painting; Method of —. J. H. Gravel, Philadelphia, Pa. U.S. Pat. 1,211,138, Jan. 2, 1917. Date of appl., July 22, 1916.

A STRONG solution of phosphoric acid, mixed with alcohol, is applied to the surface of the iron to be cleansed, and the metal is then washed with a limited quantity of water to form a relatively weak solution of phosphoric acid, whilst also removing the products of the cleansing action.—B. N.

Metal wires; Apparatus for production of —. J. Pintsch A.-G., Berlin. Ger. Pat. 293,238, Sept. 5, 1914. Addition to Ger. Pat. 291,994 (see Fr. Pat. 469,212; this J., 1915, 36.)

THE apparatus described in the original patent is so modified as to allow of the heating of several wires at once. Care must be taken to prevent contact of the wires, with resultant fritting together in the heated zone. For the same expenditure for heat and labour, a much increased output is possible.—H. J. H.

Thickening and agitating [ore] pulp; Apparatus for —. J. Van N. Dorr, Denver, Colo. U.S. Pat. 1,211,828, Jan. 9, 1917. Date of appl., June 26, 1913.

SEE Eng. Pat. 22,411 of 1913; this J., 1914, 950. Several of the vessels are arranged in series, the agitating chamber of one vessel being connected with the settling space of another.

Steel; Manufacture of —. G. J. B. Chetwynd, West Riding. U.S. Pat. 1,211,545, Jan. 9, 1917. Date of appl., Jan. 2, 1914.

SEE Eng. Pats. 1306, 11,778, 12,961, 14,431, and 16,821 of 1913; this J., 1914, 597.

Lead alloys; Manufacture of —. F. C. Frary, Niagara Falls, N.Y., and S. N. Temple, St. Paul, Minn. Eng. Pat. 101,086, July 19, 1916. Under Int. Conv., July 31, 1915. (Appl. No. 10,152 of 1916.)

SEE U.S. Pat. 1,158,672 of 1915; this J., 1915, 1256.

Lead alloys; Manufacture of —. F. C. Frary, Niagara Falls, N.Y., and S. N. Temple, St. Paul, Minn. Eng. Pat. 101,087, July 19, 1916. Under Int. Conv., Aug. 2, 1915. (Appl. No. 10,153 of 1916.)

Electrochemical chlorination of benzene and toluene. Fichter and Glantzstein. See III.

Electrolytic behaviour of tungsten. Koerner. See X.

PATENTS.

Furnace; Electric —. J. W. Moffat, Toronto, Canada. U.S. Pat. 1,208,817, Dec. 19, 1916. Date of appl., Mar. 21, 1916.

THE furnace is composed of a stationary stack, closed below by a plate provided with a number of openings adapted to register with similar openings in the top of a reduction chamber, the latter and a crucible being in fixed relationship with each other, and adapted to be tilted as a unit. The stack is provided with means for pre-heating the charge by the gases from the reduction chamber. The stack and reduction chamber are normally in communication, but communication with the stack is cut off when the reduction chamber and crucible are tilted.—B. N.

Treating materials electrolytically; Process of —. W. E. Greenawalt, Denver, Colo. U.S. Pat. 1,209,835, Dec. 26, 1916. Date of appl., May 13, 1913.

METALLIC salts in a finely-divided condition are electrolysed, the anode electrolyte being separated from the cathode liquor by a diaphragm, and both liquids being simultaneously agitated to keep the material in suspension during the electrolysis, whilst maintaining a relative motion between the electrodes and the finely-divided material. The electrolyte is withdrawn from one compartment, and passed through the other, but without allowing it to mingle with the liquid in the latter compartment. The material is subjected to the action of a direct current, using insoluble anodes, thus causing a disintegration of the anode material, and the loosening of the disintegrated anode material is facilitated by the action of an alternating current working in conjunction with the direct current.—B. N.

Electrolysis of water with gasholders dipping into the electrolyte. Elektrizitäts Akt.-Ges. vorm. Schuckert und Co., Nuremberg. Ger. Pat. 291,909, Sept. 1, 1914.

THE lower parts of the gasholders are provided with openings so arranged that in the event of the gas pressure becoming excessive, gas escaping from one holder cannot get into the other one and irregularities in the liberation of the gas do not affect the pressure at the outlet.—B. V. S.

Platinum electrodes. Chem. Fabr. Grünau Landshoff und Meyer Akt.-Ges., and E. Bürgin, Grünau. Ger. Pat. 295,178, May 24, 1914.

ALUMINIUM is used as a support and conductor for platinum electrodes. The platinum may be in the form of wide-mesh gauze of fine wire, large surface and great stability and reliability of action being still obtained. Even with aluminium at the anode, there are no counter currents, the "valve" action of the aluminium being still retained. There is no corrosion even at the points of contact of the aluminium and the platinum, although the aluminium is not completely covered by the platinum nor protected from the liquid. The aluminium may be in the form of a tube carrying a stream of water and it may be coated with a layer of Bakelite or similar insulating material.—B. V. S.

Electric furnaces. M. M. Kohn, New York. Eng. Pat. 103,062, May 17, 1916. (Appl. No. 7014 of 1916.)

SEE U.S. Pat. 1,187,630 of 1916; this J., 1916, 897.

Manufacture of rigid pieces of metal insulated against electrolysis and corrosion. Eng. Pat. 18,047. See X.

Fatty acids of high purity and melting point; Process for producing —. J. Starrels, New York. U.S. Pat. 1,209,512, Dec. 19, 1916. Date of appl., Mar. 1, 1916.

LIQUID glycerides or semi-solid fats (lard, etc.) are hydrogenated in presence of nickel until their iodine value is reduced to about 0 and their melting point is raised to about 62° C., and the resulting solid glycerides are hydrolysed (e.g., by means of Twitchell's process). Finally hydrocarbons and colouring matters formed during the hydrogenation are removed, by means of a solvent or otherwise, from the fatty acids.—C. A. M.

Fatty product from fixed oils and fats and process of manufacturing same. E. Klein, New York. U.S. Pat. 1,209,723, Dec. 26, 1916. Date of appl., Jan. 12, 1916.

OIL-BEARING material is agitated with potassium and sodium hydroxides, sodium carbonate, and a solution of a salt (sea salt, rock salt, natural or artificial Seignette salt), while being heated and subjected to the action of hot compressed air and steam, which are injected into the mass at the bottom of the tank. At the same time a cooling medium is applied to maintain the temperature at about 58° C., and, after 2 hours, the mixture is left to separate into layers. The uppermost layer is decanted and again treated in a tank so as to separate the higher fatty acids, and, after admixture with fibre, the unsolidified mass is decanted and heated indirectly by steam, while steam and hot compressed air are injected into it at about 93° to 110° C. Subsequently the mass is agitated first alone and then with a decolorising and

bleaching agent (constituents of powdered oyster shells and coal ashes), accompanied by hot compressed air, while heated by indirect superheated steam (about 110° C.), and, after settling, is decanted. The resulting product is a tasteless, odourless, neutral and permanently colourless liquid, which solidifies at -2° to +3° C., and has a sp.gr. of 0.901 to 0.914 at 15.5° C. It does not absorb oxygen or moisture from the air and therefore does not become rancid; it decomposes when distilled *in vacuo*, and is sparingly soluble in alcohol, but readily soluble in ether.—C. A. M.

Unsaturated [fatty acids and esters]; Conversion of — into saturated compounds. E. B. Higgins, Wallasey. U.S. Pat. 1,211,704, Jan. 9, 1917. Date of appl., Apr. 19, 1913.

SEE Eng. Pat. 18,282 of 1912; this J., 1913, 917.

Production of stable colloidal solutions. Ger. Pat. 295,164. See I.

XIII.—PAINTS; PIGMENTS; VARNISHES; RESINS.

PATENTS.

Pigment and paint; Magnesium-containing —. O. W. Pickering, Springfield, Mass., Assignor to Pickering Paint and Pigment Co. U.S. Pat. 1,211,346, Jan. 2, 1917. Date of appl., June 2, 1916.

FLOCCULENT magnesium aluminate is incorporated with a drying oil, with or without driers, or with other suitable medium.—C. A. M.

Resin or other material; Apparatus for heating or melting and delivering —. C. W. Goodyear, Dudley. Eng. Pat. 102,835, Jan. 13, 1916. (Appl. No. 561 of 1916.)

THE apparatus in which the resin, etc., is melted by means of a steam coil or the like is provided with one or more delivery conduits, through each of which the heating medium is made to circulate in a separate conduit system returning to the heating tank. The apparatus is particularly suitable for varnishing the interior of shrapnel or other shells.—C. A. M.

Phenolic condensation product. W. B. Jones, Perth Amboy, N.J., Assignor to General Bakelite Co., New York. U.S. Pat. 1,209,165, Dec. 19, 1916. Date of appl., Mar. 5, 1913.

A COATING composition contains a phenolic condensation product, *e.g.*, an ester, and a cellulose ester, and a solvent containing a chlorinated hydrocarbon, *e.g.*, tetrachloroethane.—F. W. A.

Plastic composition and process of making same. L. V. Redman, Lawrence, Kans., Assignor to Redmanol Chemical Products Co., Chicago, Ill. U.S. Pat. 1,209,333, Dec. 19, 1916. Date of appl., Apr. 4, 1912.

AN amorphous condensation product is obtained by the anhydrous interaction of a phenolic or hydroxy-aromatic compound with an active methylene compound containing nitrogen (*e.g.*, solid hexamethylenetetramine), and a hydroxylated aromatic compound of the general formula R.X, where R represents an aromatic radicle, and X a non-reactive group. Heat may be used to promote the reaction, in which the nitrogen is liberated as ammonia.—C. A. M.

Resin-like condensation products; Process for the production of —. F. Pollak, Berlin. U.S. Pat. 1,210,982, Jan. 2, 1917. Date of appl., June 4, 1912.

XV.—LEATHER; BONE; HORN; GLUE.

Hide and leather fibres; Structure of —. W. Möller. *Collegium*, 1916, 16—26, 51—68, 92—118, 127—151, 180—208, 236—247, 270—291, 317—330, 349—355. *Z. angew. Chem.*, 1916, 29, Ref., 519.

EACH hide fibre consists of a great number of fibril complexes, each complex containing an undetermined number of fibrils, between which gelatin is found in swollen hide. During swelling and falling, the fibrils and their complexes undergo alterations of position, etc., including twisting, the fibrils of fallen hide however being straight. The interfibrillary penetration of alkali during swelling is easily recognised with the ultra-microscope. Chrome, aldehyde, and chamois leathers show a closer structure of fibres than vegetable-tanned leathers, and are naturally less easily acted upon by boiling with water. Whilst the unswollen hide fibre is more or less optically empty, the leather fibre shows a distinct ultra-microscopic structure, which with vegetable-tanned leather gives information as to the subdivision and amount of tannin taken up, and which can be brought into relation with the physical properties of the leather. The fibrillary structure of gelatin is proved by the ultra-microscope to be a network.—F. C. T.

Tannin colloids; Vegetable —. A theory of their constitution and mode of action. W. Möller. *Ledertechn. Rundschau*, 1915, 441—457; 1916, 1—16, 43—50, 81—92, 125—127, 175—180, 227—235, 266—269, 311—317. *Z. angew. Chem.*, 1916, 29, Ref. 519. (See also this J., 1915, 807.)

ALL vegetable tanning materials contain a peptiser and a peptisable substance, the proportions of which determine the colloidal properties of the aqueous extract. The tannin is the peptiser, the peptisable substances including polymerised tannin, ellagic acid, catechin, and phlobaphenes, according to the nature of the material. The peptiser forms a solid solution with the hide substance and plays a double rôle in the tanning process, first converting suspensions into colloidal emulsions, and then bringing the peptised particles to the fibril surfaces where the depeptisation takes place. The resistance of the leather to water is in inverse proportion to the amount of peptiser taken up in the solid solution. The shape and size of tannin particles have an important influence on the yield of leather, and hide has a selective power with regard to sub-microns. The phenomena of tanning result solely from irreversible colloidal actions, there being no purely chemical changes. The ancient process of bark tanning is an example of slow peptisation taking place during the tanning. By the use of liquors peptised matter is more regularly brought

to the hide fibres, and in drum tannage this is not only accelerated but the peptised matter comes to the fibre in liquid form.—F. C. T.

Quebracho extract manufacture in Argentine and Paraguay. Board of Trade J., Feb. 15, 1917.

ARGENTINE and Paraguayan manufacturers of quebracho extract have recently concluded an agreement for the purpose of limiting production. The increased demand for tanning extract due to the war, brought about a steady rise in price, until, early in 1916, the figure of 230 pesos gold per metric ton had been reached. The result was that extract factories considerably increased their output. But, later, with the increasing use of substitutes, such as oak and chestnut extracts, the price of quebracho extract dropped to 100 pesos gold per metric ton. The object of the agreement is the reduction of the output of extract factories to meet the estimated world's consumption. Extract will be delivered at a uniform price to one selling company which will distribute profits *pro rata* among producers. Six Companies in Argentina and four in Paraguay, having a total output of 165,000 metric tons of extract, are reported to have entered the combine. The capital invested in the quebracho industry in Argentina alone is estimated at 100,000,000 pesos currency. Exports of quebracho extract from Argentina rose from 80,153 metric tons in 1914 to 100,213 metric tons in 1915, and will probably show a further increase during 1916. Following the conclusion of the agreement, the price of quebracho extract rose to 150 pesos gold per metric ton.

NOTE:—Peso gold = 4s. (par rate). Peso currency = 1s. 9d. (about).

Artificial leather and leather substitutes: Examination of —. R. Lauffmann. *Kunststoffe*, 1916, 6, 54—56, 66—68, 82—84, 93—94. *Z. angew. Chem.*, 1916, 29, Ref., 520.

FATS and unsaponifiable fatty matter, incompletely sulphonated oils, and part of the caoutchouc, gutta-percha, oxidised oils and resins, pitch, tar, or asphalt present, are removed by extraction with ether and petroleum spirit, and glue, etc., gums, starch, tannin, glycerol, alkali soaps, and soluble inorganic matter removed from the residue by extraction with water. The residue from this treatment is treated with hydrochloric acid and shaken with ether to extract the fatty or resin acids of insoluble soaps, the bases and other inorganic matter being found in the aqueous layer. A further extraction with acetone removes cellulose esters, nitro- and acetylcellulose, as well as free sulphur and part of any vegetable fibrous matter present. Fully sulphonated oils, oxidised oils, decomposition products of leather and hide, and further portions of pitch, etc., are removed by alcoholic potash, and from the residue further portions of caoutchouc and gutta-percha and the remainder of the pitch, etc., are extracted by pyridine. A final extraction with toluene completely removes caoutchouc and gutta-percha, leaving a residue containing only plant fibre, etc., and insoluble inorganic matter. Details for the examination of the various extracts are given in the original paper.—F. C. T.

Waterproofing of flexible and porous material [e.g. leather]. J. W. Barber, Newton, Mass., U.S.A. Eng. Pat. 102,813, Jan. 3, 1916. (Appl. No. 64 of 1916.)

WATERPROOFING substances such as colophony,

petroleum jelly, paraffin wax, ozokerite, etc., singly or in mixture, are dissolved in naphtha or other suitable solvent, or melted, and leather or other material is impregnated by a short immersion at a suitable temperature not above 60° C. Two baths are used, the second consisting of harder materials than the first, for the purpose of preventing subsequent exudation.—F. C. T.

Fur skins; Process in tanning —. R. Nasse, Assignor to A. Prohofskey, St. Paul, Minn. U.S. Pat. 1,210,968, Jan. 2, 1917. Date of appl., Jan. 3, 1916.

SKINS are treated with a mixture of an aqueous solution of inorganic substances such as potash alum, salt, and sodium borate, with a fermented or unfermented aqueous solution of wheat flour, yeast, and alcohol.—F. C. T.

Casoin; Process for manufacture of horny substances from —. A. Bartels, Harburg, Germany. U.S. Pat. 1,211,526, Jan. 9, 1917. Date of appl., Dec. 28, 1915.

SEE Eng. Pat. 10,019 of 1915; this J., 1916, 935. The moistened casoin may be mixed with an aqueous solution of hexamethylenetetramine and glycerin.

XVI.—SOILS; FERTILISERS.

Soil; The organic matter of the —. I. Some data on humus, humus carbon, and humus nitrogen. R. A. Gertner. *Soil Sci.*, 1916, 2, 395—442.

THE total nitrogen and total carbon contents of eight mineral soils, of three peats, of a strongly acid "muck" soil, and of five different kinds of unchanged vegetable materials, were determined on air-dried, unheated samples. The matter extracted by 4% ammonia (calculated as NH_4OH) solution was analysed for carbon, humus, and nitrogen, and that removed by 4% sodium hydroxide solution for carbon and soluble nitrogen, these estimations being performed on samples which had, and which had not, been previously leached with 1% hydrochloric acid. The residues from the sodium hydroxide extraction were leached with acid, again extracted with the alkali, and the carbon and nitrogen in the extracts determined; these elements were also determined in the 1% acid extract and in the liquid obtained by leaching the residues from the last process with water. The analytical data led to the following conclusions: The so-called "humus" extracted from soils and peats is not a typical soil product, for similar extracts are obtained from undecomposed vegetable matter. The "*matière noire*" of Grandeau contains much colourless material, the presence of which is masked by the black compound or compounds. The "humus" from sphagnum-peat, from brown peat, and from unchanged vegetable materials has a reddish-brown colour which in concentrated solutions appears black. A 4% solution of sodium hydroxide does not extract the same matter from a soil as a corresponding ammonia solution, nor does it extract the same quantity: hence results obtained with the two different solvents are not comparable. The ammoniacal extract of soil (after leaching with 1% hydrochloric acid) contains less carbon and has a deeper colour than that obtained with sodium hydroxide. In general, soil nitrogen is very similar to the nitrogen in undecomposed vegetable matter (e.g., oak leaves, sweet fern

leaves, oat plants, alfalfa hay), but it differs from it in being much less soluble in 1% hydrochloric acid, and also much less of it goes into solution in 4% sodium hydroxide. All the mineral soils, and a calcareous peat, contained an intensely black pigment which was absent from the acid peats and the vegetable materials. This pigment contained relatively little of the soil nitrogen, and it probably has little to do with soil fertility, *per se*. It is a true soil product and may be of bacterial origin: in amount it rarely exceeds 40% of the so-called humus extracted by alkalis. Humus determinations based on alkali extractions are valueless, and should be superseded by determinations of total organic carbon.—E. H. T.

Soil; The organic matter of the ——. II. A study of carbon and nitrogen in seventeen successive extracts. The black soil pigment. R. A. Gortner. *Soil Sci.*, 1916, 2, 539—548.

Two attempts were made by slightly different methods to isolate the black pigment of the soil, but without success, the separated materials containing 37.47% and 51.17% of ash. The pigment is soluble in ammonia solution and in very dilute sodium hydroxide, but insoluble in a 4% solution of the last-named, and use was made of these facts in attempting the isolation. The first six extractions with sodium hydroxide removed relatively more nitrogen than carbon from the silt loam soil employed, but the subsequent extractions, as well as the pigment solutions obtained after purification by precipitation with acid and flocculation of the clay, contained relatively more carbon than nitrogen. The ratio of carbon to nitrogen was much higher in the final soil residue than in the original soil. The impure pigment first isolated was a hard, black solid, from which extraction with alcohol in a Soxhlet apparatus removed a colourless, crystalline substance which has not yet been investigated. Purified in this way, the pigment resembled anthracite in colour and hardness, but the high ash content indicated the probable presence of much colloidal clay. On an ash-free basis, the purer product contained: C 61.3%, H 4.3%, N 2.8%, and O 31.6%. With the exception of the high nitrogen content, these figures are practically identical with those obtained by Detmer for his "humic acid" (1871). The substance forms a black solution in sulphuric acid, and intensely black solutions in ammonia solution and very weak alkali solutions, from which it is precipitated by acids and by solutions of the heavy metals; it is insoluble in all the ordinary organic solvents.—E. H. T.

Soil; Influence of salts on the bacterial activities of ——. J. E. Greaves. Soil Sci., 1916, 2, 443—480.

A rich sandy loam soil, well supplied with all plant nutrients except nitrogen, and possessing ammonifying and nitrifying powers about equal to the average soils of the arid regions, was treated in 100-grm. portions with 2 grms. of dried blood and measured amounts of salts, the whole being then incubated at 28°—30° C. for 4 days, and the ammonia determined by distilling with magnesia and collecting in standard acid. The salts employed were the chlorides, nitrates, sulphates, and carbonates of sodium, potassium, calcium, magnesium, manganese, and iron. It was established that their toxicity towards ammonification was determined chiefly by the nature of the acid radical, and that as a general rule the chlorides were the most harmful, and the carbonates the least toxic, nitrates and sulphates occupying the intermediate positions. No general relation was found between the concentration and the toxic power, and the latter varied with the nature of the

salt. The degree of inhibition caused by the added salt is to some extent connected with the increased osmotic pressure exerted, but is probably mainly due to the action of the salt on the living protoplasm of the cells. Those salts which are normally found in alkali soils (*e.g.*, NaCl, CaCl₂, Na₂SO₄) are among the most harmful to ammonification. With the exception of the chlorides of calcium and potassium, the nitrates of calcium and magnesium, and the sulphates of sodium and potassium, all the salts used produced stimulating effects in certain concentrations. Thus sodium chloride in the concentration of 7.2 parts of sodium per million of soil increased ammonification, and only began to become toxic when 14.4 parts was present; the chlorides of magnesium, ferric iron, and manganese, were stimulating up to 1.9, 23.2, and 31.3 parts of metal per million, respectively. Calcium sulphate stimulated in all concentrations up to 200 parts per million, and became toxic at 400 parts per million. With the possible exception of manganous chloride, all the manganese salts could stimulate ammonification, the sulphate being the most powerful. In low concentrations, the iron compounds were all beneficial; ferric chloride exerted its maximum effect at 2.9 parts per million, ferric nitrate and sulphate and ferrous carbonate requiring double the amount. The carbonates showed the stimulating effect through the widest range of concentrations: the maximum amounts of sodium, potassium, magnesium, and iron (Fe⁺⁺) which the soil could carry without diminished ammonification were 2300, 3128, 60.8, and 186.0 parts per million respectively. Manganese and calcium as carbonates showed no toxic action in any of the concentrations employed. The extent of stimulation appears to be determined largely by the nature of the metal present. The amounts of sodium, calcium, potassium, and magnesium chlorides required to reduce ammonification by one-half are roughly the same as those necessary to diminish the growth of wheat to the same extent. Salts most active in stimulating higher plants are also most effective in stimulating bacteria, the causal sequence being probably, bacterial stimulation, increased available plant-food, plant stimulation.—E. H. T.

Ammonification and nitrification [in soils]; The nature of ——. K. Miyake. Soil Sci., 1916, 2, 481—492.

THE curves showing the rates of increase of ammonia and nitric acid produced in a soil are very similar to the curve of an autocatalytic chemical reaction in which one of the products accelerates the change. Experimental results obtained by Lipman and Warrington on the rates of increase of ammonification and nitrification, respectively, are shown to be in full accordance with this view. The maximum increase of ammonia and nitric acid per unit of time is found to occur when these processes are half-completed; and the relationships can be expressed by the equation: $\log \frac{x}{A-x} = K(t-t_1)$,

where x is the amount of product produced at time t , A is the total amount produced, K is a constant, and t_1 is the time at which the processes are half-completed.—E. H. T.

Soils: Sulphur oxidation in —, and its effect on the availability of mineral phosphates. J. G. Lipman, H. C. McLean, and H. C. Lint. *Soil Sci.*, 1916, 2, 499—538. (See also this J., 1916, 1268.)

VARYING amounts of sulphur (flowers or precipitated) [S], of a very finely ground Tennessee brown rock phosphate (so-called "floats") [P],

and of a mixture of these two [S + P], were added to 100-grm. portions of sea sand inoculated with a soil infusion, of a manured greenhouse soil, and of a sandy loam (Sassafras) soil, contained in glass tumblers, which were then incubated at 22–24° C. for 30 weeks, the moisture content being kept constant. At intervals of two weeks determinations were made of the available phosphoric acid by the ammonium citrate method, of the water-soluble phosphoric acid, of the relative acidity, and of the sulphate present. In the sand cultures, the presence of either sulphur or of phosphate alone did not appreciably affect the amounts of available phosphoric acid, but a very great increase (about 800%) resulted from the combined [S + P] treatment. The acidity remained nearly constant in the control and [P] samples, increased about 14 times in the [S] vessels, and about 130 times in the [S + P] portions. In the greenhouse soil similar changes took place, but in the [S + P] tumblers the available phosphoric acid increased about 29 times, and the acidity about 436 times at the end of 30 weeks; the acidity in [S] increased 938 times in 18 weeks. It follows from this that in the [S + P] mixture, much of the increased acidity due to the oxidation of the sulphur was neutralised by the tricalcium phosphate, phosphoric acid being set free. The greenhouse soil was much superior to the sand as a culture medium. The results with the Sassafras loam soil were similar in nature but different in degree, indicating that the biological changes throughout the experiments were affected by the physical and chemical nature of the media. The water-soluble phosphoric acid content increased greatly in all cases where sulphur and "floats" were applied together; the greatest accumulation took place in the greenhouse soil and the least in the loam. The amount of sulphur oxidation increased *pari passu* with the liberation of available phosphoric acid, and generally, the results confirmed Lipman's theory that the micro-organic oxidation of sulphur in the soil renders available the phosphorus of mineral phosphates. The phosphate not only functions by neutralising the acid formed but also by supplying energy to the sulphur organisms. The most favourable water content of the soil is about $1\frac{1}{4}$ times the optimum (i.e., 50% of the water-holding capacity); unduly high or low moisture contents inhibit the oxidation and the liberation of available and water-soluble phosphoric acid. Soil, whether previously sterilised or not, became more active after inoculation with soil well supplied with sulphur-oxidising organisms. The amounts of sulphur and "floats" used in the experiments were in the ratio 1 : 3; in farm practice the ratio could be reduced to 1 : 2, but the proportion of fertilisers to soil should be relatively high.—E. H. T.

Soils; Ferrification in ———. [Determination of iron in soils.] P. E. Brown and G. E. Corson. Soil Sci., 1916, 2, 549–573.

The total iron content of a soil is satisfactorily determined by heating 5 grms. of soil with 15 grms. of sodium peroxide in a nickel crucible to a low-red heat, treating with hydrochloric acid, and making up the solution to 500 c.c. After heating 100 c.c. of this liquid with nitric acid to the boiling point, the iron is precipitated with ammonia, the filtered and washed hydroxide is dissolved in sulphuric acid, and after reduction with zinc, the ferrous solution is titrated with permanganate. Alternatively, the 100 c.c. of solution may be boiled with 20 c.c. of sulphuric acid, reduced with stannous chloride, treated with 10 c.c. of mercuric chloride solution, allowed to stand for 10 mins., and finally titrated with permanganate in presence of 25 c.c. of manganese sulphate solution. Since

the determination of the "ferrifying" power of a soil—i.e., the extent to which ferrous iron is oxidised to ferric—should involve the estimation of ferrous compounds in presence of ferric, a large number of attempts were made to devise a satisfactory method, but without success, failure being due to the adsorption of ferrous compounds by the soil and the action of organic matter in either oxidising or reducing the iron content. When soil is extracted with acids in a neutral atmosphere, the organic matter carried through disturbs the permanganate titration; and water does not dissolve the ferrous carbonate. Hence the ferrifying power had to be determined by means of water and sand cultures. In the former 100 c.c. of sterile water was treated with 0.1 gm. of ferrous carbonate and a soil infusion, fresh or sterile. After incubation the culture was filtered until clear, then treated with stannous chloride and titrated with permanganate. Ferrification was considered to have taken place if the iron content of the solution was greater in the bacterial culture than in the sterile, deferrification if it was less. For the sand cultures 100 grms. of clean, sterilised quartz sand was inoculated with fresh or sterile infusion and 0.1 gm. of ferrous carbonate added. The moisture content was kept at the optimum, and after the incubation the sand was shaken with water, filtered, and the iron in the filtrate determined. Both ferrification and deferrification were found to take place, and the extent of these processes appeared to vary with the content of organic matter, the temperature, and other factors. The infusion of a cultivated soil produced the greatest ferrification. The ferrifying bacteria flourished best in the water cultures, but no relation was observed between ferrifying power and content of organic matter. In the sand cultures, however, the conditions more nearly approximated to those of the field; and it was found that a high percentage of organic matter was related to increased ferrification; when organic matter was low, deferrification ensued. In addition to the iron bacteria, pure cultures of common organisms like *B. coli* and *B. pyocyaneus* were able to induce ferrification, as were also some of the common moulds.—E. H. T.

Potash in certain orthoclase-bearing soils; Availability of — as affected by lime or gypsum. L. J. Briggs and J. F. Breazeale. J. Agric. Res., 1917, 8, 21–28.

HEAVY applications of lime and gypsum are sometimes made to the soils of California on which citrus plants are grown, with the object of liberating the potash from the orthoclase and pegmatite in those soils. In the authors' experiments finely-ground samples of these minerals and of a virgin soil of granitic type were shaken for several days with solutions of calcium hydroxide and sulphate in graduated concentrations. The calcium hydroxide solutions did not materially affect the solubility of the potash in either pegmatite or orthoclase, but the gypsum solutions reduced the solubility of the potassium in orthoclase to an extent increasing with the concentration of the calcium sulphate. Neither addition had any appreciable effect upon the solubility of the potassium in the virgin soil, but gypsum reduced the solubility of the potassium in a citrus soil which had been under cultivation for some time. Wheat seedlings showed no increase of potassium when grown in water containing finely-ground orthoclase and calcium sulphate, over the amount in the wheat grown in water containing only orthoclase, whilst wheat seedlings grown in a citrus soil to which calcium sulphate had been added showed a decreased absorption of potassium.

—C. A. M.

Nitrogenous fertilisers; A vegetation experiment on the availability of— in an arid soil. C. B. Lipman and W. F. Gericke. *Soil Sci.* 1916, 2, 575—581.

LIPMAN'S method of determining the efficiency of nitrogenous fertilisers by the laboratory incubation test (this J., 1916, 1168) was checked by pot experiments on barley growing in Oakley blow-sand soil treated with (1) dried blood, (2) steamed bonemeal, (3) cottonseed meal, (4) ammonium sulphate, (5) sodium nitrate, and (6) calcium nitrate. In the first series these fertilisers were applied in amounts equivalent to those used in the incubation tests (i.e., 1% for the organic manures), and in the second the quantities used contained an amount of nitrogen equivalent to that in dried blood applied at the rate of 800 lb. per acre. The former series was a failure; the latter gave results closely resembling those obtained in the incubation tests. The order of efficiency was: for grain and straw-yields, 4—3—2—1—5—6; for total dry weight, 4—3—2—5—1—6; for roots, 4—3—5—6—1—2. In the last case 4 and 3 were much superior to the rest. In answer to the criticism of Kelley (this J., 1917, 94)—that the incubation tests are invalid owing to the use of excessive quantities of fertilisers—it is admitted that the laboratory conditions are dissimilar to those obtaining in the field, and also that better results would be obtained by using less of the fertilisers, but it is contended that even with the large quantities of the latter, the results are sufficiently accurate to show their relative fertilising powers.—E. H. T.

PATENTS.

Seeds, crops, plants, etc.; Treatment of growing—. A. J. Grinberg, New York. Eng. Pat. 2941 of 1915; date of appl., Jan. 20, 1916.

THE vitality of plants, whether in health, sickness, or disease, can be greatly improved by the use of a mixture containing bran, sawdust, and lime, to which is added ammonia liquor, corn (maize) starch, water, and scrap iron to generate heat by oxidation. It is best applied when mixed with 800 parts of soil, and during the autumn or winter; the roots absorb certain bacteria which enter the sap and promote health or cure disease. The liquid portion, e.g., starch $\frac{1}{2}$ oz., ammonia liquor $\frac{1}{2}$ oz., and water 1 quart, may be applied, separately and periodically, to the roots by means of pipes. Treated with this preparation, it is stated that grain crops can be doubled, and diseases due to insects and parasites, as, e.g., phylloxera, can be eradicated.—E. H. T.

Manure; Manufacture of— by means of bacteria. W. Thompson, Wexford. Eng. Pat. 103,142, Jan. 11 and Aug. 9, 1916. (Appl. Nos. 428 and 11,222 of 1916.)

PEAT is saturated with the effluent from a septic tank (or from farmyard manure) which has, preferably, been exposed to the air, at 20°—30° C., and treated with a very little milk. In this way the peat is broken down by aerobic organisms, the action of which is furthered by spreading the mixture in thin layers on trays. If a liquid manure be required, the freshly treated peat is mixed with twice its bulk of soft water and allowed to stand, more water being added subsequently if desired. After the aerobic treatment, dry, finely powdered slaked lime (or soil, or sand) is added to render the material neutral, to accelerate the drying, and to prevent "coagulation," i.e., setting to a tough mass on drying. Setting can also be prevented by stirring or blowing in air

from below. A more active manure can be obtained by inoculating the prepared material with special aerobic cultures. The finished product should be allowed to stand for 18—20 days before it is put on the land.—E. H. T.

XVII.—SUGARS; STARCHES; GUMS.

Sugar dealings; Restrictions on —.

THE Food Controller has issued three new Orders relating to sugar. The Dealings in Sugar (Restriction) Order, 1917, provides that no person shall on or after the 15th February, 1917, without a permit issued under the authority of the Royal Commission on the Sugar Supply, either on his own behalf or on behalf of any person:—(a) buy, sell, or deal in, or (b) offer or invite an offer, or propose to buy, sell, or deal in, or (c) enter into negotiations for the sale or purchase of or other dealing in, any sugar outside the United Kingdom, whether or not the sale, purchase or dealing, is or is to be effected in the United Kingdom.

The other two Orders relate to brewing sugar. The Brewers' Sugar Order, 1917, provides broadly that no brewers' sugar may be delivered from any warehouse except under the authority of the Food Controller, and that all brewers' sugar now in transit must be delivered into a warehouse. Certain exceptions, however, to this provision are made, especially as regards sugar sold to a brewer or brewers' sugar manufacturer, and to sugar imported for brewing purposes under special licences issued by the Royal Commission on the Sugar Supply. It is further provided that no brewing sugar shall be sold retail at prices exceeding current retail prices for granulated sugar.

The Brewers' Sugar (Returns) Order, 1917, requires persons who, at 8th February, 1917, own or have power to dispose of stocks of brewers' sugar exceeding three tons in weight to make a return on or before 22nd February to the Food Controller on a form to be obtained on application to the Ministry of Food, Grosvenor House, W.

"Brewers' sugar" is defined as sugar not above 89° of polarisation.

In connection with these two Orders the Royal Commission on the Sugar Supply announces that the granting of licenses for the importation of sugars under 89° of polarisation is suspended until further notice. This announcement does not apply to sugar already afloat, or to British West Indian Grocery Crystallised, British West Indian Muscovados, or British West Indian Grocery Syrup Sugar.

Sugar from the avocado; d-Mannoketoheptose, a new —. F. B. La Forge. *J. Biol. Chem.*, 1917, 28, 511—522.

FROM 3.5 kilos. of the pulped fruit of *Persa gratissima* (avocado or alligator pear), which is the source of *d*-perceitol, the author isolated 50 grms. of a new sugar, *d*-mannoketoheptose. It occurs in the free state in the fruit and is the first heptose isolated from a natural source. It melts at 152° C. (uncorr.) without decomposition, is not fermentable, has $[\alpha]_D^{20}$ = about +29 in aqueous solutions, and exhibits no mutarotation. The *p*-bromophenylhydrazone melts at 179° C. and the phenylosazone at 200° C. Its configuration is

and on reduction with sodium amalgam it yields the two corresponding heptitols, perseitol (*d*-α-mannoheptitol) and *d*-β-mannoheptitol (cp. Peirce, *J. Biol. Chem.*, 1915, 23, 327). Perseulose, produced from perseitol by *Bact. xylinum* (see Bertrand, this J., 1908, 869; 1909, 919) probably has the configuration

—J. H. I.

Molasses; Colouring matter of —. II. H. Stoltzenberg. *Ber.*, 1916, 49, 2675–2677. (See also this J., 1916, 1169.)

AFTER the removal of the colouring matter, $\text{C}_{26}\text{H}_{24}\text{N}_2\text{O}_8$, and a hygroscopic acid from the lead acetate precipitate obtained from the portion of molasses insoluble in alcohol, a syrup of bitter astringent taste remained. This contained a further quantity of colouring matter, which was removed by benzooylation in presence of sodium hydroxide, and precipitation with sulphuric acid. From the yellow filtrate a bitter principle in the form of a brown resinous acid of the composition, $\text{C}_{34}\text{H}_{40}\text{N}_2\text{O}_{15}$, was isolated. It is insoluble in benzene, soluble in absolute alcohol, and sparingly soluble in water. It melts on mercury at 61° C. to resinous globules. It is an excellent adhesive. —G. F. M.

XVIII.—FERMENTATION INDUSTRIES.

Malt; Dealings in and manufacture of —.

THE Food Controller has issued an Order, under date 3rd February, which provides that, except under the authority of the Food Controller, (a) no maltster or dealer in malt shall, on or after the 10th February, 1917, agree to sell any malt to any brewer for sale, or make delivery to any brewer for sale of any malt, other than malt deliverable under contracts made before that date; (b) no brewer for sale shall, on or after the 10th February, 1917, agree to buy any malt or to take delivery of any malt other than malt deliverable under contracts made before that date; and (c) no brewer for sale shall manufacture any malt from any barley agreed to be bought on or after the 10th February, 1917.

Malt diastase; Influence of the hydrogen ion concentration on the activity of —. L. Adler. *Biochem. Zeits.*, 1916, 77, 146–167. *J. Chem. Soc.*, 1917, 112, i., 61–62.

THE optimal hydrogen ion concentration for the action of malt diastase is $\text{pH}=4.9$. Its action is very effective between the limits pH 4.6 and $\text{pH}=5.2$. As the hydrogen ion concentration passes these limits in either direction, the activity of the enzyme rapidly decreases. Neutral salts are not without action on the diastatic activity, but this influence is small compared with that of the hydrogen ion concentration.

Fermentation; Studies in —. II. Autolysis of starch. W. Biedermann. *Fermentforschung*, 1916, 1, 474–504. *J. Chem. Soc.*, 1917, 112, i., 62.

THE author has previously shown that dilute boiled starch solution can be hydrolysed with comparative rapidity by saliva ash, and that this effect is due to an enzyme liberated from the starch under the conditions of experiment. It is now shown that a similar hydrolysis (autolysis) occurs without any addition if the starch solution is made at 70°–90° C. Reaction occurs considerably more rapidly at 35°–45° C. than at the ordinary temperature, and only the portion of starch which remains in solution suffers autolysis. Solutions which have been actually boiled generally become hydrolysed after a much longer period; extracts prepared by grinding starch with water do so much more rapidly. The diastatic power of such an extract is similar to that of a very dilute saliva solution, and transforms starch completely into sugar. Of the salts contained in saliva, the chlorides, particularly calcium chloride, promote diastatic action. The marked action of saliva ash in promoting the decomposition of starch solutions which have been subjected to prolonged boiling suggests that this mixture of salts promotes the new formation of the diastase (amylase) from starch. The action of the ash is much more pronounced than that of the individual chlorides (CaCl_2 , NaCl , KCl) contained in it; artificial mixtures of salts of similar activity have not been obtained up to the present time.

Fermentation; Activators of —. H. Euler and H. Hammarsten. *Biochem. Zeits.*, 1916, 76, 314–320. *J. Chem. Soc.*, 1917, 112, i., 71–72.

IT has been shown by Euler and Cassel (this J., 1913, 762) that the addition of ammonium formate and other substances increases the fermentation of yeast. It is now found that the formate does not also increase the amount of yeast formed. It is also found that the addition of phosphates, which increases the rate of fermentation in acid (but not in alkaline) solutions, does not cause a parallel increase in the growth of the yeast.

Albumin; Formation of — by yeast from different sources of carbon. T. Bokorny. *Munch. med. Woch.*, 1916, 63, 791–792. *J. Chem. Soc.*, 1917, 112, i., 72. (See also this J., 1916, 612.)

IN the large-scale production of yeast the carbon nutriment is the most difficult problem. Although urea can serve as a source of nitrogen, its carbon is not assimilated by yeast. According to the investigations of Naegeli and others, organic acids (citric, acetic, tartaric), as well as glycerol, asparagine, peptone, mannitol, and other carbohydrates, can be used as sources of carbon for yeast, and the nature of the latter determines the utility of the different sources. Pentoses are unfermentable, but, in suitable circumstances, can serve as sources of carbon. Dextrins are scarcely fermented by yeast cultures, but readily by crude yeast. Alcohol is utilised as a source of carbon by many moulds and bacteria. The growth of many yeasts is more vigorous in solutions containing alcohol than in sugar solutions. Brewers' yeast requires the presence of sugar during cultivation because the fermentation is a protection against bacteria. The development of other moulds is checked by the rapid formation of alcohol. Attempts to replace a portion of the sugar by methyl alcohol were unsuccessful, but good results were obtained with glycerol.

Enzymes: Poisoning of—*in the living [yeast] cell.* H. and B. Euler. *Fermentforschung*, 1916, 1, 465—470. *J. Chem. Soc.*, 1917, 112, i., 72—73.

THE authors have endeavoured to determine to what extent yeast suffers permanent damage after its fermentative power has been lessened by poison. Resorcinol has been used in the latter capacity, since that part of it which has not penetrated into the cell can be readily removed. In 0.5% solution the fermentative power of yeast is not completely destroyed in 24 hours, but this effect is produced by a 2% solution; all the cells are not killed, however, since fermentation sets in to some extent when the yeast is transferred to a non-poisonous sugar solution. 0.5% resorcinol, unlike a similar amount of toluene, does not promote the fermentation of sodium pyruvate by yeast. The degree of poisoning probably depends on the amount of poison absorbed. The activity of yeast is increased by minute quantities of resorcinol, a maximum action being observed at a concentration of about 0.0015%.

Beverages containing maltose, glucose, or maltose and glucose: Rate of turbidity in—A. W. Homberger and C. S. Marvel. *J. Amer. Chem. Soc.*, 1917, 39, 156—162.

THE authors investigated the behaviour, on storage, of pure aqueous solutions containing 0—3% of alcohol and 1.25% of sugar consisting of maltose, dextrose, or equal quantities of both. The solutions were prepared by dissolving the sugar in boiling distilled water, then adding the alcohol, and transferring the liquid to bottles previously heated for an hour in boiling water. Half of the bottles were closed with paraffined corks and sealing wax, whilst still hot; the others were cooled in an ice safe and similarly sealed after the contents had been saturated with carbon dioxide. The solutions containing only maltose as sugar, remained clear for six weeks, but all those containing dextrose showed turbidity and sediment, and in some distinct mould growths were visible. In some cases turbidity became apparent after 1—2 days. The sediments, examined under the microscope, showed an organised structure resembling the mycelia of a mould, and when transferred to nutrient solutions they produced growths of *Penicillium glaucum*. The authors conclude that the turbidity was due to partial development of spores of *P. glaucum*, which were not completely destroyed by the method of sterilisation employed, and that dextrose, but not maltose, acts as a chemical stimulus to spores of the mould, enabling them to develop to some extent even in absence of nitrogenous and mineral substances.—J. H. L.

XIXA.—FOODS.

Milk: Chemical changes produced by the addition of lime-water to—A. W. Bosworth and H. I. Bowditch. *J. Biol. Chem.*, 1917, 28, 431—435.

THE addition of lime-water to milk, which normally contains a quantity of insoluble dicalcium phosphate, results in the precipitation of more calcium phosphate, the insoluble phosphates under these conditions being a mixture of di- and tricalcium phosphates; at the same time, the acidity of the milk is reduced. When milk to be used for feeding infants is treated with lime-water and then diluted with water to twice its original volume, or more, the soluble calcium and phosphorus may be reduced to amounts less than those present in human milk.—W. P. S.

Blood: Determination of amino-acid nitrogen in—J. C. Bock. *J. Biol. Chem.*, 1917, 28, 357—368.

ETHYL and methyl alcohols are unsuitable for the precipitation of blood proteins previous to the determination of the amino-acid nitrogen (see Greenwald, this J., 1915, 689). The Greenwald method of precipitating the proteins by means of trichloroacetic acid is, however, satisfactory. Coagulation of blood at a boiling temperature in slightly acid solution does not increase the quantity of nitrogen in the filtrate, provided that the traces of protein which escape coagulation are properly removed.—W. P. S.

Iron and alumina [in foods]: Determination of small quantities of—R. Berg. *Chem.-Zeit.*, 1917, 41, 50—52.

THE estimation of traces of iron and alumina present in food and animal matter can be carried out, with an error not greater than 0.03 mgrm. Fe_2O_3 , by the following method:—After combustion of the organic matter the ash is dissolved in acid, the solution made alkaline with ammonia, and just acid with hydrochloric acid. A few drops of ammonium acetate are added, the solution heated to boiling, and the precipitate filtered off. After washing several times with a hot, very dilute ammonium sulphate solution, the precipitate is dissolved in hydrochloric acid and again precipitated as above. The precipitate is dissolved in hydrochloric acid, ammonia added, and the precipitate, which contains silica and iron and aluminium phosphates, is dried, ignited, and weighed. By fusion with potassium bisulphate and extraction with acidulated water, the silica is left as a residue, and after weighing, the amount of iron and aluminium phosphates is determined by difference. Ammonia is added to the filtrate and the precipitate obtained is washed and dissolved in hydrochloric acid. The solution is placed in a stoppered conical flask. Zinc chloride and sodium hydroxide are added, the solution is made just acid with hydrochloric acid, and potassium iodide added. The flask is then well stoppered and kept at 60—65° C. in a water bath for 20 minutes. Starch solution is added and the liberated iodine titrated with N/250 sodium thiosulphate. The liberation of iodine is in accordance with the equation: $\text{Fe}_2\text{Cl}_6 + 2\text{KI} = 2\text{FeCl}_2 + 2\text{KCl} + \text{I}_2$. The alumina is estimated by difference, and manganese, calcium, and magnesium can be estimated in the filtrate from the first precipitation of iron and aluminium phosphates.—J. N. P.

PATENTS.

Food for poultry and animals; Manufacture of —. R. Mason and W. C. Buchanan, Glasgow. Eng. Pat. 102,815, Jan. 4, 1916. (Appl. No. 131 of 1916.)

WASTE and bad eggs, with or without their shells, are broken up, mixed with about 1% of their weight of formaldehyde or boric acid, then heated at 240° F. (116° C.), and powdered.—W. P. S.

Feast or yeast products; Removal of bitter flavour from —. A. G. Salamon and L. J. Riley, London. Eng. Pat. 102,855, Mar. 4, 1916. (Appl. No. 3262 of 1916.)

DRIED yeast is extracted about 10 successive times with alcohol containing not less than 10%, or more than 20%, of its volume of water. The extraction is carried out at 70–75° C., and the alcohol may contain 5% or more of methyl alcohol. The extracted yeast is then dried, and the alcohol may be recovered from the extracts.—W. P. S.

Extract from fish or other aquatic animals; Process of producing a nutritious —. W. V. Coons and B. Hewitt, Victoria, British Columbia. U.S. Pat. 1,209,399, Dec. 19, 1916. Date of appl., Nov. 6, 1915.

CLEANED fish is minced and extracted several times with cold water and then with hot water. The fat is removed from the latter extract, the cold water extract is added, and the mixture boiled. The albumin in the cold water extract is thus coagulated and removes impurities from the mixture; the clear liquid portion is then drawn off and evaporated.—W. P. S.

Butter; Process of renaturing —. H. B. Eigelbner, Oak Park, Ill. U.S. Pat. 1,210,918, Jan. 2, 1917. Date of appl., Mar. 2, 1915.

THE butter is washed with hot water containing lime, then with water alone, and next agitated for several hours with hot saturated sodium chloride solution containing a small fraction of 1% of zinc chloride. The fat is finally separated, again washed with hot water, and dried.—W. P. S.

XIXF.—WATER PURIFICATION; SANITATION.

Drinking water; Removing the taste due to algae in —. A. C. Houston, Brit. Med. J., 1916, 2, 817. Pharm. J., 1917, 98, 139.

POTASSIUM permanganate, added in quantities of 2·5 to 5 lb. per million gallons, has proved much more effective than hypochlorites in removing the nauseous taint due to the growth of algae in the reservoirs under the control of the Metropolitan Water Board. The use of hypochlorites involves the risk of merely replacing one taste by another, or even of introducing a superadded taste.

Typhoid and paratyphoid bacilli in faeces and water; Search for —. F. Dénert and G. Mathieu. Comptes rend., 1917, 164, 121–126.

IN using the Malachite Green method for the separation of the typhoid group of bacilli from the coligroup, the divergent result frequently obtained are due to variations in the purity of commercial Malachite Green. The suitability of the dye can be tested by making a 1 in 3000 solution in peptone-water; in this medium the paratyphoid B bacillus should develop and cause decolorisation in 24

hours. In examining faeces by this method, typhoid and paratyphoid bacilli were always isolated in those cases in which blood cultures were positive, and sometimes both varieties of paratyphoid bacilli were isolated when blood cultures had shown one only. The water of the river Seine, when examined by this method, was found to contain paratyphoid bacilli.—J. H. J.

Carbon dioxide in air; Colorimetric method for determining —. H. L. Higgins and W. McK. Marriott. J. Amer. Chem. Soc., 1917, 39, 68–71.

IF a current of air containing carbon dioxide be passed through a solution of sodium bicarbonate until the solution is saturated, the reaction (hydrogen-ion concentration) of the solution will depend on the relative amounts of alkali bicarbonate and free carbonic acid present. This, in turn, will depend on the partial pressure of the carbon dioxide in the air with which the mixture has been saturated, and will be independent of the volume of air blown through, provided saturation has once been attained. High pressures of carbon dioxide change the reaction of the solution toward the acid side. Low pressures have the reverse effect. Hence the reaction of such a solution is a measure of the partial pressure of carbon dioxide in the air with which it has been saturated. The reaction of such a solution may be determined by adding to it an indicator such as phenolsulfonephthalein, which shows over a considerable range of reaction definite colour changes, and comparing the resulting colour with solutions of known reaction containing the same amount of indicator. Solutions of a given reaction may be prepared by mixing acid and alkaline phosphates in definite proportions. Such solutions owing to their high "buffer" value, may be kept unaltered for long periods of time, and can be used as standards for comparison. The method is not applicable in the presence of acid or ammonia fumes. As outdoor air always contains practically the same percentage (0·03%) of carbon dioxide, the standard bicarbonate solution may be easily checked.

—J. B. C. K.

Lime-sulphur animal dips; Chemical composition of —. R. M. Chapin. U.S.A. Dept. Agric., Bull. No. 451, Dec. 14, 1916, 1–16.

APPLICATION of the methods of analysis previously described (this J., 1916, 486, 705) has shown that in the preparation of lime sulphur solutions the main reactions which take place are as follows:—

- (1) $3\text{Ca}(\text{OH})_2 + 12\text{S} = 2\text{CaS}_3 + \text{CaS}_2\text{O}_3 + 3\text{H}_2\text{O}$.
- (2) $10\text{CaS}_3 + 3\text{Ca}(\text{OH})_2 = 12\text{CaS}_4 + \text{CaS}_2\text{O}_3 + 3\text{H}_2\text{O}$.
- (3) $\text{CaS}_4 + \text{S} = \text{CaS}_5$.

The second reaction does not occur until practically the whole of the free sulphur has been dissolved. Hydrolytic decomposition of polysulphides takes place in all lime-sulphur solutions in accordance with the equation:—(4) $\text{CaS}_x + 2\text{H}_2\text{O} \rightleftharpoons \text{Ca}(\text{OH})_2 + \text{H}_2\text{S} + (x-1)\text{S}$, the tendency to change from left to right increasing with the rise of temperature. The products on the right hand side also react as in equation (1), the final result in the case of CaS_3 being—(5) $\text{CaS}_3 + 3\text{H}_2\text{O} = \text{CaS}_2\text{O}_3 + 3\text{H}_2\text{S}$. The equilibrium of the solutions thus depends on the presence of an excess of hydrogen sulphide, the necessary amount of which excess varies with the temperature and concentration of the solutions. When exposed to the air lime-sulphur solutions are oxidised—(6) $\text{CaS}_x + 3\text{O} = \text{CaS}_2\text{O}_3 + (x-2)\text{S}$, whilst above a certain concentration of the hot solution (between 3·33 and 3·95% of mono-sulphide sulphur) the following reaction tends to progress from

left to right—(7) $\text{CaS}_2\text{O}_3 \rightleftharpoons \text{CaSO}_3 + \text{S}$. A well-boiled solution can never show a final excess of calcium hydroxide over monosulphide, unless such excess was originally present. As lime is only sparingly soluble at any stage, it would seem advisable to increase the time of boiling with an increase in the concentration. The effect of making the solutions concentrated is not only to decompose the thiosulphate, but also probably to utilise both lime and sulphur less completely, and to cause the polysulphides to contain a smaller proportion of pentasulphide. Finished solutions if kept on the sediment containing free lime will slowly undergo the changes represented in (1) and (2). If decanted from the sediment, and protected from air, the liquid will tend to change in accordance with equation (5), until a certain concentration of hydrogen sulphide is reached, when equilibrium will be established as in (4). For the practical preparation of animal dips on the basis of these data, it is suggested that 8 lb. of commercial quicklime (98.3% calcium oxide) or 10.5 lb. of commercial hydrated lime should be boiled for 1 hour with 10 lb. of fine sulphur and rather more than 10 galls. of water, so that the final product amounts to 10 galls. The final solution should contain nearly 18% (grms. per 100 c.c.) of sulphide sulphur, and should be diluted with 9 to 10 vols. of water for dipping sheep, and with 7 to 8 vols. of water for cattle.—C. A. M.

New method for the estimation of nicotine in tobacco.
Tingle and Ferguson. See XX.

PATENTS.

Liquids; Appliance for purification of ——. E. A. Pratt, New York. U.S. Pat. 1,208,830, Dec. 19, 1916. Date of appl., Apr. 22, 1915.

THE liquid to be purified is passed through a conduit provided with several "sterilising lamps" in one side and a photo-sensitive cell in the opposite side. There is an electrical connection between the lamps and the sensitive cell and a source of electricity. When the lamps are in action, the varying opacity of the liquid causes variations in the conductivity of the sensitive cell, which variations are arranged, by means of the electrical connection, to control the action of the lamps.

—J. H. J.

Air; Machine for subjecting — to violet and ultra-violet rays. N. W. Davis, Assignor to E. M. Markel, Des Moines, Iowa. U.S. Pat. 1,209,132, Dec. 19, 1916. Date of appl., Jan. 11, 1916.

A BRUSH electric discharge is produced between a silicon disc and a glass disc covered with conducting material. An air conducting tube is connected with the space between the discs, so that the air current which passes through the apparatus is subjected to violet and ultra-violet rays generated from the brush discharge. The apparatus may be composed of several units, each consisting of a glass disc, with a backing of non-conducting material, spaced from a silicon disc by non-conducting blocks, the space between the discs being connected to a tube. Each unit is provided with an electric circuit. The tubes from the units run to a common receiving tube which has means for drawing a regulated air current through one or all the tubes. When the electric circuit is closed, the air current is subjected to violet and ultra-violet rays and is ozonised.—J. H. J.

Sewage-water; Apparatus for purifying ——. G. P. Breddin, Cologne, Germany. U.S. Pat. 1,210,759, Jan. 2, 1917. Date of appl., Feb. 7, 1914.

THE apparatus consists of an inclined rotating

sieve of conical form, provided with blades round the periphery, and with a floor under the descending side of the sieve and a cover over the ascending side. There is also a rotating brush, driven by the axis of the sieve, for cleaning the top of the sieve.

—J. H. J.

Alcohol from garbage; Method of and apparatus for manufacturing ——. F. E. Young, Canton, Ohio. U.S. Pat. 1,210,250, Dec. 26, 1916. Date of appl., Aug. 9, 1915.

THE garbage is cooked in a closed tank by forcing steam through it, grease is separated from the steam, and the alcohol carried over by the steam is condensed. The residual garbage is pressed, grease is separated from the press-water, and the latter fermented. The pressed garbage is dried and the vegetable matter is separated and converted into glucose; the latter is then fermented with the above fermentation liquid, and the alcohol is distilled off.—J. H. J.

Water; Treatment of — for softening, sterilising, and like purposes. H. J. Magrath, London. U.S. Pat. 1,211,735, Jan. 9, 1917. Date of appl., July 21, 1915.

SEE Eng. Pat. 18,867 of 1914; this J., 1915, 1030.

Furnace for burning refuse. W. Piernay, Assignor to Stettiner Chamotte-Fabr. A.-G. vorm. Didier, Stettin, Germany. U.S. Pat. 1,211,875, Jan. 9, 1917. Date of appl., May 16, 1914.

Manufacture of manure by means of peat. Eng. Pat. 103,142. See XVI.

XX.—ORGANIC PRODUCTS; MEDICINAL SUBSTANCES; ESSENTIAL OILS.

Morphine alkaloids; Investigation of the ——. W. J. von Braun and K. Kindler. Ber., 1916, 49, 2655—2663.

ATTEMPTS were made to reproduce the physiological properties of codeine by introducing the supposed physiologically active groups into other positions of the molecule by syntheses from cyan-normorphine and cyan-norcodeine (Ber., 1914, 47, 2312), and also by reproducing them in the much simpler molecule of a reduced tertiary quinoline base. For this purpose *p*-aminobenzyl-carbamino-nor-morphine, diamino-phenyl-nor-codeine, dimethylamino-N-hydroxyethyl-nor-codeine, and N-methyl-8-hydroxymethylthalline were synthesised, but in every case an indifferent substance resulted, or one of weak physiological action dissimilar to codeine.—G. F. M.

Suprarenin [adrenalin]; Content of — in the ordinary commercial preparations, and the methods of estimation. F. Johannessohn. Biochem. Zeits., 1916, 76, 377—391. J. Chem. Soc., 1917, 112, ii., 55.

ADRENALINE can be estimated colorimetrically

by Folin's phosphotungstic reagent (this J., 1913, 159), and biologically by the perfusion method of Löwen and Tröndeleburg when present by itself, but not in the presence of novocaine or alpin. When these substances are present, however, the colorimetric method of Frankel, Allers, and Bayer can be used (iodic acid in the presence of sulphuric acid). This method has been employed for estimating the adrenaline content of various commercial preparations and of the conditions under which these may be preserved without loss of the adrenaline.

Nicotine in tobacco: New method for the estimation of —, A. Tingle and A. A. Ferguson. Trans. Roy. Soc. Canada, 1916, [iii], 10, 27—31. J. Chem. Soc., 1917, 112, ii., 55—56.

BASED on results already given (this J., 1917, 45), the authors have worked out a new method for the estimation of nicotine in tobacco. A mixture of 20 grms. of tobacco, 40 grms. of barium hydroxide, and 150 c.c. of water is distilled with steam into a 500 c.c. flask until the distillate gives no alkaline reaction with phenolphthalein. To the distillate 20 c.c. of sulphuric acid is added, and the liquid evaporated to about 50 c.c. This solution is made strongly alkaline with potassium hydroxide, a few drops of baryta water being added for clarification. The solution is then made up to 100 c.c., the precipitate allowed to settle, the supernatant liquid filtered, and its rotation then determined in the polarimeter. In a modification of the method, the nicotine is extracted from the steam distillate by chloroform. These two methods gave concordant results, higher than those obtained, using the same specimen of tobacco, by the methods of Töth and of Kissling.

Alkaloids: Chemical and physiological detection of several — in the same solution. E. Philippi. Arch. Farm. Sperim., 1916, 22, 120—130. J. Chem. Soc., 1917, 112, ii., 56.

THE characteristic reaction of strychnine with sulphuric acid and potassium bichromate is not shown by 1 mgrm. of strychnine nitrate in the presence of 0.04 grm. or more of quinine bisulphate, a transitory, garnet-red coloration being produced, which becomes green or greenish-grey; with smaller quantities of quinine, the reaction is distinct, but transient. The same effect is observed when salts of the alkaloids with the same acid or the free alkaloids are used. Crystals of strychnine picrate can be obtained in the presence of a large excess of quinine, but they are not then characteristic. The alkaloids are most simply and certainly separated by the use of sodium potassium tartrate; quinine tartrate is insoluble in solutions of alkali sulphates and tartrates, whereas the strychnine salt is soluble. Mixtures which do not give the characteristic reaction with potassium bichromate do not cause the characteristic symptoms in the frog.

Saponin from Yucca filamentosa. L. H. Chernoff, A. Viehoever, and C. O. Johns. J. Biol. Chem., 1917, 28, 437—443.

THE rootstocks of *Yucca filamentosa* yielded about 6% of a new saponin, $C_{41}H_{60}O_{14}$, which is soluble in water, phenol, and glacial acetic acid, and is not precipitated from its aqueous solution by lead acetate, basic lead acetate, or barium chloride. Haemolysis was observed after 15 mins. in a 1:20,000 solution of the saponin containing rabbit's blood and kept at 37° C. Hydrolysis of the saponin yielded a crystalline sapogenin, m.pt., 175° C., and dextrose; glucuronic acid also

appeared to be formed. The saponin occurs as brownish amorphous masses in the fibro-vascular bundles of the roots and leaf bases. —W. P. S.

Chrysarobin. O. Hesse. Annalen, 1917, 418, 350—378. (Compare Tutin and Clewer, this J., 1912, 253; 1913, 1126.)

THE composition of samples of commercial chrysarobin (using Hesse's nomenclature) is as follows:—

	A.	B.	C.	D.
Insol. in benzene (chrysarobol, etc.)	3.5	6.6	16.7	3.7
Chrysophanic acid	1.2	4.4	8.3	1.3
Emodin methyl ether	0.2	0.6	3.0	trace.
Emodin	—	0.3	0.8	—
Chrysophanol	29.0	31.1	20.6	33.3
Emodin methyl ether	28.3	28.4	20.2	20.4
Emodinol	25.7	20.6	18.9	22.3
Other substances, loss	11.2	8.0	11.5	10.0

The figures in columns A and B resulted from the analysis of four and two samples respectively of chrysarobin (German Pharm. V), and C and D are English samples (acidum chrysophanic). The formation of iodine by the action of hydriodic acid on chrysarobin is due to the presence of chrysophanic acid and similar anthraquinone derivatives. Extraction with benzene (b.pt. 80°—90° C.) is preferable to using petroleum spirit (30°—50°). Chrysophanol and emodin are readily isolated from the product crystallised from benzene or benzene-benzene and demethylated by means of hydriodic acid. Contrary to the statements of Tutin and Clewer (*loc. cit.*) ararobinol and dehydroemodinanthranolmonomethyl ether are not present. A method is outlined for increasing the therapeutic effect of chrysarobin by extracting the warm benzene solution with N/5 caustic potash in absence of air and carbon dioxide, and rapidly evaporating the benzene solution exposed to air. The composition of a sample of araroba powder has also been investigated.—F. W. A.

β -Amino- β -methylhydrindene from o-xylylene cyanide. Investigations in the indene series. III. J. von Braun, O. Kruber, and E. Danziger. Ber., 1916, 49, 2642—2651.

IN addition to the corresponding diamine, o-xylylene cyanide gives on reduction with sodium and alcohol a hydrindene derivative in about 36% yield, which, separated by fractional distillation from the reaction product, forms a colourless oil of b.pt. 118°—119° C. at 18 mm. pressure. It forms a hydrochloride, m.pt. 241° C., and a crystalline hydrobromide m.pt. 290°—293° C. It is characterised by its notable physiological action in increasing the blood pressure to a greater extent even than β -phenylethylamine or *p*-hydroxyphenylethylamine, and, particularly by subcutaneous injection, it has a powerful stimulating action on the respiratory and motor centres. Reasons are given for assigning to the base I constitution of a β -amino- β -methylhydrindene.

—G. F. M.

Urotropine [hexamethylenetetramine]: Reactions of —, P. Carles. Ann. Chim. Analyt., 1917, 22, 8—9.

HEXAMETHYLENETETRAMINE is soluble in water, the solution being neutral to litmus; the substance should volatilise completely when gently ignited, and its 5% aqueous solution, after the addition of nitric acid, should not yield any reactions for chlorides or sulphates. A red coloration is obtained when 0.1 grm. of hexamethylenetetramine

is mixed with 0.1 grm. of salicylic acid and 5 c.c. of sulphuric acid and the mixture heated. If an aqueous hexamethylenetetramine solution is treated with sodium hypobromite solution and the mixture then neutralised with dilute hydrochloric acid, a yellow precipitate forms.—W. P. S.

Hexamethylenetetramine ; Bromine and iodine compounds of —. K. Sugimura and K. G. Falk. *Biochem. Bull.*, 1916, 5, 17—21. *J. Chem. Soc.*, 1917, 112, ii., 54.

A METHOD of estimation of hexamethylenetetramine can be based on the formation of the tetraiodide.

β -[Camphorylidene-3]-propionic acid (methylenecamphoracetic acid). H. Rupe and E. Burekhardt. *Ber.*, 1916, 49, 2547—2563.

THE ethyl ester of methylenecamphoracetic acid (II) is produced by the action of sodium acetate on methylenecamphor chloride (I) in alcoholic solution:—

Hydrolysis of the ester with fuming hydrochloric acid yields the free acid, m.pt. 106°C ., which can be oxidised by ozone to camphorquinone, and reduced by sodium amalgam to an acid of m.pt. 51°C — 52°C . Methylenecamphoracetic acid is converted by caustic potash into the potassium salt of β -[hydroxy-3-camphoryl-3]-propionic acid, the lactone of which melts with decomposition at 207°C . With concentrated sulphuric acid, a δ -lactone, m.pt. 66°C ., is produced. When heated alone to 160°C . under reduced pressure, or if the ester is heated to 160°C . with water, methylenecamphoracetic acid loses carbon dioxide and forms ethylenecamphor, boiling at 101°C — 102°C . under 10 mm. pressure, which appears to be the *trans*-isomer corresponding to the *cis*-isomer prepared by Haller and Minguin (*Comptes rend.*, 1904, 138, 578) by removing hydrogen bromide and carbon dioxide from the bromine derivative of camphocarbonic acid. Diazonium salts in alkaline solution combine with methylenecamphoracetic acid to produce highly coloured formazyl derivatives. By coupling methylenecamphoracetic acid with diazobenzenesulphonic acid in presence of alkali, a red solution is obtained, which, when made faintly acid with acetic acid, dyes silk a bright wine-red and wool deep red ("Tango"); wool completely exhausts the bath. —F. Sp.

Vitamine ; Fractionation of the phosphotungstic acid precipitate with acetone for the preparation of — from yeast. C. Funk. *Physiol. Abstr.*, 1916, 1, 42. *J. Chem. Soc.*, 1917, 112, i., 52.

THE phosphotungstates from an alcoholic yeast extract are largely soluble in acetone; the bulk of the vitamine is, however, contained in a small fraction insoluble in acetone. Phosphotungstates may be decomposed with lead acetate, instead of barium hydroxide; this new method yields clear solutions, facilitates purification, and avoids the use of alkali.

Guanidine ; Preparation of —. J. S. Sharpe. *J. Biol. Chem.*, 1917, 28, 399—401.

A GOOD yield of guanidine may be obtained by

heating 100 grms. of dry ammonium thiocyanate in a short-necked Jena flask, immersed in an oil-bath, to 190°C — 200°C . for 20 hours. The mass is cooled, extracted with hot water, and filtered. The filtrate, which contains guanidine thiocyanate, is evaporated to dryness and weighed, and for each 1 part by weight 0.58 part of potassium carbonate dissolved in sufficient water is added. The whole is evaporated to dryness again, potassium thiocyanate is removed by repeated extraction with 90% alcohol, and crude guanidine carbonate is left. It may be purified by dissolving it in a little water, adding six times the volume of 90% alcohol, and allowing to crystallise. Yield, 15—20 grms. of pure guanidine carbonate.—F. Sp.

Creatine and creatinine determinations ; Impure picric acid as a source of error in —. O. Folm and E. A. Doisy. *J. Biol. Chem.*, 1917, 28, 349—356.

ATTENTION is directed to the fact that certain specimens of picric acid, particularly those sold in the wet condition, contain some impurity, and, owing to the more or less intense coloration they give when neutralised with sodium hydroxide, are quite unsuitable for use in the colorimetric determination of creatinine. When 20 c.c. of saturated picric acid solution is treated with 1 c.c. of 10% sodium hydroxide solution, the coloration obtained and observed after 15 minutes should be not more than about twice as deep as the colour of the saturated picric acid solution.—W. P. S.

Glycollic acid ; Preparation of —. E. J. Witze-mann. *J. Amer. Chem. Soc.*, 1917, 39, 109—112.

120 GRMS. of commercial barium carbonate was added slowly to a filtered solution of 50 grms. of commercial monochloroacetic acid in 500 c.c. of water, and the mixture was heated on a water bath under a reflux condenser for about 40 hours, or until no more carbon dioxide was evolved, being thoroughly agitated every few hours towards the last. The excess of barium carbonate was filtered off, and the hot solution treated with 52.1 grms. of 95% sulphuric acid (95% of the calculated amount necessary for complete precipitation of the barium as barium sulphate). After filtering off the barium sulphate and washing, the filtrate and washings were treated with small amounts of sulphuric acid until the solution showed only a slight positive test for barium. The solution was filtered again and concentrated *in vacuo*. A small amount of barium sulphate separated and was filtered off. The concentration was continued as long as water was distilled over at the bath temperature used at the beginning. The concentrated solution, which smelled strongly of hydrochloric acid, was heated on the steam bath in an evaporating dish for two hours, and yielded 40 grms. of a thick straw-yellow syrup (calculated yield of glycollic acid 40 grms.). A drop or two of this syrup was induced to crystallise by scratching with a glass rod and was used to inoculate the syrup. 16.5 grms. (41%) of the crystallised acid was separated in the first crop. In another experiment, using 100 grms. of monochloroacetic acid, the almost colourless syrup crystallised spontaneously, and the first crop of crystals weighed 30 grms. (37.5% of the calculated yield). When concentrating the aqueous solution on the water bath the evaporation must be interrupted in time or no crystals can be obtained. In case of failure to obtain crystals, the syrup may be treated with excess of barium hydroxide, heated until it remains permanently alkaline, and treated as before, using greater care at the final stage of the evaporation.—J. B. C. K.

Lactic acid in biological products; Identification and determination of —. L. I. K. Phelps and H. E. Palmer. J. Amer. Chem. Soc., 1917, 39, 136—149.

*RACEMIC, *d*- and *l*-lactic acids were prepared and their quinine and guanidine salts studied. After separation from other acids, lactic acid may be accurately determined as guanidine or quinine salt, and quinine lactate may be separated from quinine propionate and butyrate owing to its much smaller solubility in carbon tetrachloride. Lactic acid can be quantitatively converted into ethylester, and in this form separated by fractional distillation from the esters of acetic and formic acids, which boil at much lower temperatures, and from those of citric and tartaric acids which boil at much higher temperatures. The following is an outline of procedure, based on these facts, by which the authors succeeded in separating lactic acid (about 0.1 grm.) from equal or smaller amounts of formic, acetic, propionic, butyric, and citric acids, and recovering it as quinine salt with a loss of less than 4% as a rule. The mixed acids, suspended in vaseline at 100°—110° C. in a small Wurtz flask connected with a condenser, were esterified by vapours of absolute alcohol containing dry hydrochloric acid, with zinc chloride as second catalyst. From the distillate, containing ethyl formate, acetate, lactate, propionate, and butyrate, the first two were completely and the last two partially removed by distillation with use of a Hempel column filled with glass beads. The residue containing ethyl lactate with some propionate and butyrate, was freed from hydrochloric acid by means of silver carbonate, the esters were hydrolysed by barium hydroxide, and after the excess of the latter had been removed as carbonate the filtered liquid was evaporated to dryness and the mixed barium salts were quantitatively decomposed by quinine sulphate. After filtration from barium sulphate the solution was freed from water by distillation with alcohol under 15 mm. pressure. The quinine propionate and butyrate were extracted from the residue with carbon tetrachloride, and the lactate was dissolved in chloroform, the solution filtered, and evaporated to dryness, and the residue dried *in vacuo* at 75° C. and weighed.—J. H. L.

Volatile fatty acids; New method of steam distillation for the determination of — including a series of colorimetric qualitative reactions for their identification. D. C. Dyer. J. Biol. Chem., 1917, 28, 445—473.

IN the steam distillation method described, the volume of the solution from which the acids are distilled is maintained constant at 150 c.c. throughout the distillation. Under these circumstances, the distilling constants (proportions distilling over in succeeding fractions) are indicated by straight lines when plotted on a simple logarithmic chart, whilst the distilling variables of mixtures of these acids are indicated on the same chart by curved lines. With neighbouring acids the curves are very flat, and the further the acids comprising the mixture are removed from each other (in the series), the greater will be the curvature of the graph. The lowest acid of the series in a mixture may be identified with certainty, since the line representing the distilling constant will eventually reach a point where it will begin to run parallel to some straight line on the chart which represents that acid. This same point indicates where the other acid of the mixture has run out, and the probable nature of this second acid may be found by reference to a table which is given. The qualitative tests described for the identification of the volatile acids depend on the different solubilities of the iron and copper salts of the acids in amyl alcohol, ether, and petroleum spirit.—W. P. S.

Volatile fatty acids; Duclaux's method for the estimation of —. F. W. J. Boekhout and J. J. O. de Vries. Centr. Bakt. Par., 1916, ii, 46, 505—513. J. Chem. Soc., 1917, 112, ii., 50.

THE authors have investigated Duclaux's method (Ann. de l'Inst. Pasteur, 1895), and confirm the figures given in his tables for formic, acetic, and propionic acids; in the case of butyric and valeric acids, the results obtained were somewhat different from those recorded by Duclaux. It is shown that if the differences between the quantities of acid found in each successive fraction of the distillate are calculated into percentages of the acid remaining in the flask at the commencement of the distillation of each fraction (this quantity of residual acid being first calculated into 110 c.c. of the solution), a constant number is obtained for each fraction and is the same for each individual acid. This number is 3.5 for formic acid, 5.9 for acetic acid, 11.8 for propionic acid, 19.1 for butyric acid, and 26.0 for valeric acid. This method may be applied to the analysis of mixtures of the acids.

[Organic] acids; Identification of —. E. E. Reid. J. Amer. Chem. Soc., 1917, 39, 124—136.

THE preparation of *p*-nitrobenzyl esters is suggested as a means of characterising organic acids. The author describes the preparation of a number from alkali salts of the acids and *p*-nitrobenzyl bromide (*e.g.*, about 1 grm. of each in the case of monobasic acids) by boiling for 1—2 hours in just sufficient 63% alcohol to dissolve the reacting substances. The melting points of the esters were determined after systematic recrystallisation from dilute alcohol.—J. H. L.

Aldehydes; Colour reactions of aromatic —. P. Pooth. Schweiz. Apoth. Zeit., 1916, 54, 377—382. J. Chem. Soc., 1917, 112, ii., 52. (Compare Häussler, Z. anal. Chem., 1913, 53, 363, 691.)

THE condensation of aromatic aldehydes with sulphonated aromatic amino-compounds leads to the formation of characteristic, distinctly coloured azomethines, which can be employed in the identification of aldehydes. Aromatic aldehydes yield more distinct colorations with naphthionic than with sulphanilic acid; in most cases, the azomethine separates directly on cooling. The test is performed as follows: 3—4 c.c. of an aqueous solution of sodium sulphanilate or naphthionate (10%) is heated in a porcelain dish on the boiling-water bath; a boiling alcoholic solution of the aldehyde is added, which causes the appearance of a pale yellow to red coloration, and the solution is evaporated to dryness, the colour generally being deepened thereby. Before evaporation, a few drops of the solution are removed, diluted with water, cooled, and treated with a few drops of dilute sulphuric acid; in many cases the colour is deepened, in others completely changed. Certain of the reaction products, particularly those derived from nitro-aldehydes, are sensitive to daylight. The products obtained from substituted aldehydes are less stable.

Mercuric lactate and its aqueous solutions; Stability of —. Preparation of mercuric lactate. M. François. J. Pharm. Chim., 1917, 15, 33—41.

SOLUTIONS of mercuric lactate undergo spontaneous reduction on keeping, at the ordinary temperature, with formation of mercurous lactate, which is regarded therapeutically as far more toxic than the mercuric salt; at the same time, free lactic acid, acetaldehyde, and carbon dioxide are produced. The decomposition is more rapid, the higher the concentration of the salt and, whereas

in a 0.1% solution only 1.25% of the mercuric lactate present suffered decomposition in 3 months. in a 1.0% solution 11.52% had been reduced in the same time. It is therefore not permissible to prepare the medicinal 0.1% solution by the dilution of a concentrated stock solution of the salt. In the presence of an excess of mercuric oxide, the decomposition of mercuric lactate becomes extremely rapid, even in the case of highly dilute solutions. On the other hand, crystalline mercuric lactate is perfectly stable, and the solid salt may be kept apparently indefinitely. The decomposition of the solutions may be determined by precipitating the mercurous compound by sodium chloride, collecting the precipitate of mercurous chloride, drying, and weighing. To prepare mercuric lactate, 100 grms. of lactic acid is diluted with 400 c.c. of water, a little pumice added, and the solution boiled until 180 grms. of water has evaporated. The anhydrides are thereby hydrolysed and the solution, after cooling, is treated with 105 grms. of yellow mercuric oxide, added in small portions. After standing some time, with frequent agitation, the solution is filtered and the filtrate placed in shallow dishes to a depth of 1 cm. Crystallisation is started by adding a crystal and rubbing; the crystalline mass is broken up every day until the liquid has evaporated. The crude salt, containing traces of mercurous lactate, is washed by trituration of 50 grm. portions with 10 c.c. of water, draining, and rinsing with two portions of 5 c.c. each of water. Mercurous lactate may be prepared by heating together 100 grms. of lactic acid, 400 of water, and 100 of mercuric oxide on the boiling water-bath for 1½ hours, filtering, and digesting the filtrate at 100°C. for 8–10 hours. The deposit of sparingly soluble mercurous lactate is filtered off after standing all night, and the digestion is repeated daily with the filtrate until the whole of the mercuric lactate has been reduced to the mercurous salt.—J. F. B.

Glycerin for medicinal purposes.

On February 12th the Ministry of Munitions issued a memorandum in the following terms as to restrictions in the use of medicinal glycerin:—

The Ministry of Munitions announces that owing to additional demands for glycerin for war purposes, it has become necessary to place further restrictions on the issue of medicinal glycerin, and that supplies in future will be reserved for the manufacture of the preparations of the British Pharmacopœia and for such uses of special importance as may be sanctioned by the Ministry of Munitions. Those supplies will, however, be small, and must be used with the utmost economy.

Applications for permit to obtain supplies should be addressed to:—The Director of Propellant Supplies, 32, Old Queen Street, Westminster, S.W., and should give the following particulars: 1. Quantity applied for. 2. Stock of glycerin held. 3. Purpose for which supply is required. (In case of extra British Pharmacopœia preparations formulæ should be given.) 4. Applicant's average yearly consumption of glycerin for above purposes. 5. Name and address of proposed suppliers.

The medical profession have been informed of the need for economy in prescribing glycerin, and it is anticipated that the requirements for dispensing will be greatly reduced. The stocks of glycerin in the hands of pharmacists should be sufficient to meet these reduced requirements, and, therefore, no glycerin will be issued for dispensing meantime. The surplus stocks held by pharmacists and all stocks held by retailers who are not in a position to use them for those restricted purposes should be disposed of either to other pharmacists who are short of stock or to wholesale houses for making B.P. preparations.

Ethyl alcohol in dilute solutions (0.1 to 1.0%): Method for determination of —, and its application to urine. Villedieu and Hébert. J. Pharm. Chim., 1917, 15, 41–44.

ETHYL alcohol in dilute solutions (0.1–1.0%) may be determined by conversion into iodoform, the results being calibrated by determinations made with standard alcohol solutions under identical conditions. 100 c.c. of the dilute alcohol solution is mixed with 10 c.c. of caustic soda prepared by diluting commercial caustic soda lye (sp. gr. 1.35) with an equal volume of water. This mixture is treated gradually with iodine solution (105 grms. of iodine and 108 of potassium iodide per litre) until a coloration indicates an excess of iodine. The solution is allowed to stand for 3 hours, a few drops more of iodine are added to restore the colour, and the liquid is left for 18 hours in a cool place. After crystallisation of the iodoform, if necessary by rubbing and allowing to stand for a longer time, the deposit is collected on a filter, washed with cold water, dried on blotting paper, and placed together with the filter in 30 c.c. of alcoholic potassium hydroxide with which it is boiled for 20 mins. The iodoform is converted into potassium iodide which is determined, after acidification with nitric acid, by the addition of 20 c.c. of N/100 silver nitrate solution and titration of the excess with N/100 thiocyanate. The results of determinations made with standard solutions of alcohol, expressed in terms of c.c. of N/100 silver solution consumed = y , may be plotted in the form of a straight line represented by an equation of the form of $y = ax + b$ where x = the percentage of alcohol by vol., $a = 7.50$ and $b = 1.25$.

Hence $x = \frac{y - 1.25}{7.50}$. In applying the method to

the determination of alcohol in urine, 200 c.c. of the sample is distilled with 1 c.c. of phosphoric acid and the test carried out on the first 100 c.c. of distillate. The liquid to be tested must not reduce Fehling's solution nor produce a colour with Schiff's reagent; the absence of acetone should also be verified by Legal's or Denigès' test.

PATENTS.

Hydrogen peroxide; Stable product containing — and method of making the same. F. W. Weber, Perth Amboy, N.J., Assignor to The Roessler and Hasslacher Chemical Co., New York. U.S. Pat. 1,210,570, Jan. 2, 1917. Date of appl. May 8, 1915.

A STABLE solid product containing urea, hydrogen peroxide, and hippuric acid is obtained by dissolving hippuric acid in a solution of urea, evaporating the solution to dryness, adding the residue to hydrogen peroxide, and separating the resulting crystals.—T. H. B.

Hog cholera; Process of manufacturing a vaccine for the prevention of — and product therefrom. C. W. Duval, Assignor to M. J. Couré, New Orleans, La. U.S. Pat. 1,210,053, Dec. 26, 1916. Date of appl., Mar. 22, 1916.

A VACCINE product for the prevention of hog cholera is produced by removing from an infected hog parts containing the virulent virus, desiccating

and powdering the mass, attenuating the virus of the powder, mixing it, while suspended in sterile water, with desiccated and powdered inactivated antitoxic serum, and sensitising it.—F. Sp.

Medicinal compound. [Triglyceride of ricinoleic ozonide.] W. J. Knox, Assignor to General Research Laboratories, New York. U.S. Pat. 1,210,949, Jan. 2, 1917. Date of appl. July 30, 1911.

THE toxic property of the ricin constituent of castor oil is destroyed by treating the oil with ozone, forming the ozonide of ricinoleic triglyceride.—F. Sp.

Essential oils; Extracting——. E. J. Sheehan, Assignor to W. S. McKay, Pasadena, Cal. U.S. Pat. 1,211,969, Jan. 9, 1917. Date of appl. Feb. 8, 1915.

ESSENTIAL oil is extracted from a material containing it by rupturing the oil-bearing cells and extracting the oil from them with a solvent obtained by distilling and condensing the volatile constituents of an essential oil of the same character. The material is then drained, and subjected to the action of heated vapours to remove the remaining solvent and essential oil. The vapours are condensed, and the essential oil is separated and combined with the solution obtained by the extraction and with the non-volatile residue of the oil from which the solvent was obtained.—F. Sp.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

PATENT.

Photographic developers; Renewal of——. K. Pape, Danzig-Neufahrwasser. Ger. Pat. 295,236, Mar. 14, 1916.

THE activity of used or stale developer is renewed by treatment with an alkali or alkali carbonate.—B. V. S.

XXII.—EXPLOSIVES; MATCHES.

PATENTS.

Guncotton and similar products; Washing device for——. H. Jakob, Ebenhausen, Assignor to Selwig und Lange, Brunswick, Germany. U.S. Pat. 1,211,450, Jan. 9, 1917. Date of appl. Apr. 1, 1916.

GUNCOTTON is washed by passing it along a conveying tube into which, in two different places, water is supplied tangentially and obliquely downwards in the direction in which the guncotton is moving. Between the two water inlets is a chamber provided with a perforated wall forming part of the conveying tube; the wash-water passes through the perforations to a drainage pipe outside.—F. Sp.

Nitro-starch; Process for the manufacture of——. S. S. Sadtler, Springfield, Pa. U.S. Pat. 1,211,761, Jan. 9, 1917. Date of appl. Jan. 31, 1916.

STARCH is treated with a solution of caustic soda "adapted for swelling it and removing impurities." It is then washed, treated with an oxidising agent capable of liberating nascent oxygen to remove

further impurities, washed again, nitrated, freed from excess of acid, and boiled in the presence of a small amount of residual acid.—F. Sp.

Solids with liquids of very low boiling point [e.g. liquid oxygen]; Apparatus for impregnating——. L. Sieder, Munich. Ger. Pat. 295,270, Mar. 23, 1915.

THE apparatus is particularly intended for soaking easily oxidised solids with liquid oxygen to make explosive cartridges. It consists of a Dewar vessel, closed with a stopper through which passes the stem of a tap funnel and a short tube reaching just below the stopper. By applying pressure through the latter, liquid can be forced up from the Dewar vessel into the funnel wherein the material to be soaked is placed. The two tubes may be combined in a suitably bored double tap which controls both tubes at the same time.—H. J. H.

Blasting cartridges. W. Weber, Hayingen, Germany. Eng. Pat. 9485, June 29, 1915. Addition to Eng. Pat. 8606, June 10, 1915.

SEE U.S. Pat. 1,157,270 of 1915; this J., 1916, 276.

Vacuum mixing machine for substances sensitive to pressure and friction. Ger. Pat. 294,776. See I.

XXIII.—ANALYSIS.

Nickel; Determination of—— in the presence of zinc and iron. S. Rothschild. Chem.-Zeit., 1917, 41, 29–30.

THE estimation of nickel by electrodeposition from an ammoniacal solution cannot be carried out accurately in presence of zinc or manganese, nor with a sodium sulphite solution, when cobalt is present. It was found that precipitation of nickel sesquioxide by alkali and bromine water does not serve entirely to exclude zinc. A separation can be brought about by dimethylglyoxime, but nickel precipitated in this way is contaminated by iron if this is present in the solution. This contamination by iron occurs even in presence of a large excess of citric acid and was found to be due to adsorption. To overcome these objections in the estimation of nickel, it is recommended to precipitate with dimethylglyoxime, dissolve the precipitate in nitric acid, heat for several minutes together with hydrogen peroxide, add a large excess of ammonia, and electrolyse in the usual manner.—J. N. P.

Nitrogen; Determination of total——. Accurate method of estimating ammonia volumetrically after destruction of organic matter in the presence of mercury. E. Justin-Mueller. Bull. Sci. Pharmacol., 1916, 23, 167–169. J. Chem. Soc., 1917, 112, ii., 39–40.

WHEN organic substances are destroyed in the presence of mercury according to Kjeldahl's method, a portion of the ammonia remains combined in the form of mercury ammonium compounds, and is not estimated by the method of Ronchère (this J., 1907, 841). Low results are also obtained after addition of sodium sulphide or hypophosphite, but, according to the author, the results are accurate when potassium arsenite is used to decompose the mercury-ammonium compounds. The estimation is performed in the following manner: urine (10 c.c.) is heated with concentrated sulphuric acid (5 c.c.) and mercury (ca. 0.1 grm.). If the urine contains sugar the quantity of acid is increased in the ratio of 10%

of the sugar content. As soon as the solution becomes colourless, the heating is discontinued, the solution cooled, and diluted to 50 c.c. with water. Five c.c. of the dilute solution is mixed with 10 c.c. of the arsenite solution and 5 drops of phenolphthalein, and neutralised by sodium hydroxide (10%); the precipitate is allowed to settle for a few seconds, filtered, the residue washed three times with water, and the ammonia estimated in the filtrate by the formaldehyde method of Ronchès. The potassium arsenite solution is prepared by dissolving arsenious oxide (5 grms.) with the help of potassium hydroxide (11.20 grms.) or N/1 potassium hydroxide (200 c.c.) and making up the solution with water to 1000 c.c.

XXIV.—MISCELLANEOUS ABSTRACTS.

Organic compounds: Relation between the chemical constitution of— and their capacity to coagulate acid gold hydrosols. J. A. Gann. Koll. Chem. Beihfte. 1916, 8, 251—298. J. Chem. Soc., 1917, 112, ii., 21—22.

THE coagulating capacity of a large number of substances has been examined by measuring the "gold number" (Zsigmondy, this J., 1902, 192), the substances investigated including albumoses, peptones, polypeptides, dyes, alkaloids, amines, and various heterocyclic compounds. The results obtained show that the coagulating capacity of these nitrogen compounds depends on the presence of basic nitrogen groups, but that, apart from this, it varies considerably with the constitution of the substance. The auxochromic hydroxyl group increases the activity, although its effect is less marked than that of the amino-group. Certain configurations, such as those peculiar to the azines, thioazines, oxazines, and acridine derivatives also increase the coagulating activity, whilst chromophoric groups have the opposite effect, and this is the more pronounced the more strongly acid the chromophoric group is. The less active a substance is found to be, the greater is the effect which is produced by the introduction of a new group. With certain exceptions, the gold number for a particular substance is almost inde-

pendent of the concentration of the coagulant. It varies, however, to some extent with the degree of dispersity, the concentration, and the acidity or alkalinity of the gold solution. The coagulation process is in most cases to be regarded as brought about by ions, although in the case of the albumins it may be due to the mutual interaction of oppositely charged colloidal particles. The behaviour of gelatin shows that it may act either as a protective colloid or as a coagulant, and the actual results which have been obtained with this substance are discussed in detail with special reference to its amphoteric character.

Trade Report.

Prohibited exports.

By virtue of Orders in Council, dated Feb. 2nd and 19th, exportation of the following from the United Kingdom to all destinations is prohibited:—Bones in any form and bone ash; anthracene oil, creosote, creosote oils (except wood tar oil), green oil, and mixtures and preparations containing these; zinc oxide; guano; compound and organic manures; apatites, phosphates of lime and alumina; zinc dust; albumen; gas carbon; casein and its preparations; acetic anhydride; potash, muriate, nitrate, sulphate, and crude manurial potash salts, and mixtures containing any of these substances; dextrin; glucose; tantalum, tantalum alloys and ores containing tantalum; coconut oil, cotton seed oil, ground nut oil, and palm kernel oil; oleomargarine; lard and imitation lard; malt; malt sugar; margarine; extract of meat; starch; refined tallow.

Exportation of the following is prohibited to all destinations abroad other than ports and destinations in British Possessions and Protectorates:—Potash salts and mixtures containing such salts, not otherwise prohibited; all animal and vegetable fats and oils (not including essential oils), and articles and mixtures containing these, not otherwise prohibited; goods made wholly or partly of rubber, gutta-percha, or balata.

Books Received.

STANDARD METHODS OF GAS TESTING. U.S. Bureau of Standards, Circular No. 48. Second Edition. Government Printing Office, Washington. 202 pages, 10×7 in. Price 40 cents. (See this J., 1915, 201.)

HEALTH CONSERVATION AT STEEL MILLS. By J. A. Watkins. U.S. Bureau of Mines, Technical Paper 102. Government Printing Office, Washington. 36 pages, 9×5½ in. Price 5 cents.*

A SERIES of suggestions in regard to eliminating unhealthful conditions in steel mills.

SAFE PRACTICE AT BLAST FURNACES. By F. H. Willcox. U.S. Bureau of Mines, Technical Paper 136. Government Printing Office, Washington. 73 pages, 9×5½ in. Price 20 cents.*

This paper, which is described as "a manual for foremen and men," gives an account of the dangers of the different kinds of work about blast-furnaces, pointing out how the risk of accident may be lessened or avoided. Suggestions on methods of organising and conducting "safety work" are included. The pamphlet contains 43 illustrations.

UNDERGROUND WASTES IN OIL AND GAS FIELDS AND METHODS OF PREVENTION. By W. F. McMurray and J. O. Lewis. U.S. Bureau of Mines, Technical Paper 130. Government Printing Office, Washington. 28 pages, 9×5½ in. Price 5 cents.*

A DISCUSSION of the methods of avoiding waste in oil and gas fields due to dissipation into other strata, invasion of water, use of improper methods of drilling or recovery, etc.

ORE SAMPLING CONDITIONS IN THE WEST. By T. R. Woodbridge. U.S. Bureau of Mines, Technical Paper 86. Government Printing Office, Washington. 96 pages, 9×5½ in. Price 15 cents.*

A DESCRIPTION of the methods employed in sampling ores in the Western part of the United States, prepared in the hope of improving and ultimately standardising the methods in use.

METHODS OF SAMPLING DELIVERED COAL, AND SPECIFICATIONS FOR THE PURCHASE OF COAL FOR THE GOVERNMENT. By G. S. Pope. U.S. Bureau of Mines, Bulletin 116. Government Printing Office, Washington. 64 pages, 9×5½ in. Price 15 cents.*

A REVISION of Bureau of Mines Bulletin 63 on the same subject.

THE HISTORY AND DEVELOPMENT OF GOLD DREDGING IN MONTANA. By H. Jennings. With a chapter on placer-mining methods and operating costs, by C. Janin. U.S. Bureau of Mines, Bulletin 121. Government Printing Office, Washington. 63 pages, 9×5½ in. Price 30 cents.*

THESE papers were read at the Second Pan-American Scientific Congress held in Washington, Dec. 27, 1915, to Jan. 8, 1916. The bulletin contains 30 illustrations.

THE TECHNOLOGY OF MARBLE QUARRYING. By O. Bowles. U.S. Bureau of Mines, Bulletin 106. Government Printing Office, Washington. 174 pages, 9×5½ in. Price 30 cents.*

A FULLY illustrated description is given of the most efficient and economical methods now in use for producing and preparing marble.

LARKSPUR POISONING OF LIVE STOCK. By C. D. Marsh, A. B. Clawson, and H. Marsh. U.S. Dept. of Agriculture, Bulletin 365. Government Printing Office, Washington. 91 pages, 9×5½ in. Price 25 cents.*

AN account of experiments carried out for three years in Colorado. Larkspur was found to be poisonous to horses and cattle, but not to sheep; horses in pasture or on the range do not eat sufficient to produce ill-effects, however, so that losses of stock from larkspur poisoning are confined to cattle.

PRODUCTION OF EXPLOSIVES IN THE UNITED STATES DURING 1915. By A. H. Fay. U.S. Bureau of Mines, Tech. Paper 159. Government Printing Office, Washington. 24 pages, 9×5½ in. Price 5 cents.*

FIGURES are given showing the amount of explosives, excluding exports, produced in the United States in 1915. Notes on coal-mine accidents due to explosives, and lists of permissible explosives, lamps, and motors tested prior to May, 1, 1916, are included.

* A certain number of these publications can be obtained free on application to the respective Government Departments. In the case of the U.S. Government publications, when this supply is exhausted copies can be obtained at the prices mentioned from the Superintendent of Documents, Washington, D.C., U.S.A.

Official Notices.

REPORTS OF THE PROGRESS OF APPLIED CHEMISTRY.

The first volume of these reports will be issued at the end of this month. The manuscript of some of the sections not having come to hand, the volume will not be as comprehensive as was at first proposed, but it was decided to present an incomplete volume rather than delay publication any further.

CROSS AND BEVAN ESSAY PRIZE OF £20 AND LATHAM RESEARCH GRANT OF £300.

The Council have pleasure in announcing that a gift of £20 has been made by Messrs. Cross and Bevan as a prize for an essay on "The Interconnection of Economic Botany and Chemical Industry."

A further sum of £300 has also been presented by their friend, Mr. T. P. Latham, of Weybridge, to be paid in three annual instalments to such one of the competing essayists as may be judged to be of conspicuous ability, as a grant towards his expenses, on the condition that he apply himself, during three years, to research of approved character on a subject cognate with that discussed in his essay.

The immediate object of the donors is to promote the study of economic botany with special reference to its bearing on chemical industry, giving the widest possible interpretation of the relationship.

They desire, under the auspices of the Society, to assist in forming public opinion in this direction and to discover and further the career of a student of promise who may wish to devote himself to work in such a field.

The Essay Prize will be open to all members of the Society who are British subjects. The Research Grant will be limited to competitors under 25 years of age at the time of sending in the essay.

Essays are to be submitted to the Council of the Society not later than the close of the year 1917. The awards will be made promptly. Neither the prize nor the first grant will be given unless the essayist or essayists shall be deemed to have real merit. The Latham Research Student will be required to submit a report at the close of each year, to satisfy the Council that he has made and is likely to make proper use of the grant.

Edinburgh Section.

Meeting held at Edinburgh on Tuesday, February 13th, 1917.

PROF. JAMES WALKER IN THE CHAIR.

WIREDRAWING

BY A. T. ADAM.

That wire is not a purely modern product is evident from the frequent mention of it in ancient writings. The earliest record dates as far back as 1700 B.C. Gold wire is mentioned in the 39th Chapter of Exodus as having been used to decorate the holy garments of Aaron. We find reference to it also in Homer and Pliny. Metal heads with

imitation hair made of wire were recovered from the ruins of Herculaneum. Wire ropes also were not unknown to the ancients. The excavations at Pompeii brought to light a piece of bronze wire rope nearly 15 feet long and about 1 inch in circumference. This rope is now in the Museo Borbonico at Naples. It consists of three strands laid spirally together, each strand being made up of 15 wires twisted together. Its construction does not therefore differ greatly from that of wire ropes made to-day. It would seem, however, that these early specimens of wire were made by hammering metal (*i.e.* gold, silver, and bronze) into thin sheets and cutting these into fine threads. The first mention of wire drawing occurs in the "History of Augsburg," dated 1351, and in the "History of Nuremberg," dated 1360, where we find the word "Drahtzieher" (wire-drawer). We hear of it soon after in France, but the first mention of it in Britain is in 1565 when a Saxon, named Christopher Shultz, and Caleb Bell came over with a number of foreigners, under the permission granted by Queen Elizabeth, to draw wire through drawing-plates and dig for metals. Caleb Bell had charge of a wire mill which was driven by a water wheel at Holywell, from which mill he supplied toilet pins to Queen Elizabeth.

In the reign of Charles I. the production of wire had attained considerable proportions and an attempt was made by that monarch to introduce protection for the home industry by prohibiting the importation of foreign wire.

At the present day the world's output of wire is enormous. The proportion of the total steel product of the United States of America absorbed in the manufacture of wire rods has been estimated at no less than 20 per cent. Wire in all shapes and sizes is met with at every turn: in fences, nets, telegraph and submarine cable wires, railway signal wires, ropes, springs, pins, needles, bicycle spokes, musical instruments, etc., etc.

In this paper we are dealing chiefly with steel wire, and the following account of the processes involved in manufacture, has reference only to this commodity. The raw material of the wire mill consists of wire rods in coils which are obtained from the steel "ingot" and "billet" respectively by hot-rolling. It is difficult to define clearly a wire rod, because plants are now in operation which are drawing or rolling cold bars in round, square, or hexagon, etc., up to 2½ inches in diameter at least, probably more. In speaking of a wire rod, however, one generally means material which has been rolled hot to about ½ inch diameter and under.

Before the rods can be drawn through a die they must be freed entirely from scale or oxide. It is extremely important that every particle of scale be removed, otherwise the hole through which the wire is drawn will be torn out. The rods are therefore pickled in sulphuric or hydrochloric acid. The strength of the acid used depends on the conditions of working. When the coils are dipped in the pickling tank, it is usual to have a solution containing anything from 2 to 8% of free acid, in which case the operation of cleaning takes about two hours. Slow cleaning is almost essential when the gauge of the wire is small. A strong solution can be used when the gauge is large or when the wire is drawn through the bath continuously instead of being dipped in the form of a coil. The process of pickling may be hastened by using a hot bath. The acid bath works best when it has been in operation a few days, *i.e.* when the specific gravity has been increased by sulphate or chloride of iron. If the specific gravity be too

high, however, the cleaning action will cease unless heat is used. I have found the percentage of free acid in a spent tank as high as in a freshly made up tank. The specific gravity of the former was 1.28, and of the latter 1.03.

Mechanical means have been tried to assist the acid in cleaning the higher class wires, but without much success. This is unfortunate because acid is apt to make the wire brittle unless great care is taken to remove it completely. When all the scale has been removed from the wire it is thoroughly washed with water from a hose. The cheaper qualities of wire are then dipped in hot lime and dried, but with the higher grade wires, which have to receive several passes through the draw-plate without annealing, it is necessary to give them a water coat. This is done by keeping the coils continually under a spray of water until a brown rust is formed; during this operation the wire must not be allowed to become dry. The wire is lined to neutralise any acid remaining and to prevent corrosion. The coil is then dried in a bluing oven at 100° C. where the last traces of acid should be driven off. The wire is then ready for cold drawing. The cleaning operation has to be performed not only on the raw wire rod, but on the drawn wire, each time it has been annealed to facilitate further drawing.

The cleaned wire is taken to the wire-drawer's bench. This consists of a series of drums, technically known as "blocks," tapered from the bottom upwards. Each block revolves on a vertical spindle which projects through the top of the bench and all are driven by means of bevel wheels from one horizontal line shaft running beneath the bench. Each block can be started or stopped independently without stopping the line shaft. One end of the wire is pointed to enable it to be put through the die, the end is then gripped, and a short length is pulled through. The diameter or gauge of this piece is accurately measured before starting. If correct a sufficient length of wire is pulled through to go round the drum or block which is at present out of gear. The point end of the wire is gripped in a vice at the top of the block which is then dropped into gear, and the whole coil is drawn through from a swift near the bench. The reduction effected at each pass through the die varies from 5% to 20% of the diameter according to the nature of the material. The draw-plates are made from the so-called "self hardening steels," *i.e.*, steels which do not require to be tempered, but harden when cooled in air. They contain a high percentage of carbon (about 2%). Some of the alloy steels are used nowadays for draw-plates of special make: for example, one well-known make contains 14% Cr and 3% C; these elements form a very hard double carbide with the iron. The hole in the draw-plate through which the wire passes is first punched hot, then sized and shaped correctly when cold with hardened and tempered tapered punches. Very fine wires are drawn through jewelled dies, diamonds and rubies being chiefly used. Before the wire enters the die it passes through tallow or olive oil soap which acts as a lubricant. Some wires are drawn wet, in which case a liquid lubricant is used. Various "secret" lubricants are in vogue for the wet process, sour beer being a favourite ingredient of most of them. When the wire is to be drawn wet it is polished, to give a bright metallic surface, and is then coated with copper by immersion in a bath of copper sulphate. The copper being softer than the steel forms a kind of cushion between it and the die. It is drawn into the wire and gives it a yellow colour. The process of drawing is repeated until the wire is finished or too hard to be drawn further without heat-treatment.

An improvement in the process of wire-drawing

was made some time ago with the introduction of the continuous mill. In this plant the wire passes through one die after another without being run on to the "block" after each pass, the number of dies employed being limited by the amount of reduction possible before the wire requires annealing. In order to take up the strain, a power-driven barrel is placed between adjacent dies, and the wire is wound two or three times round each barrel in succession.

A pull is thus obtained from each revolving barrel sufficient to draw the wire through the die placed behind it.

The process of drawing metals into wire has a very marked effect on their physical properties. The metal loses ductility and becomes harder and more brittle with each pass through the die. The tensile strength is increased while the percentage elongation is decreased. The elastic limit is also raised, but within the limit of elasticity the modulus remains unchanged. The extent to which these changes take place naturally varies with the material. The most striking change is the extraordinary increase in tensile strength and elasticity. The hardness and brittleness do not increase in the same proportion. Steel which contains more than 0.5% C if quenched in water from a red heat becomes glass-hard and brittle, but even the most severely drawn wire never becomes so hard and brittle as this, although the ultimate strength of hard drawn wire is much higher than that of quenched steel. The tensile strength of the finished wire varies from about 40 tons to 170 tons per sq. inch according to the nature of the steel. A piano wire 0.0284 inch diameter, tested at Watertown Arsenal, showed the enormous strength of 211 tons per sq. inch. Such wires receive special heat treatment in order to enable them to stand the excessive cold work to which they must be subjected.

The hardening effect due to drawing sets a limit to the reduction that can be effected without annealing. Annealing alters the internal structure of the wire and completely obliterates the hardening effect of drawing, making the wire quite ductile again. It is not necessary to heat wire above the critical point of the steel, where the crystalline structure undergoes a complete transformation (this point lies between 700° and 800° C.). The effects of cold work can be almost entirely removed by heating to 600° or 650° C., but for high class work it is usual to anneal completely. Various modifications of the ordinary annealing process are in operation which constitute the more or less "secret processes" of the trade. The most important of these is what is technically called the "patenting process." In this process the wires are passed continuously through a long furnace, each wire having a separate flue or channel and cooled in air or sometimes in a lead bath. The main object in these processes is to produce in the steel the constituent known as "sorbite" which is tougher than the constituent known as "pearlite" found in slowly cooled steel. "Sorbite" is really a phase of "pearlite" produced by more rapid cooling. During these annealing processes the wire is oxidised and scale forms, which necessitates further pickling and causes considerable loss of metal. To minimise this many manufacturers exclude air during the heating operation either by annealing in sealed pots or by introducing non-oxidising gases to the furnace.

In hot rolling the crystalline grains of a metal are not permanently elongated but merely broken up into a large number of smaller grains. The effect of cold drawing on the crystalline grains is quite different from this. The grains of a wire are elongated and, after several passes through the die, the structure, as seen in a longitudinal section, is quite fibrous in nature. If the wire were semi-

transparent and could be viewed by transmitted light the structure would doubtless resemble that of some hemp fibres, *i.e.*, the elongated grains would be seen as parallel bundles or even running into one another, giving an interlacing structure.

It is not generally realised that hard and rigid bodies like the common metals possess a considerable degree of plasticity at atmospheric temperature. The fact that metals could be made to flow and to behave in other respects like fluids of high viscosity, such as pitch or glue, has been demonstrated in various ways, notably by Tresca, Spring, and Tammann. It is not, however, the most plastic or malleable metals which are most readily drawn into wire. According to Desch "the order of plasticity revealed by some of the most familiar metals is—K, Na, Pb, Tl, Sn, Bi, Cd, Zn, Sb," but these are not the most ductile metals. The order of ductility of the more important metals is given by Sir Roberts Austen as: Au, Ag, Pt, Fe, Ni, Cu, Zn, Sn, Pb. If this be true it would seem that wire drawing does not depend entirely on plasticity. Indeed, as we have said above, the constituent called "sorbite" in steel is said to be more suitable for wire drawing than the more plastic constituent called "pearlite." However, the rate at which traction is applied has great influence in testing plasticity and ductility.

The plastic deformation involved in drawing a hard crystalline solid like iron or steel into wire is not identical with that of an amorphous substance like pitch. The flow of pitch has been shown to be that of a fluid of high viscosity, while the microscope has shown that the flow of crystalline bodies is of quite a different nature.

The studies of Tyndall and Forbes on the behaviour of glaciers were the first attempts to throw some light on the subject. It is well known that glaciers move like highly viscous fluids. This movement was explained by Forbes as being due to the plastic flow of ice-crystals under the action of slowly applied stresses. Tyndall opposed this view and stated that the flow was due to regelation, that is, the pressure on the ice, by lowering the melting point, caused the formation of a small quantity of liquid water which carried the grains of ice along with it, freezing and consequent cementing of the mass taking place as soon as the stress was relieved. For long controversy raged over the cause of glacier flow, and some metallurgists applied the regelation theory to explain the flow of metals. That regelation, under pressure, occurs in some metals such as bismuth is possible, but this is hardly a feasible explanation of the flow of such a metal as iron or steel. Nor is the probable existence of slight plasticity of the metal crystals themselves sufficient explanation of the rapid flow which occurs in wire drawing, swaging, or punching.

The discovery of "slipbands" in crystalline bodies by Ewing, Rosenhain, and others, together with the researches of Sir George Beilby on the nature of polish, indicate the most plausible explanation of the facts. If a piece of metal with a smooth polished surface be strained or bent, a number of fine lines appear running in definite directions in each separate grain. These lines have been shown to be stepped in character, and their occurrence exactly resembles the production of step faults in geological strata. The direction of these "slipbands" is along the cleavage planes of the crystals. When a metal is subjected to alternating stresses these slipbands increase and finally form fissures, ultimately causing fracture of the material. In this way the phenomenon of "fatigue" in metals is explained; but it is well known that "fatigued" metals are hard and brittle like cold-drawn wire, and the experiments of Beilby offer an excellent explanation of this. These have shown that the effect of

polishing is to cause a surface flow of the substance being polished, and have proved the existence of a thin layer of flowed structureless material strongly resembling in its behaviour a highly viscous fluid. It would seem then that when a wire is drawn through a die slipping takes place in the metal along innumerable gliding planes, and sufficient viscous matter is formed to carry the crystalline material with it. When the traction is removed this sets in the form of an amorphous cement around the crystals. It is impossible by the most severe treatment to convert the whole mass into the amorphous modification. Hence, as already explained, there is a limit to the hardening effect of drawing. The hard amorphous material is not a stable modification and therefore cannot be truly called a phase. When the rigidity of the metal is decreased by heating, even to comparatively low temperatures like that of boiling water, partial recrystallisation takes place, and this is more marked when the temperature is raised to 400° to 500° C. The examination of the micro-structure of steel wire affords considerable support to this amorphous cement theory, and this, taken in conjunction with the physical properties, seems to place the matter beyond doubt.

The author exhibited several specimens of wire and wire rope and a number of photomicrographs of sections of wire, expressing his indebtedness for the use of these to Messrs. W. N. Brunton and Son, of Musselburgh.

MOTOR SPIRIT.

BY J. G. ANNAN, B.S.C., F.I.C.

Within the last few years the enormous expansion of the applications of the petrol engine to the motor car and to transport vehicles generally has led to an unprecedented general interest in the sources and methods of manufacture of motor spirit, and this interest has been greatly stimulated by the enormous absorption of motor spirit for war purposes, and by the recent restrictions which have been rendered necessary on that account.

It appeared that it might be of interest to give a general account of the principal methods, the rapid development of which, in the United States at least, greatly minimised the threatened shortage due, amongst other causes, to the enormous consumption for war purposes and to the supplies from several of the European petroleum fields being cut off from this country and its allies by belligerent operations.

Leaving out of account a moderate but rapidly growing annual contribution from Mexico, amounting to something like 10,000,000 gallons, the bulk of the 165,000,000 gallons of motor spirit imported by this country last year has been derived from the United States and from the Dutch Indies in nearly equal proportions.

As regards the Dutch Indies, the petroleum from this source is unusually rich in the lighter fractions, and probably on that account a large increase in the motor spirit supplies was possible without departing from the usual methods of manufacture.

It was otherwise with the United States, where an immediate increase in the exports of motor spirit was rendered difficult mainly because the domestic consumption had greatly increased while the production of motor spirit showed, temporarily at least, a decided tendency to diminish. The increase in domestic consumption was caused by the great expansion in the number of motor cars in use in the United States, the number registered increasing from about 1,800,000 at the end of 1915 to over 3,000,000 at the close of 1916—this being in addition to the growth in the application of the petrol motor in other directions. The

falling off in production was due to the rapid decline of the Cushing field in Oklahoma, which from producing 12 million gallons daily of crude oil, containing 25% to 30% of motor spirit, fell to less than 2½ million gallons daily. The new production brought in to replace this only contained 15% to 17% of motor spirit.

The position was, therefore, that the United States had to meet a greatly increased and urgent export demand and was at the same time faced with a rapidly increasing domestic consumption combined with a serious falling off in the crude oil supplies which were richest in motor spirit.

There appeared to be three methods, all of which had fortunately advanced well beyond the experimental stage, by which the motor spirit yields from the existing crude oil supplies could be materially augmented:—

(1) By widening the motor spirit cut so as to take in portions of the distillate which were formerly included in the burning oil or kerosene, whereby larger yields of motor spirit could be obtained, although the specific gravity of the latter would be raised thereby.

(2) By extending the casinghead gasoline industry, which consisted in collecting the hydrocarbon or casinghead gas which is ejected with the petroleum from the well, and recovering the heavier hydrocarbon constituents in liquid form by suitable methods, the product being termed "casinghead gasoline."

(3) By "cracking" the relatively less valuable heavy oils whereby they are converted into lighter spirit.

As a matter of fact, all three methods have been applied and have materially assisted in maintaining and even increasing the supplies of motor spirit sent to this and the allied countries.

Widening of the motor spirit cut: In the early years of the petrol driven motor car, motor spirit consisted of an article having a specific gravity of about 0.680 and having a distillation range of from about 95° to about 270° F. (35° to 132° C.) Such a spirit consisted mainly of pentane, hexane, and heptane, with some butane, octane, and decane, and owing to its low boiling point had the great advantage of volatilising readily even in carburettors of the most primitive type. Any attempt at that time to supply a spirit appreciably heavier for the then existing carburettors and engines invariably gave rise to more or less vigorous complaint. As engine and carburettor design progressed and the demand for motor spirit increased, and doubtless as the motoring public advanced in knowledge and experience of the petrol engine, the specific gravity of the spirit manufactured and satisfactorily used very slowly increased until, with carburettor and engine of most modern design, a very much heavier spirit is now more easily consumed than was formerly believed possible.

The figures obtained in fractionations of a series of representative samples of motor spirit bought within the last few weeks at random on the open market are shown on p. 246 under heading Nos. 2 to 12 inclusive, from which it appears that the specific gravity of the best brands of motor spirit averages about 0.725, and that all the members of the paraffin series from butane up to hexadecane are now present.

Column headed No. 1 shows a fractionation of a sample of the motor spirit in use about seventeen years ago and mentioned above as containing all the members of the hydrocarbon series from butane up to decane. Columns headed Nos. 2 to 6 inclusive give the fractionation results of well known foreign makes of motor spirit which have been produced by a straightforward distillation of petroleum in the ordinary way. Column headed No. 7 shows a fractionation of a spirit made by the "cracking" of a heavy oil, this process being

operated to a certain extent in this country. Columns Nos. 8 to 12 inclusive give fractionations of current qualities of Scotch shale spirit.

Probably the increase of motor spirit supplies due to the more recent increase in the specific gravity does not exceed 10%, but the actual increase in volume of motor spirit arising from the widening of the motor spirit cut is more important than appears because it could be, and was, adopted by practically all manufacturers, no special provision being necessary in the way of extra plant and expenditure, while as a matter of fact for various reasons the recovery of casinghead gasoline and the "cracking" of heavy oils attained their greatest development in the United States.

Casinghead gasoline.—Casinghead gas is the name given to the hydrocarbon gases which issue with the crude oil from the petroleum wells. In the early days of the petroleum industry the casinghead gas was regarded and treated as a waste product, which after being utilised as far as possible for local heating and other purposes, was simply burned as the easiest method of disposal in enormous jets which incidentally provided a tropical climate in the immediate vicinity and illumination of the surrounding country on an unnecessarily lavish scale.

The composition of the gas varies from well to well, and two different qualities of gas are recognised and distinguished by the terms "dry" and "wet." The "dry" casinghead gas may consist almost entirely of hydrogen, methane, ethane, propane, and butane, while the "wet" gas may contain these and in addition the pentanes, hexanes, and heptanes, the only normally liquid constituents of crude oil which at ordinary underground temperatures have vapour pressures of such magnitude that they are distilled in quantity from the crude oil, whence we expect pentane, hexane, and heptane to form the principal constituents of casinghead gasoline.

Generally speaking, the amount of gas from an average well will amount to several thousand cubic feet per 24 hours, and several such wells have to be grouped in order to provide a volume of gas large enough to render the gasoline extraction remunerative.

There are two systems of casinghead gasoline extraction, termed respectively the "compression" and the "absorption" process.

The compression process is most commonly used at present, but as the drier gases come to be dealt with the absorption process must be also utilised to a corresponding extent. For gases yielding less than 1½ gallons of gasoline per thousand cubic feet the absorption process is preferred. In the compression process the gas from several wells is piped to a convenient centre where one or more single or double stage compressors are installed which force the gas at a pressure of from 50 to 300 lb., depending on the nature of the gas, through a series of water-cooled metal condenser coils, whereby the casinghead gasoline separates out and is collected in suitable tanks also under pressure, while the incondensable gases are piped away to the point of consumption. One single unit compressor plant costs from £2400 to £3000 to instal and will handle about 500,000 cubic feet of gas per day.

The absorption process consists in passing the casinghead gas, usually under pressure, through a series of perforated pipes immersed in heavy oil contained in tanks, whereby the heavier constituents of the gas are dissolved and retained by the heavy oil while the unabsorbed "permanent" gases pass away to the point of consumption as before. By a steam distillation of the heavy oil the casinghead gasoline is subsequently recovered and stored in tanks under pressure.

The composition of casinghead gasoline is more

complicated than might be imagined from its method of recovery. The physical changes occurring under compression and cooling comprise not only condensation of vapour and liquefaction of gases but also the solution of the residual gases in the liquids so produced. Generally speaking, however, the condensate going to the tanks consists principally of pentane, hexane, and liquefied butane, but some heptane and liquefied propane are also present.

The yield of casinghead gasoline varies with the composition of the gas, and ranges from eight gallons for a rich gas down to a fraction of a gallon per thousand cubic feet for a poor gas which would not repay the cost of gasoline recovery. The average yield, however, amounts to about $2\frac{1}{2}$ gallons per thousand cubic feet. The total production of casinghead gasoline, which amounted to only a few thousand gallons in 1904 and to 30,000,000 gallons in 1913, rose to an estimated production of about 80,000,000 gallons in 1916.

At one time much of the casinghead gasoline was shipped as such, but owing to its excessive volatility it was unsuitable as a motor spirit and somewhat dangerous to transport on account of the pressure liable to develop under weather conditions which were by no means abnormal. Such pressures, amounting sometimes to about 50 lb. per square inch were, considering the nature of the material, not desirable.

One method of minimising this objection was to "weather" the gasoline by exposing it more or less freely to the atmosphere, whereby the more volatile constituents were dissipated, but the losses incurred thereby were very excessive and often amounted to 50% in twenty-four hours' exposure.

The method now generally followed, however, is to mix the casinghead gasoline with heavy naphtha in suitable proportions, whereby the objectionable excessive volatility is largely reduced, and the mixture can be shipped and marketed as motor spirit.

The specific gravity of casinghead gasoline is often as low as 0.630 and occasionally as low as 0.609 from a second stage compressor. Taking, however, an average figure of 0.645 to 0.648, the gasoline is mixed with naphtha of about 0.753 to 0.761 specific gravity in equal proportions, giving a blended gasoline or motor spirit having a specific gravity of about 0.700 to 0.705. Such a spirit would, as far as specific gravity and general appearance are concerned, be indistinguishable from a "straight" or normal refinery product, but the great difference in composition would be disclosed by the results of a fractional distillation. Where the blending has been unskillfully carried out a motor spirit of unsuitable quality might be easily obtained, and the uncertainty regarding this has led the United States authorities to investigate the advisability of fixing a standard of quality to which motor spirit should conform in that country, and this investigation is now proceeding.

"Cracking" processes.—The idea of converting the heavier hydrocarbons into lighter hydrocarbons by distilling the former under pressure appears to have originated with James Young, jun., who, in 1865-1866, patented a method of distilling heavy shale oil under pressure, the particular object in view being to increase the burning oil yields—at that time perhaps the most lucrative product of the shale oil industry. The plant patented consisted of a pot still and condenser of the ordinary type, the former being fitted with a safety valve and also a valve at the vapour outlet whereby the vapours emerging from the still could be throttled so as to maintain any desired pressure on the still. The vapours passing this valve escaped freely to the condenser and were there condensed.

In 1886 Benton took out a patent for an appara-

tus which bears some resemblance to several of the more modern forms of tube "cracking" plant.

In 1889 Dewar and Redwood patented an arrangement similar to Young's, but with, however, the important difference that the valve was placed at the condenser exit instead of the still exit, thus securing that both distillation and condensation were effected under pressure, while free communication existed between still and condenser. It was also specified in this patent that the still and condenser space not occupied by liquid should be filled with carbon dioxide or other inert gas under pressure.

Within the last few years much experimental work has been done with a view to devising commercially applicable methods for the conversion of the relatively less valuable heavy oils into motor spirit. The list of patents in connection therewith is a long one, and is being added to at frequent intervals. Broadly speaking these patents may be arranged in three groups:—

First, those in which the heavy oil is subjected to a temperature considerably above its boiling point under a pressure which is sufficient to maintain the contents of the still in the liquid condition.

Second, those in which the oil is vaporised and "cracked" in a vaporous condition; and

Third, those in which attempts have been made to "crack" at atmospheric pressure by distilling the heavy oils in contact with various catalytic agents such as aluminium chloride; but the principal objections have been the cost of recovery of the expensive catalytic agent from the still residue, and the difficulty of maintaining intimate contact between the heavy oil and the catalytic agent.

The best known process of the first of the groups mentioned above is that of Burton, one of the directors of the Standard Oil Company of Indiana, U.S., who in 1913 took out a patent for a process which is practically a reproduction of that patented by Dewar and Redwood about twenty-five years ago, and already mentioned. Burton's process has been adopted by the Standard Oil Company of Indiana and successfully developed by them on a large scale, whence its use has extended to practically all the Standard Oil Companies in the United States. The practical disadvantages attending the operation of a plant such as that patented by Burton are great, though not insuperable, as has been proved by its commercial success in the hands of the Standard Oil Company.

Generally speaking it is considered desirable to raise the oil to a high temperature in order to attain the maximum "cracking" efficiency, but the pressures required to maintain the heavy oil in the liquid state reach their safe limit at a comparatively low temperature with this type of plant. The carbon which separates in large quantity as a necessary result of the "cracking" distillation compacts to a non-conducting layer on the interior surface of the still bottom, and renders the still liable to over-heating, and the still bottom liable to frequent failure.

The results of such a failure under the pressures and temperatures applied in the Burton process, 700° to 800° F. (370° to 426° C.) and about 80 lb. per square inch, must be difficult to localise. Practical considerations of this kind have limited the Burton process to a size of still small enough to enable the results of such a failure to be kept within manageable limits.

Since the difficulties referred to appear to be inseparable from the distillation of large volumes of hydrocarbons under the high pressures necessary to attain even a moderately favourable "cracking" temperature, many more or less successful attempts have been made to vaporise the oil continuously and to "crack" the resulting vapour in a "cracking" chamber of limited size.

As described by Dr. Rittman in a recent patent.

specification, such a plant in its simplest form may consist of a 10 to 15 ft. length of 10 inch diameter metal pipe set vertically in a furnace so arranged that the temperature of the pipe gradually increases from the top to the bottom. Heavy oil continuously injected under pressure at the upper end of the tube instantly vaporises at the temperature existing there, and the resulting vapour passing down the tube through the region of higher temperature is "cracked" and finally the "cracked" products pass, still under pressure, through the condenser from which the liquid and gaseous products are distributed to the tank and gasometer respectively. The temperatures and pressures recommended as giving the best results with such a plant are as high as 900 to 1300 F. (480 to 705 °C.), and up to and over 300 lb. per square inch.

The vapour "cracking" type of plant has the advantage that the temperature and pressure can, within limits, be adjusted independently at values for which the maximum yields are obtained, and this confers an advantage which is not shared by the process of distillation in bulk under pressure.

While with the tube "cracking" process the element of danger always present in the bulk distillation process is largely removed, the former process is embarrassed to a much greater degree by the carbon accumulations both from the liability to blocking of the tubes and from the brittleness set up by the case-hardening effect of the continuous heating of the metal in contact with the carbon deposits whereby replacements and repairs are rendered difficult.

In the United States, "cracking" plant and casinghead gasoline plant are now largely worked in conjunction with one another, the former supplying the heavy naphtha and the latter the very light spirit for the production of the blended motor spirit.

The crude product from a "cracking" distillation contains in general a certain proportion of highly unsaturated hydrocarbons which render it in consequence not marketable in its original condition. The crude product is foul smelling, has a yellow colour which intensifies on standing, and when used in a petrol engine gives unsatisfactory results and excessive carbon deposits.

Skilful and energetic refining treatment is required to remove these objectionable characteristics; refining losses are high, and refining costs are consequently higher than with the ordinary refinery product.

In the more modern developments of the cracking process it should be noted that great importance is attached to both condensation and distillation being carried out under pressure of the gaseous products of decomposition. It is claimed that the yield of liquid products is increased thereby and that the proportion of unsaturated hydrocarbons contained therein is correspondingly reduced as compared with, *e.g.*, Young's original method, in which the "cracked" products are freely discharged to the condenser under atmospheric pressure. This claim appears to be supported by obvious theoretical considerations, because condensation under pressure is equivalent to increasing the concentration of the gaseous products in the system, whereby the equilibrium must move in the direction of increasing the formation of condensate and of saturated hydrocarbons and decreasing the formation of gaseous products.

It has been estimated that the production of "cracked" spirit in the United States rose from 80,000,000 gallons in 1915 to 200,000,000 gallons in 1916.

MR. JAMES MACLEOD IN THE CHAIR.

THE PREPARATION OF CHEMICALS FOR LABORATORY USE.

BY WILLIAM RINTOUL.

The purity and reliability of reagents and materials constitute one of the main factors essential to accuracy in chemical analysis and research. In the past Germany has enjoyed a monopoly of the supply of these bricks and mortar of our science, and that we have been content that this should be so provides an example of the grounds on which posterity may justly base its inevitable reproach and censure on our national neglect of science and of industries intimately connected with scientific development. Practically the whole of the energies of the limited number of chemists qualified for this work were occupied in carrying on those industries which had already been established and no spare force was available for extension. In fact, the chemists in this country were and are in the position of an army without reserves.

To this cause is due the neglect in this country of such industries as the manufacture of pure chemicals for laboratory use. So long as our energies were fully occupied in keeping alive existing industries, and so long as the quality of our supplies of imported materials remained satisfactory, we had no choice but to accept the position which had arisen. Of late years, however, the quality of supplies from these sources has been degenerating and this degeneration has been coincident with a material growth in importance of the industry involved. For these reasons, and because of the imperative necessity that in future we must be independent of Germany as far as possible, it is clear that the time has now arrived when the British Empire must consider her posi-

tion with regard to the supply of materials necessary for the proper control of so many of her industries.

With one or two exceptions, the raw materials employed in the preparation of laboratory reagents, that is to say, a wide range of chemical substances of a commercial or technical standard of purity, can readily be obtained within the Empire, and if the scientific knowledge and skill necessary for the elaboration of the methods and plant requisite for their purification can be made available, there is little doubt that this growing industry need not long remain in foreign hands, in so far as this country's requirements at least are concerned.

The difficulties to be overcome in establishing an industry such as this must not be minimised. In the case of an entirely new industry one is often hampered by the lack of available information and by the fact that each step has to be fully investigated before general principles can be established. In the case under consideration, the difficulties are of an opposite nature. An enormous literature has already grown up dealing with the preparation and properties of chemical substances, and unfortunately much that has been written is either inaccurate or misleading. This is true to such an extent that in many cases the published statements are embarrassing rather than helpful. Especially in text books is this the case, probably because of the extensive copying which has taken place, writers of such books being rather prone to accept as correct statements that have appeared in earlier works. Even when a statement which has acquired weight by reiteration alone is disproved, it is sometimes extremely difficult to persuade an author of a subsequent text book to take the responsibility of giving the corrected version the weight of his approval.

An instance of the misleading statements which find their way into the literature is to be found in the method for the preparation of dimethylaminobenzaldehyde described in one of the most recent German text books. Repeated experiments, in which the directions given were most carefully followed, failed to produce the result claimed by the author, and it was only after a considerable amount of research that a successful method for the preparation of this substance was evolved. Again, in the preparation of phthalic acid, if, as is laid down in the literature, the mixture of naphthalene, sulphuric acid, mercuric sulphate, and water is slowly heated, nearly 50% of the naphthalene distils unchanged and a low yield results, whereas if the naphthalene and sulphuric acid are first of all heated together until sulphonation is complete and then the mercuric sulphate and water are added, a much more economical yield is obtained.

At the outset, therefore, when the reagents to be prepared have been selected, it is first of all necessary that the literature dealing with each of them should be read in a carefully discriminating spirit. Only after this, can a programme of experimental work be drawn up with the object of testing the truth of the various statements which have been selected as possibly correct and so finally arriving at a definite conclusion as to the methods best suited for the preparations required. All this necessitates such a volume of experimental and research work that it is obvious from the beginning that this is not an industry which lends itself to immediate adoption on a large scale. If it is to be successful in its final condition it must be allowed to grow as the knowledge and experience on which it must be based becomes available.

Practically every new substance prepared will entail a certain amount of research work, sometimes more, sometimes less, and in order that this work may be carried out expeditiously it is necessary that a fully equipped and staffed research laboratory should be available. At the same time the

demand for research work will fall off as the industry grows, and, though it will never cease, it will become spasmodic. When a demand arises for a number of preparations which have not hitherto been investigated, a large research staff will be fully occupied, and when the final reports on this work have been compiled, other work will have to be found for the research staff while the manufacturing laboratories are developing, on a requisite scale, the processes which have been evolved. Considerations such as these suggest that it would be preferable that the preparation of pure chemicals should be undertaken under conditions which would permit of use being made of one or other of the research laboratories at present in existence in connection with certain of our principal chemical industries, rather than that the new industry should be saddled with the expense of a large, and at times partially employed, research section.

The research work required in this connection need not be confined to a technical laboratory. There exists at present throughout this and other countries a strong feeling that everything possible should be done to encourage a closer association between the University on one hand and the industry on the other. With many industries a grave difficulty will be found to exist in the highly specialised knowledge and experience necessary to accomplish useful development work, while at the same time it is exceedingly undesirable that such close specialisation should be introduced into the work of the University. In the case of pure chemicals, however, this difficulty does not exist. The work required is of a general and not a specialised nature and can readily be adapted to suit academic conditions. It possesses moreover the further advantage that the University as well as the industry would benefit by association in this work, because it can be used both as an educational implement and as a means for the solution of technical problems, and would constitute a bond not only between the University and the industry of fine chemicals but between the University and many chemical industries. The work to be carried out under the auspices of the University would be embodied in reports describing in detail the best method which had been selected or devised for the preparation of particular chemical substances, having always in view the purity of the product and—a feature often overlooked by academical workers—the comparative economy of all the methods examined. Investigations of this nature carried out by students under the guidance of their professor would inculcate the necessity of making use of the literature of a subject and engender the ability to do so. They must be carried out under the best conditions as regards purity and yield of product and economy generally, and each stage then becomes essentially an accurate operation in quantitative analysis in which not only the main reaction but also all secondary reactions must be closely followed with the view of promoting the former and discouraging the latter. The educational value of such work is obvious and that there is room for its adoption will be granted when it is considered that the analytical knowledge and skill possessed by the average University graduate when he leaves his college is at present far from satisfactory.

The importance of the purely scientific investigations which, in the past, have been the main object of University research is not to be challenged, but if some of the rather pointless communications of doubtful scientific value were replaced by authoritative statements on even the comparative value of various existing methods for the preparation of important compounds, the net result would be a material gain in useful knowledge. Now that our Universities are endeavouring to turn out graduates well equipped for technical work,

investigations having some practical bearing will probably become more general than formerly, and this again should render subjects of the nature suggested more acceptable.

It would, of course, be necessary that those responsible for the industrial policy should be kept informed as to the progress of each investigation, and thereby a further advantage would be gained. Manufacturers would for the first time be brought into touch with students approaching the end of their University training and would be in a much better position ultimately to select the men who best suit the special requirements of their business than they are at present.

The ease with which the work can be selected so as to afford subjects of greater or less difficulty should render it attractive both to Universities and to Technical Colleges, as enabling them to grade the work allotted to students in different stages of the training.

In addition to its educational value, co-operation between this industry and the Universities would doubtless result in the discovery of valuable commercial processes. The successful solution of the immediate problems arising directly out of the preparation of pure chemicals might not in themselves be of great financial value because the total quantities involved are not large and the amount of money to be invested in the industry is small in comparison with other commercial undertakings; but not the least of the charms of research work is the infinite possibility underlying it, and there are instances innumerable where a subsidiary and unlooked for discovery has dwarfed into insignificance the successful solution of the original problem. In properly organised research on the preparation of pure chemicals there is undoubtedly a great possibility of making discoveries of value in greater industries and this should provide an incentive of no mean order to those undertaking the work. The question of the ownership of discoveries arising out of a study, by the University, of problems suggested by an industry, constitutes one of the preliminary questions upon which an agreement must be arrived at; but it should not be difficult to devise a working arrangement which would be satisfactory to both parties. Again, the value of many discoveries has been lost or their useful application delayed owing to the inventor's want of knowledge as to where, and in what connection, his discovery can best be made use of; the industrial partner should provide a solution of this difficulty. The experts engaged in and responsible for the working of one industry cannot fulfil their functions properly without possessing a fairly intimate knowledge of the conditions and requirements of many other industries connected, directly and indirectly, with that in which they are engaged. They should therefore be in a particularly favourable position to bring any new discovery before the people who are awaiting it most anxiously.

Now, as regards the products of this industry; all chemicals for laboratory use must possess a known and sufficient degree of purity, and in this connection the pamphlet on "Reagents for Analytical Purposes" issued by the Institute of Chemistry and the Society of Public Analysts last year, is a step in the right direction.

Nothing is more annoying to the chemist than to find, after he has spent much time and energy on an investigation, that his work is valueless and that his results must be discarded because one of the reagents used contained an unsuspected impurity. To quote a particular example, it was only after much work had been done and valuable time expended that a quantity of so-called "pure" phenanthrene which had been purchased from a German firm and accepted on its melting point and on the authority of a well-known label, was found to contain some 70% of anthracene. That it

gave the correct melting point of phenanthrene may or may not have been a coincidence!

To ensure satisfactory purity in the output in a manufacturing laboratory such as is required for this work, it is necessary to institute a much more accurate control than suffices for ordinary manufacturing operations. As an indication of the refinements that are possible in this direction it may be of interest to quote an instance from the records of the Nobel Research Laboratories at Ardeer. Some years ago certain discrepancies in analytical results were observed and, on a rigorous investigation, it was found that these could only be ascribed to variations in the degree of purity of the substances then used for the preparation of volumetric solutions. It was decided that this question should be set at rest once and for all by the selection of some one particular substance which could be obtained or prepared in a condition of great purity. This substance was to be termed the "Ultimate Standard," as far as these laboratories were concerned, and the purity of all other chemicals used was to be determined in relation to this standard. After careful study of the problem and consultation with the authorities of the National Physical Laboratory, who were of the greatest assistance, it was finally decided that metallic silver was the substance best suited for adoption as the ultimate standard. Silver cannot, however, be used directly for the standardisation of acids or of oxidising or reducing substances, and it was therefore decided to employ subsidiary standards for general purposes of control. The substances selected for these purposes and referred to as "Working Standards" were sodium carbonate and iodine. As it is only in the determination of atomic weights that the purity of a substance undergoes a rigorous examination, the work of preparing the ultimate and working standards and correlating their purity was carried out under conditions suitable for atomic weight determinations. The purest silver obtainable was first of all electrolysed, then washed with sulphuric acid and water, and fused in lime crucibles in a current of hydrogen. The silver buttons were polished, washed with ammonia solution and water, dried, and kept in hermetically sealed glass tubes.

The electrolytic method of purification removes all metals except gold and platinum, and the absence of these as well as of carbon is proved by the complete solubility of the silver in nitric acid. No trace of copper could be detected although this metal was present in the original silver to the extent of 0.0007%.

The iodine for the working standard was purified by mixing commercially pure resublimed iodine with 10% of potassium iodide and 5% of calcium oxide and slowly resubliming the iodine in a special apparatus. The iodine collected was then resublimed twice in the same apparatus without addition. In the last sublimation a residue of 4 mgrms. was obtained from 350 grms. of iodine. The iodine from the last sublimation was powdered and kept over phosphorus pentoxide for two months and the dry iodine sealed up in small glass tubes each containing 5 or 10 grms.

The preparation of pure sodium carbonate gave much trouble, and the final product was not satisfactory as regards absolute purity. One preparation only need be described. 700 grms. of commercially pure anhydrous sodium carbonate was dissolved in 2.5 litres of distilled water at 25°. The solution was filtered into a narrow-necked flask and carbon dioxide passed into it. The carbon dioxide was previously washed with solutions of ammoniacal silver nitrate, dilute sulphuric acid, and sodium bicarbonate. After the air above the solution had been replaced the flask was closed so that only the carbon dioxide passed into it which was required to take the

place of that absorbed to form bicarbonate. When the process of saturation was complete at ordinary temperature, the solution was cooled to 0°, filtered by suction through hardened filter paper, and the precipitated bicarbonate washed with ice-cold water. The bicarbonate so obtained was then stirred in small quantities at a time into distilled water at 80°, until the solution was saturated. The solution was then allowed to cool until a small quantity of the salt had crystallised out. The mixture was then filtered quickly through a silver cone with fine holes. These first crystals contained all the mechanical impurities and were discarded. The solution was then cooled to 10°, the further crop of crystal collected in a funnel containing a silver cone and washed with small quantities of cold water. The mother liquor was concentrated three times in successive stages and each crop of crystals collected separately, the mother liquor from the last crop being evaporated to dryness. The purity of these fractions, after they had been heated in silver capsules at 250° to 300° C. until constant in weight, was determined in terms of the ultimate standard. The sodium carbonate content was as follows:—

	%
1st crop of crystals	99.906
2nd crop of crystals	99.877
3rd crop of crystals	99.896
4th crop of crystals	99.891
Residue from final mother liquor	99.857

The purest fraction, that of the first crystallisation, was again recrystallised with the following results:—

	%
Crystals	99.901
Residue from mother liquor	99.902

From this it was concluded that the limit of purification possible by this means had been reached although the final product still contained impurity to the extent of about 0.1%.

In the determination of the silver-iodine ratio the iodine was reduced to hydriodic acid by hydrazine and precipitated by a known quantity of silver. Six determinations gave the following results for the ratio of iodine to 100 parts of the ultimate standard silver: 117.691, 117.673, 117.657, 117.653, 117.650, 117.661. Mean 117.664. The following values for this ratio have been obtained by other operators:—Merignac, 117.533; Stas, 117.534; Baxter, 117.656; calculated from international atomic weights, 117.650. This agreement was considered satisfactory, and for purposes of standardisation in the Ardeer laboratories the ultimate standard is assumed to be of 100% purity. On this basis the working standard iodine contains 99.99% of iodine and the working standard sodium carbonate 99.93% of the pure substance. A supply of these standards has been prepared sufficient to last for many years and the work can be accurately repeated at any time.

It is now proposed to utilise the organisation which has grown up in the Ardeer Laboratories for the purpose of rendering available to other laboratories a supply of certain chemicals the quality of which can be absolutely relied upon.

As the principal object to be aimed at in these preparations is a high degree of purity, it is not intended that any of the operations shall be carried out on a manufacturing or large scale. The size of a working batch will be limited so that the accuracy of laboratory practice rather than of manufacture may be obtained, and in order that the products, may be characterised by their homogeneity as well as freedom from impurity. A special manufacturing laboratory has been equipped for this work. It has been furnished with all the items of plant likely to be useful in work of this nature and can command the services of all the general factory workshops and tools.

Each final operation in this laboratory results

in the preparation of a quantity of a finished material which, whatever its size may be, is given a lot number to identify it as a unit. After thorough blending, a sample of each lot is submitted to the analytical laboratory for examination, just as if the material had been purchased from an outside source. If the analytical report is satisfactory, the lot is passed for issue, and the essentials of that report are printed on the labels of the bottles containing it. These tested chemicals are issued to the usual chemical dealers for disposal. The simplest analytical report which could be issued would be a statement of the percentage of the particular substance which any preparation purports to be, leaving it to be assumed that the difference from 100 represents the impurity content. It is considered, however, that it is more useful to define the impurities which have been detected and leave the assumption to be made in the other direction. It is too much to hope that every impurity present in such a wide range of substances can be detected and its proportion determined, but the examination is made as thorough as possible and, where it is known that particular impurities interfere with the use of any reagent for a specific purpose, these of course receive special attention, both as regards elimination and detection.

MR. A. R. LING IN THE CHAIR.

ARTIFICIAL FERTILISERS—THEIR PRESENT USE AND FUTURE PROSPECTS.

BY EDWARD JOHN RUSSELL, D.S.C.

(Director of the Rothamsted Experimental Station).

Artificial fertilisers are simple salts which are added to the soil to help in the nutrition of plants; they are called "artificial" because they have usually undergone some manufacturing process. There are three classes: nitrogen compounds, phosphates, and potassium compounds; it is useful also to add a fourth: organic matter; almost anything containing these constituents will serve, provided always that the substance is not toxic to the plant, and that it is capable of going into solution in the soil water directly or as the result of decomposition in the soil, so that it can enter the plant roots. In practice, however, a third condition is essential, the price must be sufficiently low, and this rules out so many substances that the actual list of artificial fertilisers is short, and is—

Nitrogenous.—Nitrate of soda, sulphate of ammonia, calcium cyanamide, and calcium nitrate.

Phosphatic.—Superphosphate, basic slag and bone manures.

Potassic.—The Stassfurt salts.

Organic.—Excretions from animals fed on imported feeding stuffs, guano, fish and meat meals, and other manufacturing residues.

These four classes have very different properties, and they are in no sense interchangeable.

In laboratory experiments, sand cultures, etc., all the three first-named constituents are necessary for plant growth but in field practice the soil supplies something, so that artificial fertilisers are needed only to make up deficits or to raise the level of production. The only way of finding out

what is wanted is by actual trial; the hope once entertained that soil analysis would give a short and easy indication of the deficit has not been realised.

Moreover each of these different classes, besides contributing to the general nutrition of the plant, has certain specific effects which can only be discovered by trial.

The fertilisers are mainly simple salts, in other words, electrolytes; and the soil owes most of its important properties to its colloidal constituents. Now electrolytes profoundly change some of the properties of colloids, and the effects cannot always be predicted; usually they have to be discovered by direct experiment.

Further, some of the fertilisers undergo remarkable changes in the soil; nitrate of soda, for example, changes to carbonate of soda, which, as an alkali, has a strong deflocculating action on the clay, thereby greatly modifying the texture of the soil; sulphate of ammonia gives rise under certain conditions to an acid, which changes the reaction of the soil, and, as every bacteriologist knows, a change in reaction of the medium may profoundly affect the growth of organisms and of plants.

In dealing with artificial fertilisers, therefore, it is necessary to take into account not only their effect on the plant and their price, but also the changes they are likely to undergo in the soil, and the effect the products will have on the soil and on the plant. These are so complex that they can usually only be determined by direct trial.

The phosphatic fertilisers.

These present the simplest case because there is usually no complication arising from secondary actions in the soil, even rain has very little effect: phosphates applied one year will persist unchanged and can be taken up in the following year. At Rothamsted, Hall and Amos* were able to account for all the phosphates added during the preceding 55 years:—

Phosphorus balance-sheet, Hall and Amos.

P ₂ O ₅ , lb. per acre.	Broadbalk plots.		Hoosfield plots.	
	5.	7.	2.	4.
Supplied in manure	3960	3810	3390	3390
Removed in crop	790	1370	1200	1240
Balance expected in soil ..	3170	2440	2190	2150
Balance found in soil	3000	2470	2315	2000

Besides contributing to the nutrition of the plant, phosphates stimulate growth in the early stages of plant life and cause a great development of root, which makes them indispensable for potatoes, swedes, turnips, and root crops generally. Further, they help materially in grain production, hastening on the ripening processes.

Of all the phosphatic fertilisers by far the commonest is the so-called superphosphate, a mixture of calcium sulphate and monocalcium phosphate.

Superphosphate is made by treating calcium phosphate with sulphuric acid. In principle the manufacture is perfectly simple: in practice, however, it is complicated by the necessity for making the sulphuric acid on the spot, owing to difficulties of transport, and by the need for turning out a fine dry product of uniform composition. These difficulties have been successfully overcome by adjusting the quantity and strength of the acid to the mineral phosphate, and the product turned out by our best manufacturers is very satisfactory. A good deal of bone is used in ad-

* Trans. Chem. Soc., 1906, 89, 205.

mixture with mineral phosphate to make the so-called "bone super."

There has been a progressive improvement in the composition of superphosphate as shown in the following analyses of the ordinary samples on the market :—

	P ₂ O ₅ per cent.	Equivalent to Ca ₂ H ₂ (PO ₄) ₂ .
30 or 40 years ago	9.1	20
20 years ago	11.8	26
Modern samples	13.6	30
	16.0	35

This improvement in composition is largely due to the use of richer mineral phosphates, and it effects a considerable saving in freight.

The industry was founded in this country, but we have not kept our lead: before the war Germany, France, and Italy had all passed us, and Belgium was beginning to catch us up. Few of our makers have the mechanical dens, the electrical power, and other appliances of the modern Continental factories. The output of the leading countries is given in Table I.

Further, phosphatic fertilisers are wanted wherever bullocks or sheep are being produced. The addition of phosphates to the crop increases the feeding value. In many cases, however, basic slag serves as well as super for this purpose.

Large amounts are also needed in horticulture, where it proves very valuable in inducing hard growth in plants that are becoming sappy.

Taking all these circumstances into account we can safely assume that a much higher proportion could be absorbed in this country if more intense cultivation methods were adopted.

When we turn to other countries the possibilities are even greater. Professor Priamishnikow, the eminent Russian agriculturist, states† that great areas in Russia need phosphatic fertilisers; and although Russia possesses phosphatic deposits our superphosphate manufacturers ought still to be able to help in the agricultural development that may be expected in that country.

But it is in our own Empire that the need for superphosphate is greatest. Large areas of land in Australia only become fertile when superphosphate is added; thus the following results were obtained at the Roseworthy Agricultural College‡ :—

TABLE I.*

Production of superphosphate in metric tons. 1903—1910.

	1903.	1904.	1905.	1906.	1907.	1908.	1909.	1910.

World's total	5,130,900	5,863,500	6,281,024	6,463,440	8,003,880	9,158,300	8,710,200	9,604,260

* Data extracted from "Production et Consommation des Engrais Chimique dans le Monde," Inst. Internat. d'Agric., Rome, 1914.
† The quantity is not known precisely, and some put it as high as one million tons per annum. The higher figure is arrived at as follows: we import annually about 550,000 tons of mineral phosphate and we also import and produce about 100,000 tons of bone. Assuming this is all made into superphosphate it would yield 1,200,000 tons. Before the war we exported 200,000 tons, leaving one million tons for home consumption.

Thus the production has gone up enormously during the period; I do not think it has nearly reached its limit yet. In this country we used before the war about 600,000 tons per annum. Our cultivated area in the United Kingdom is 47 million acres, so that if divided up equally the consumption would be about $\frac{1}{2}$ to $\frac{1}{3}$ cwt. per acre. But this is not a fair way of procedure, because superphosphate is not applied to all crops. The better plan is to take the crops to which it is usually given, viz., swedes, turnips, mangolds, potatoes, of which we grow 3.5 million acres, so that if all the super were given to them, the average dressing would be about $3\frac{1}{2}$ to 6 cwt. per acre. The lower amount would not be an over-dressing; good practical men often give 4 cwt., and in some cases (*e.g.*, for potatoes in Lincolnshire, in the Fens, and in the Channel Islands), up to 10 cwt. per acre. Large quantities are consumed in the eastern counties where there are great areas of these crops. But in addition considerable quantities can advantageously be used for some of the wheat, barley, and oats, of which we grow nearly 8 million acres.

The special effect of encouraging root production and of hastening maturity is very valuable on heavy soils everywhere, but especially in wet districts. Thus, in Central Wales superphosphate proves extremely valuable, and is indeed often the only fertiliser needed.

Roseworthy Agricultural College. Wheat. 1910.

	Total produce per acre.	Grain per acre.	Value of grain at 3/6 per bush.	Cost of manure.
	tons, cwt. lb.	bush, lb.	£ s. d.	s. d.
No manure	1 7 47	15 20	2 13 8	—
$\frac{1}{2}$ cwt. super	1 13 13	21 43	3 16 0	2 0
1 cwt. "	1 18 38	22 45	3 19 8	4 0
2 cwt. "	2 0 61	22 15	3 17 11	8 0
3 cwt. "	2 0 64	22 14	3 17 10	12 0

In this case the crop only responds to about 1 cwt. per acre of super. Elsewhere, however, larger quantities give better results. The areas involved are very great, and it is impossible to form an estimate of the total amount that will finally be wanted in Australia.

South Africa also is likely to need considerable quantities of superphosphate. Holm and Watt have both shown that it greatly increases the yield of maize. Watt obtained still further increases when nitrate of soda was added as well, but Holm did not. Their results were:—

* Transvaal Ag. Journ., 1908, 6, 550. Experiments made on a sandy soil east of Pretoria.

† *Ibid.* 1910, 8, 369-384 (the figures are taken from p. 381). These experiments were made at the Experimental Farm, Potchefstroom.

Canada has not yet begun to use superphosphate, and might if necessary make it herself, or import it from the States. But in view of its great value for grain production I think one might safely hazard a prediction that superphosphate will sooner or later be wanted, especially as the cultivation belt is pushed further north, and the scheme of farming becomes more generalised.

India has hardly begun to use superphosphate yet, but there are indications that it is much needed for some of the crops. Mann and Paranjpe* find that superphosphate gives good results with cotton on black soils in Western India where the water supply is satisfactory, while other Indian soils appear on analysis to be so deficient in phosphates as to justify the expectation that they would respond to phosphatic fertilisers if used.

Egypt has made a beginning in the use of superphosphate: during 1912 nearly 6000 tons were imported and applied mainly to the cotton crop. Experiments with cotton are very difficult to carry out, and there is no clear indication that superphosphate is always necessary.

It has been already pointed out that superphosphate encourages ripening, and this is a very great advantage in grain production. Early ripening is not always helpful for other crops, however. In glasshouse production it is sometimes detrimental, and at the Lea Valley Experimental Station phosphates actually reduced the yield of some of the crops. In Louisiana superphosphate has sometimes diminished the yield of cotton on poor soils: the cotton is said to "burn out."† For the sugar crop also superphosphate does not seem to be wanted. Harrison's extended trials in British Guiana‡ gave no sensible increase for additions of super, and only a small increase for basic slag:—

Tons of canes per acre. Average for three years 1909-10-11.

No phosphate.	Superphosphate.	Basic slag.
20.5±0.5	21.5±0.5	24.1±0.7

In the Barbados experiments which lasted over 20 years the application of phosphates was always ineffective, indeed in some cases the yields were actually reduced.§ Thus, at Dodds the results over the 16 years, 1891-1909 were:—

Sugar cane expts., Dodds, Barbados, 1891-1909.

	Tons of cane.	Lb. of sucrose per acre.
No phosphate	30.63	8314
Superphosphate 40 lb. per acre	28.93	7851
" 80 " " "	28.72	7716
" 120 " " "	28.98	7885

Other cases will no doubt be revealed as the result of experiment.

Summing up we may say that large and increasing amounts of superphosphate are required in this country for swedes, potatoes, and corn crops: other countries can also absorb great amounts for grain and meat. Leaving out the chief superphosphate producing countries as being able now or in the near future to satisfy their own requirements, enormous amounts will be wanted for wheat in Russia, and probably also Roumania, in Australia, and I think we shall one day say Canada as well, and for maize in South Africa. The meat-producing countries of South America will also require phosphatic fertilisers. Shall we be able to supply these wants. Apart from considerations of freight, this depends mainly on whether we have enough cheap sulphuric acid: if we have, and if our manufacturers improve their processes and their works, we ought to be able to play a good part in supplying this need.

Basic slag.—This is a by-product in the manufacture of Bessemer steel. It is difficult to determine precisely how much is produced, but assuming that 250 kilos. of slag is obtained in the preparation of one ton of steel, then the amounts produced in 1910 are estimated by the International Institute of Agriculture, Rome, to be as follows:—

Production of basic slag 1910.

	Metric tons.
Germany	2,007,500
France	534,000
Belgium	488,000
United Kingdom	160,000
Austria-Hungary	74,000
Sweden	12,345
Total	3,275,845

The figures are certainly wrong for the United Kingdom, since we use 286,000 tons per annum, almost all of which is produced at home, and we also export a certain amount, but probably the order of placing the countries is correct.

Slag is extremely beneficial for grass land. Again and again experiments have shown remarkable gains, especially on heavy land. The best known results are those obtained at Cockle Park: slag improved the herbage more than the feeding of cake to the animals. The live weight increases of sheep in lb. per acre per annum were:—

	No cake. No manure.	Decorticated cake.* No manure.	No cake. Basic slag. (10 cwt. in 1897 & 1905).
1st 9 years, 1897-1905 Increase due to manuring	Plot 6. 37	Plot 1. 106.5	Plot 3. 117
2nd 6 years 1906-1911 Increase due to manuring	23	69.5 42.5	80 117
	—	19.5	94

* 597 lb. cake per acre in 1897-8, in 1903 and 1904.

These experiments have been repeated at numerous centres, and almost always with similar results. At the Midland Agricultural College the milk yield was largely increased by the use of basic slag. Slag has often proved as good as feeding cakes, and considerably cheaper.

* Bombay Bull., 76, 1915. Nitrogen also gave good results but not potash. The authors state that these dressings should be supplementary to farmyard manure.

† Louisiana Sugar Expt. Stat. Bull. No. 6, 1891.

‡ British Guiana Dept. of Agric. Rept.: a good summary is given by Professor Harrison in the West Indian Bulletin, 1913, 13, 95-218.

§ Barbados Rep. on Sugar Cane Expts., 1907-9, p. 8. Harrison finds that if the soil contains 0.008% of P_2O_5 soluble in 1% HNO_3 or 0.002% soluble in $N/200$ HCl , there will be no response to phosphates.

The War has greatly stimulated the use of slag, because feeding cakes have to be imported, and have therefore risen in price, whilst slag is a home product. Its prices per unit of phosphate have been :—

Pre-war price, 1s. 5d.	Nov., 1916. 2s. 10d.	Jan., 1917. 2s. 10d.
---------------------------	-------------------------	-------------------------

In the United Kingdom there are 34 million acres of grass. Dividing the 286,000 tons of slag consumed in this country over this area we obtain $\frac{1}{2}$ cwt. as an average dressing. A good dressing is 10 cwt. in the first year, and then 5 cwt. after an interval of 2 or 3 years. Further, slag can be profitably used on other crops as well. There is therefore a great future for it in this country.

Other countries outside Europe have hardly begun to use it: the United States does not make it. The steel is there manufactured by the open-hearth process, which gives an acid phosphatic slag, and not a basic slag. This process is also in use in this country. One of the great problems of the future is to find a way of using these acid slags: at present they are simply going to waste.

The nitrogenous manures.

Nitrogenous manures present a rather more complex case than phosphates for two reasons. In the first place practically all the nitrogen compounds hitherto tested change in the soil to ammonia, and then to nitrate. It does not always appear that the change is necessary: plants can take up ammonium compounds, although not nearly as easily as they take nitrates. But the soil bacteria are too active for them: before they have the chance to use the ammonia it is seized by the nitrifying organisms and converted into nitrate.

Thus, in practice all nitrogenous manures, except the nitrates, have to undergo a preliminary decomposition in the soil. It is therefore necessary in all cases to know whether this change will proceed easily or not. The ease of decomposition is spoken of as the "availability" of the manure.

Secondly, as has already been pointed out, the nitrogenous manures nearly all have some secondary effect on the soil; in consequence the action is not always quite what would be expected on general grounds.

The general effects of nitrogenous manures are to increase leaf development and growth generally. They are therefore useful for all crops, indeed they are of more general application than any of the other fertilisers.

The artificial nitrogenous fertilisers, however, are not the only source of nitrogen to the farmer: he can also use farmyard manure, clover crops, and imported feeding stuffs, to increase his supply; he does this to a large extent. These other sources are serious competitors with the artificial fertilisers.

Nitrate of soda.—This is the most popular of the nitrogenous fertilisers, prior to the war the world's annual production, almost entirely from Chile, being about 2½ million tons per annum. The Chilean Government estimate that at this rate the deposits will last at least another 136 years: the production, however, has been steadily increasing as shown by the curve in Fig. 1: this also shows how much the production of nitrate of soda exceeds that of sulphate of ammonia.

Nitrate of soda owes its popularity as a fertiliser to the circumstance that it is ready for use by the crop, and has no further change to undergo: it is therefore the quickest in action of all nitrogenous fertilisers. In temperate climates this rapidity of action has two advantages; the fertiliser is less exposed to the wasting processes in the soil, and it produces an immediate effect on the crop. Thus, in cold wet weather a dressing of nitrate of soda at once improves the crop, and may make all the difference between success and failure. No other fertiliser has quite so good an effect, and we can never hope to do without an ample supply of nitrates.

World's production of nitrogenous fertilisers.

In this country, therefore, nitrate of soda is rather better than sulphate of ammonia. The results of long-continued experiments at Rothamsted are given in Table II.

Thus the superiority of nitrate of soda amounts to about 5% for barley and hay crops, and is greater for wheat and mangolds. Taking all things into account if one puts the effect of nitrate

TABLE II.

of soda at 100, that of sulphate of ammonia would be between 90 and 95.

Part of its effect arises from the circumstance that the sodium has a beneficial effect as well as the nitrogen. It has been shown that the sodium economises the use of potassium partly by replacing some of the potassium in the plant, and also by liberating potassium from complex compounds in the soil.

As already stated nitrate of soda tends to change in the soil to sodium carbonate, which deflocculates the clay rendering it very sticky. This does no great harm on light soils or loams, but it is a disadvantage on heavy soils. Nitrate of soda is therefore not desirable on such soils, nor is it on alkali soils, *e.g.*, in the Deccan, or wherever the texture of the soil is easily damaged. On lighter soils deficient in calcium carbonate, however, this formation of sodium carbonate may be beneficial. At the Rhode Island Experiment Station Wheeler started with a soil so "deficient in carbonate of lime that only an occasional clover plant could withstand the existing conditions." By the long continued use of nitrate of soda the productiveness was markedly improved, even without the use of lime.*

At Rothamsted the conserving effect of nitrate of soda on the lime in the soil lessens the rate of loss by 200 to 300 lb. per acre per annum.

Lastly, nitrate of soda is very easily washed out from the soil; unlike sulphate of ammonia it is not absorbed in the slightest degree by soil, and the whole dressing may be washed out in a single heavy rainfall. This only rarely happens in our country, but it is not uncommon in tropical and sub-tropical countries, and in consequence, as we shall see, sulphate of ammonia in these cases proves on the whole a better fertiliser.

A further disadvantage of nitrate of soda is that in absence of oxygen it is reduced by certain soil bacteria to nitrites, which are toxic to plants, and finally to gaseous nitrogen. The necessary conditions rarely arise in this country, but they do in the swampy soils of the paddy rice fields of India and Japan. In such cases nitrate of soda not only has no good effect, but may even depress the yield by reason of the toxicity of the nitrite.

* Wheeler, Manures and Fertilisers, 1913, p. 141.

Most of the nitrate of soda is used in Europe and North America, the tropical countries and Asia only taking very little. Of recent years its use has begun in Egypt, mainly for the wheat crop. In 1912 no less than 21,000 tons was imported, most of which was for wheat, and the remainder for cotton and maize.

Table III. gives the total consumption in the different countries. Figures are not obtainable for the agricultural consumption, but in the country it amounts to about 80% of the whole in normal peace times.

Other nitrates.

Synthetic calcium nitrate.—As a fertiliser calcium nitrate closely resembles sodium nitrate, but it appears to be free from the disadvantage of making heavy soils sticky. Further experience is needed before any very definite statements can be made, but so far as present knowledge goes nitrate of lime is a promising addition to the list of nitrogenous manures.

The first samples to be placed on the market were not easy to use as they so readily absorbed moisture and became converted into a sticky pasty mass, but this difficulty is gradually being overcome, and samples coming to hand before the war showed considerable improvement.

Potassium nitrate.—This substance is dearer than a mixture of nitrate of soda and sulphate of potash supplying the same ingredients, and therefore it is not used in this country. Being much less bulky than the mixture it finds considerable application in countries where valuable crops are raised and freights are high; thus it is used in the Canary Islands and elsewhere under similar conditions.

Commercial nitrate of potash contains nearly 14% of nitrogen.

Ammonium nitrate.—Ammonium nitrate is the most concentrated nitrogenous fertiliser available, containing no less than 35% of nitrogen, and this would be a valuable recommendation wherever freight is any consideration. But unfortunately it is highly soluble and deliquescent, and seriously damages the young leaves wherever it touches them. The crop may, of course, get over the injury, but there is always a risk that it may not, and this circumstance rather militates against the use of ammonium nitrate.

Trials at Rothamsted in 1911 gave the following results:—

	Potatoes, tons per acre.	Mangolds, tons per acre.
Dung and minerals alone	7.2	17.5 18.1
Dung and minerals + nitrate of ammonia	9.0	18.3 19.1
Dung and minerals + nitrate of lime	8.6	20.1 21.8
Dung and minerals + nitrolim	8.7	17.9 18.8

Owing to the drought the mangolds did not grow well.

Sulphate of ammonia.—Sulphate of ammonia is obtained as a bye-product from coal; it is largely produced from gas works and coking ovens. The official statistics of production in this country for the year prior to the war are as follows:—

1913.	
Gas works	182,180
Coke and carbonising works and producer gas	167,421
Iron works	19,956
Shale works	63,061
Total	432,618*

* The figures are taken from the Alkali Inspector's Report, 1915, where the data for 1912 and 1914 are also given. For convenience all compounds of ammonia and ammonia itself are expressed as sulphate and included in this table. It is understood, however, that only about 85% of this total is actual sulphate, the remainder being ammonia liquor, etc.

In a good gas works 1 ton of sulphate of ammonia is produced for every million cubic ft. of coal gas, and in a carbonising plant 22 to 34 lb. of sulphate of ammonia is made for every ton of coal carbonised. There is little doubt that these figures, especially the lower ones, could be improved upon. It is also possible to obtain ammonia from peat, though as a matter of fact little if any is so obtained in this country.

The world's production of ammonia increased considerably during the 10 years prior to the war, as shown in Table IV.

Similar results are obtained in Java, and in consequence sulphate of ammonia is used there almost exclusively. In 1912 the imports were valued at :—

Sulphate of ammonia	£5,233,000
Nitrate of soda	37,900
Sulphate of potash	2,400
Other fertilisers	1,720,000

With less rainfall the results do not always work out like this. At Barbados* the results are sometimes one way and sometimes the other. In

* The figures for "other countries" include some round figure estimates.

But this increase has failed to keep pace with the consumption, and in consequence prices have risen.

Sulphate of ammonia is largely used in this country for potatoes, the dressings varying from 1 or 2 cwt. on ordinary farms up to 6 cwt. in the Channel Islands. It is also used to an increasing extent as a spring dressing for corn with very good results. Altogether some 60,000 tons are used annually in the United Kingdom, but there is little doubt that this figure could profitably be greatly increased.

Sulphate of ammonia has two important properties that give it a definite advantage over nitrate of soda in certain special circumstances.

1. It does not easily wash out from the soil: it is readily absorbed, and in this state resists even tropical rainfall; it is therefore used in tropical countries in preference to nitrate of soda.

In these countries sugar is the chief crop to which it is applied. Harrison summarises his numerous trials with sugar in British Guiana as follows :—

BRITISH GUIANA EXPERIMENTS WITH CANE SUGAR.

Tons of canes per acre.

	Series A.	Series B.	Series C.
No nitrogen	18.0 ± 0.4	17.7 ± 0.5	17.4 ± 0.6
Sulphate of ammonia	29.0 ± 0.7	30.3 ± 1.3	28.3 ± 1.3
Nitrate of soda	—	—	20.8 ± 1.3
Nitrate of lime	23.6 ± 0.6	22.5 ± 1.4	22.6 ± 1.4
Nitrolim	22.6 ± 0.6	20.9 ± 1.3	20.8 ± 1.3
Dried blood	—	20.4 ± 1.3	—

Another way of putting the result is that 10 lb. of nitrogen in the various substances gave the following increases in tons of cane :—

	1910-11.	Tons of cane.
Sulphate of ammonia	1.9 ± 0.23	
Nitrate of lime	0.87 ± 0.25	
Nitrolim	0.62 ± 0.21	
Nitrate of soda	0.57 ± 0.29	
Dried blood	0.45 ± 0.29	

Rainfall 6 months Oct., 1909—March, 1910 = 46.9 inches.
Rainfall 6 months Feb., 1911—July, 1911 = 58.8 inches.

1911-13 nitrate of soda came out better than sulphate of ammonia.

	Tons of cane.	Sucrose, lb. per acre.
Sulphate of ammonia	19.42	5433
Nitrate of soda	19.97	5558
Nitrate of lime	19.60	5433
Nitrolim	18.52	5169

In other years, however, sulphate of ammonia has given the best results, and on the whole it is preferred by the planters.†

At Antigua and St. Kitts‡ there was no difference in action between sulphate of ammonia and nitrate of soda. But the rainfall for the whole year was only between 40 and 60 in.—not nearly as heavy as in British Guiana.

Cotton.—At Barbados chemical fertilisers produced no notable results at first, but afterwards yields began to fall off, and the experiments were then repeated. It was found that fertilisers were now effective as shown in Table V. (p. 256.)

Table V. shows that additional nitrogen increases the yield considerably, and to some extent additional phosphorus also does, but not so much.

In Louisiana.§ away from the tropical rains, nitrate of soda proved if anything better than sulphate of ammonia.

2. It suffers no loss and gives rise to no toxic products under anaerobic conditions: it is therefore superior in these conditions to nitrate of soda, which, as already stated, breaks down with formation of toxic nitrite or with evolution of gaseous nitrogen, representing a dead loss of material. For this reason it is more suitable for paddy rice, i.e., rice grown in swamp soils: thus in Japan sulphate of ammonia is therefore used in preference to nitrate of soda for the rice crop, the imports for the three years 1909, 1910, and 1911, being in metric tons :—

Calcium cyanamide or nitrolim; sometimes called simply cyanamide.

When gaseous nitrogen is passed over heated calcium carbide direct union takes place and a substance CaCN_2 is produced. This is the calcium salt of an acid usually called cyanamide on the view that its constitution is $\text{CN}\cdot\text{NH}_2$, but which is more probably a tautomeric substance, the acidic form being the di-imino compound, $\text{NH}:\text{C}:\text{NH}$.

The calcium salt rapidly decomposes in the soil with formation of ammonia :—

which then nitrifies in the usual way. The change, however, does not easily take place in the laboratory except at elevated temperature.

For a long time it was supposed that this decomposition was brought about by bacteria. Of recent years, however, unknown changes have been attributed to colloids, and the decomposition is now put down to them. The question is of great practical importance because the rate of conversion into ammonia determines the value of the substance as a fertiliser. If the decomposition is brought about by the soil colloids we should expect the substance to have more fertilising value on clays and loams than on sands where little colloidal matter is present.

The calcium cyanamide of commerce is not a pure product but contains considerable amounts of impurity. The crude product first obtained contains about 1 or 2% of unchanged calcium carbide, which might be dangerous in the store. It is therefore decomposed by spraying with water. The resulting product is known as dusty nitrolim, and is stated to have the following composition :—

Mean composition of nitrolim.

	%
* Calcium cyanamide	53.5
† Dicyanodiamide	0.3
Calcium oxide	24.0
Free carbon	12.0
Calcium carbide	0.2
Oil	3.0
Moisture	4.0
‡ Other substances	3.0

100.0%.

* Total nitrogen

18.8%.

† The percentage of dicyanodiamide is usually higher than this in samples obtained in this country.

‡ Including silica, iron and alumina, and traces of sulphur and phosphorus.

In this form the material is in too fine a powder for use on the farm; it gets into the eyes, mouths and noses of the men and causes endless grumbling; moreover, on a windy day it blows away. The material is therefore granulated by further treatment with water and subsequent drying. The

percentages of nitrogen in the various products is as follows :—

	%
Chemically pure CaCN_2	35
Calcium cyanamide, raw product, about	20
Calcium cyanamide, after hydration, about	19
Calcium cyanamide, after granulation, about	15

A certain amount of lime is invariably present, and in presence of water this has a very interesting and somewhat unfortunate effect. Under its influence (and that of other alkalis and of acids) cyanamide readily polymerises to dicyanodiamide :—

which, like cyanamide, is considered by Werner to be a tautomeric substance, the constitution of the tautomers being :—

Dicyanodiamide, however, is neither basic nor acidic and does not form salts. Unfortunately for agriculturists, it is toxic to plants, so that it has no beneficial or even a bad effect as manure, at any rate in pot experiments. It is also rather stable in the soil and only slowly breaks down, so that the bad effect is liable to persist. The following results have been obtained in our laboratory :—

	Amount of dicyanodiamide present expressed as percentage of the nitrogen.	Pot expt. Yield of mustard. Dry matter, grams per pot. 50 mgs. N per kilo. of soil.	Laboratory expt Percentage of added nitrogen converted into nitrate in 35 days.
Control	—	16.7	—
Cyanamide I. ..	7	46.0	54
Cyanamide II. ..	25	40.5	17
Cyanamide III. ..	78	18.8	8
Dicyanodiamide ..	100	18.8	1

Similar results have been obtained by Brioux with buckwheat and flax. In his experiments

* For the literature, and a discussion of the mechanism of this change, see Morrell and Burgen, *Trans. Chem. Soc.*, 1913, **105**, 576-589, and Werner, *ibid.*, 1915, **107**, 715-726.

oats and mustard suffered no depression, but they were no better than the controls.*

Neither this difficulty, nor the physical one of distribution, is insuperable, and it is reasonable to expect that both will ultimately be overcome.

Comparison of the new fertilisers with the older ones.

A number of trials have been made to compare the new fertilisers with the old, some of which are summarised in Table VI. (p. 258).

Organic nitrogen compounds, including those contained in feeding stuffs, etc.—Although these are not artificial compounds they come into the discussion because in practice they are very serious competitors. Their value depends on the important and interesting fact that their constituents can be used twice over: the imported feeding stuffs are given to cattle to fatten them for the butcher, and then the animal excretions, which contain the most important fertilising constituents, can be used to fertilise crops. For this reason many farmers prefer these feeding stuffs to artificial fertilisers. Moreover the organic matter is itself of great value, having important physical effects on the soil. On light soils these organic substances may prove more effective than the inorganic substances. Extreme cases arise where artificial fertilisers are of practically no value, while the organic manures lead to considerable increases in crop: such cases are not common in this country and are usually confined to dry sands, but they are not infrequent in sub-tropical conditions, as, for example, in Madras, Java, etc. Here neither nitrates, potash, nor phosphates give profitable crop increases, while the oil cake residues have considerable fertilising value. Thus Knight shows† that safflower cake gives better results than sulphate of ammonia with sugar cane in Western India: his results are given in Table VII.

now being made with them. Oil cakes and farmyard manure have hitherto been the chief fertilisers and they will probably always play an important part, but it is now demonstrated that artificial manures can in many instances be used with advantage. The results of the experiments made in Western India have been collected by Mann and Paranjpe.*

Thus tobacco gave the following results in lb. per acre:—

	Satara district.	Gujarat.
Complete artificials	1535	2069
Nitrogen (nitrate of soda) and potash only	1297	1514
Nitrogen only	1152	1758
Farmyard manure (local practice)	1116	1468

In this country, however, organic matter cannot be regarded as necessary for crops, however desirable it may be from the point of view of getting a tilth. Large crops of wheat, barley, mangolds, and grass are regularly grown at Rothamsted on land which for 70 years has received no organic manure and the crops show no signs of falling off. A strict comparison was made by the Hansens on a light loam and on a sand at Askor (S. Jutland) where farmyard manure was compared with a dressing containing equal amounts of nitrogen, potash and phosphates in the form of artificials (nitrate of soda, superphosphate, and kainit) and almost always gave poorer results.† (Table VIII., p. 259).

Potassic fertilisers.

By far the largest deposits of potassium salts occur at Stassfurt in Germany and no other sufficient source is yet in sight. Agriculture and horticulture are undoubtedly suffering from the deficiency brought about by the war.

TABLE VII.

Sugar cane experiments: Cake and sulphate of ammonia (Knight).

	Deccan black soil.	Lighter sandy soils.
	Cane, lb. per acre.	Cane, lb. per acre.
750 lb. ammonium sulphate containing 150 lb. nitrogen	62,304	54,860
1200 lb. safflower cake containing 75 lb. nitrogen + 375 lb. sulphate of ammonia containing 75 lb. nitrogen	80,336	58,674
2400 lb. safflower cake alone containing 150 lb. nitrogen	—	60,945

This result is very common when the water supply is irregular. A further illustration is afforded by Mann and Paranjpe's experiments on the manuring of cotton in Western India.‡

"Again and again," they say, "we have applied manures to the crop in its earliest stages: the cotton plants have immediately responded (as they always will) and grown much more vigorously than the adjoining plots. A drought has followed: the better grown plants have required more water than the smaller unmanured plants, and it has not been present: the results have been that the manured plants have never recovered from the check received, and the crop finally obtained is no better than that which has grown more regularly without the manure."

They also report that on the black soils where the moisture supply is more satisfactory fertilisers do act.

Elsewhere also in India artificials are proving of great value and a number of experiments are

One or two supplies are coming on to the market the sources of which are not publicly disclosed: two of them have the following composition:—

	Sample No. 32.	Sample No. 45.
K ₂ O soluble in water	13.0	25.8
Further amount extracted by 2% citric acid	<i>Nil</i>	<i>Nil</i>

These substances of course are very good and if they were available in sufficient quantities at reasonable prices would prove of great value.

Many attempts have been made to utilise other potassium minerals of which vast quantities are available. Voelcker at Woburn‡ experimented with felspar, granite and phonolit, but found them all ineffective. Prianschnikow§

TABLE VIII.

Comparison of the increase in crops on sand and loam produced by farmyard and artificial manures (Hansen and Hansen, Askor).

		Averages 6 years, 1894—1910.				
		Rye.	Oats.	Grass and clover.	Mangolds.	Potatoes.
Loam	Unmanured	54	60	69	42	64
	Farmyard manure	89	89	90	93	131
	Artificial manure	100	100	100	100	100
Sand	Unmanured	47	43	30	38	52
	Farmyard manure	70	74	92	77	102
	Artificial manure	100	100	100	100	100

Each plot receives 36.5 lb. of nitrogen, 26.3 lb. of phosphorus, and 31.1 lb. of potash per acre in the form of nitrate of soda superphosphate and kainit or of 3.6 tons farmyard manure. The dressings are given yearly.

at Moscow, however, obtained definitely beneficial results with three out of a number of minerals tested, viz., nephelin, mica schist, and biotite.

Attempts have been made to obtain a soluble potassium compound as a by-product in the manufacture of Portland cement, but so far as I know they have not been altogether successful. A sample sent in to us contained only 0.4% of K_2O soluble in water, a further 0.2% only being extracted by 2% citric acid. Wood ashes may supply some potash, but not a great deal. Seaweed is an almost inexhaustible source which we have hardly yet begun to exploit systematically; it is greatly to be hoped that some steps will be taken to establish a proper seaweed industry.

Relation of crop yield to amounts of nitrogen supplied.

In general the yield increases as the dressings of fertiliser increase, though the law of diminishing returns operates and prevents indefinite increase in crop. The best known instance is found on the Broadbalk wheat field, Rothamsted:—

	Series I.	Series II.	Series III.
Number of varieties used ...	27	11	19
Yield of canes per acre:—			
No nitrogen	17.8	13.4	19.1
Low nitrogen (40 per acre) .	23.5	—	—
Normal nitrogen (60 per acre)	—	19.8	27.4
High nitrogen (80 per acre)	28.1	—	—
High nitrogen (90 per acre)	—	23.8	—

The nitrogen was applied as sulphate of ammonia.

Except with very small dressings the efficiency of the utilisation process is not very great, in some cases only some 50 or 60% of the nitrogen being used by the crop. Suitable investigation generally results in an improvement in the efficiency of the process, and sometimes in a reduction in the consumption of fertiliser. Thus in India before the manuring of the sugar cane was properly investigated, Mollison found that the cultivator frequently applied fertiliser containing 750 lb. of nitrogen per acre. He began by recommending 500 lb. instead, and later on showed that maxi-

TABLE IX. *Crop yields with increasing nitrogen supply. Broadbalk wheat field, Rothamsted.*

	Grain, bushels per acre.	Increase per 200 lb. ammonium salts, bushels per acre.	Straw, cwt. per acre.	Increase per 200 lb. ammonium salts, cwt. per acre.
Mineral manure alone per acre	14.5	—	12.1	—
Mineral manure + 200 lb. ammonium salts per acre	23.2	8.7	21.4	9.3
Mineral manure + 400 lb. ammonium salts per acre	32.1	8.9	32.9	11.5
Mineral manure + 600 lb. ammonium salts per acre	36.6	4.5	4.1	8.2

The rule is also demonstrated in the Irish experiments with potatoes:—

Manures applied.	Yield of potatoes per acre, 5 years 1908-12	
15 tons farmyard manure, 4 cwt. superphosphate, 1 cwt. muriate of potash.	Tons.	Cwt.
+ 1 cwt. sulphate of ammonia	11	2
+ 2 cwt. sulphate of ammonia	11	6
+ 3 cwt. sulphate of ammonia	11	11

In like manner Harrison has shown in British Guiana that the yields of sugar cane are closely dependent on the amount of readily available nitrogen either naturally present in the soil or added as manure. The following is a summary of his results*:—

imum crops could be obtained by the use of 350 lb. More recently it has been shown that if the water supply is carefully regulated so as to avoid excessive irrigation no more than 250 lb. is needed, and there are indications that even less can be applied if better implements are used for distributing and working the manure into the soil. Thus the scientific investigator has been able to reduce the consumption of nitrogen by 66% without any loss of crop.*

All these strivings after economical usage tend to increase the consumption of artificial manures by widening the circle of cultivators who use them.

How much artificial manure can be employed per acre?

This question is of vital importance to the manufacturer because it gives him information

* West Indian Bulletin, 1913, 13, 128.

* Dept. of Agric. Bombay, Bull. 61, 1914. J. B. Knight: Sugar Cane, its Cultivation, etc.

as to the extent of the demand that might be worked up. It is impossible to form any precise estimate because, as has already been stated, the organic fertilisers and imported and home grown feeding stuffs constitute a serious competing and complicating factor the effect of which cannot be completely gauged.

Table X. gives a comparison showing the amounts consumed in different countries; the details of the more important are given in Table XI.

production, and it is reasonable to anticipate a great expansion in the demand if the supply is forthcoming. This is an after-the-war problem, but chemists will have no difficulty in seeing its close connection with the present problems of the supply of explosives.

DISCUSSION (INCOMPLETE).

Mr. W. E. OAKDEN remarked that there was one point in Dr. Russell's paper which he had a little

Note.—1 Metric Quintal per hectare = 0.797 cwt. per acre.

From these it appears that we have considerable leeway to make up in this country before we reach the consumption of Germany, and that Germany is (or was) far behind Belgium, but we are not as bad as we have sometimes supposed. The position of Great Britain arises not so much from ignorance or prejudice on the part of the farmer as from the circumstance that the fiscal and economic conditions in this country have tended to favour the production of grass rather than of corn and roots, while in Germany and Belgium the conditions have favoured the production of corn and roots rather than of grass. Now grass land only requires a fraction of the manure given to corn and roots, and therefore our system of husbandry calls for less fertiliser than that of Belgium or Germany. Our system also produces less food: in peace time that was not supposed to matter, but in war time its weakness is exposed. If a change in our system comes, and if it leads to less grass and more corn, we shall automatically consume larger quantities of artificial manures.

But it is in our Empire that we may look for the greatest increase in consumption. The experiments show that phosphates and nitrogenous fertilisers bring about large increases in crop

difficulty in fully reconciling with his previous impressions. A few years ago Sir William Crookes had advanced the opinion that the world's supplies of natural nitrates would be practically exhausted at the end of 20 years from that particular time, or anyhow the supplies would be totally inadequate to meet the necessary requirements for the world's wheat production, and yet Dr. Russell had stated that the Government of Chili estimated that their nitrate resources would last over another hundred years. He would like to know which calculation was the correct one. He believed it was owing to that prognostication of Sir William Crookes that chemists had been so strongly stimulated in working out successfully special synthetic processes for the production of nitrates from the nitrogen of the atmosphere by means of the electric furnace.

Dr. J. A. VOELCKER said that Dr. Russell had made little reference to the difficulties of the moment or the prospects of the future. Under "nitrogenous fertilisers" he had mentioned nitrate of soda, nitrate of ammonia, nitrate of lime, nitrolim, and sulphate of ammonia. But it was well known that only one of these, viz., sulphate of ammonia, was at all procurable at the present

time. The influence of potassic fertilisers was also dealt with at length, but it was of no use speaking about these, for none of them could be obtained. And in treating of phosphatic fertilisers there were only two of them, viz., superphosphate and basic slag, that entered now into practical consideration, and there were great difficulties attaching to obtaining even these, for a farmer ordering them now might have to wait any time between one month and three months before he could get them supplied to him. What he (the speaker) had hoped to hear was how these difficulties could be got over, what substitutes for them might be found, and also to get some information as to the extent to which the land might be deteriorating from the absence of these various supplies of fertilisers to it.

As regards particular points mentioned by Dr. Russell, he considered that the general preference shown by farmers for nitrate of soda over sulphate of ammonia was based more on custom than on anything else, and that it would be found generally that sulphate of ammonia would answer the purposes quite as well. It was true that nitrate of soda was used, as Dr. Russell had said, more as an "emergency" dressing, but, after all, there was not above 10 days' difference in the actual "working" of the two fertilisers. Moreover, though Dr. Russell had been inclined to attribute the superiority of sulphate of ammonia for sugar production—as instanced in the West Indies—solely to differences of rainfall, he (Dr. Voelcker) thought that apart from this—as shown in the case of sugar-beet on the Continent—there was, where sugar production was concerned, an advantage attaching to sulphate of ammonia. Like Dr. Russell, he had been experimenting with nitrolim, and chiefly with reference to the alleged harm caused by the presence of dicyanodiamide. His experiments were with wheat and his results were quite different from those set out by Dr. Russell. In the examination of a number of commercial samples of nitrolim he had found them to contain dicyanodiamide in amounts much greater than the 0.3% which the Rothamsted sample contained, but there was no evidence of injurious action from it so far as the wheat crop was concerned, nor even when a practically pure dicyanodiamide was used was there deterioration to a greater extent than 10 or 20%.

Mr. KAPIBRAM VAKIL, referring to the fertilisers used in sugar cane cultivation, pointed out that in the Neera Valley Canal area in the Bombay Presidency the cultivators had found that castor cake containing from 4.5 to 5% nitrogen was the most economical fertiliser, and was preferred to other oil cakes, *e.g.*, safflower. Similar results had also been noted in Southern India, especially for soils which showed tendencies to efflorescence and contained sodium salts like chloride and carbonate in large proportions.

BASIC SLAG AS AFFECTING AGRICULTURAL DEVELOPMENT.

By PROFESSOR D. A. GILCHRIST, M.Sc., Armstrong College, Newcastle-upon-Tyne;

and

PROFESSOR HENRY LOUIS, M.A., D.Sc., Armstrong College, Newcastle-upon-Tyne.

Phosphatic manures have enormously developed the production of farm and garden crops. Soils can obtain nitrogen by the growth of leguminous plants, and to a certain extent, by other means without the direct addition of nitrogen to the soil; but the phosphates removed by crops must be returned by direct manuring, and farmyard manure does not return these phosphates in a sufficient manner because so much of these are retained by

the animal. Bones and bone ash were used to some extent to replace phosphates early in the nineteenth century. When Liebig and Lawes, about 1840, found that bones and mineral phosphates could be rendered more effective by treatment with sulphuric acid so as to make part of the phosphates soluble, an enormous impetus was given to the growth of swedes and turnips, the crops of which were greatly increased by the judicious application of soluble phosphates (superphosphate) upon soils where phosphate exhaustion had been long in progress. Worn-out pastures, also suffering from phosphate exhaustion, gave a remarkable response to these phosphatic manures. When superphosphate had been used for a considerable time it came to be realised that this manure did not give as good results on peaty soils or on soils poor in lime as on soils in which a fair amount of lime was present. The conclusion was therefore reached that the soluble phosphates in superphosphate gave the best results when they were precipitated into insoluble phosphate in the soil, and were thus well distributed in the soil in a fine state of division. Until about 1880 the supply of phosphatic manures was met to some extent by bone meal, but chiefly by mineral phosphates, the bulk of the latter being converted into superphosphate, while a small quantity was used as ground phosphates. The discovery by Messrs. Gilchrist and Thomas that it was possible to remove phosphorus from iron and to transfer it to the slag in making steel, gave rise to the so-called Gilchrist-Thomas or basic Bessemer process of steel making, and it was soon found that the slag produced in this operation possessed valuable manurial properties.

The late Dr. Andrew Aitken, Chemist of the Highland and Agricultural Society of Scotland, conducted trials for that Society at the Pumpherton Agricultural Station, near Edinburgh, some years before 1889, which proved that rock phosphates or mineral phosphates, when finely ground, gave quite good results. About this time, however, basic slag came into general use and phosphate of lime could be purchased in this manure at about 9d. a unit, whereas the same in finely-ground rock phosphate cost over 1s. 2d. a unit. As Dr. Aitken found that basic slag phosphates gave better results than mineral phosphates, the use of the latter, which had begun among farmers in Scotland, was stopped, and basic slag came into general use, as it was somewhat more effective and cost less per unit of phosphate of lime.

Not all iron ores produce pig-iron suitable for the basic Bessemer process; it so happens that certain of the ores occurring in vast quantities in Germany are particularly adapted to it, and owing to this circumstance, Germany came rapidly to the front as a large producer of basic steel and of basic slag as a by-product. Basic slag thus came into competition with rock phosphate: the German chemists, whose object it was to push the sale of the former, discovered that whereas the calcic phosphate in rock phosphate was practically insoluble in citric acid, that in basic slag was readily soluble in that acid, and they succeeded to a large extent in persuading agriculturists that the fertilising value of all phosphates depended not upon the percentage of total phosphoric acid, but upon the percentage of citric soluble phosphoric acid present. It does not appear that this dictum was supported by any definite field experiments; it sounded quite plausible, and was apparently adopted by agricultural chemists in this country without proper investigation, and without any perception of the commercial object that underlay this apparently scientific hypothesis. Rock phosphates were thus discredited, basic slag was pushed as a fertilising agent, and in this way the German steel makers were able to make a profit out of their by-products. This gave them an advantage that enabled them to develop their steel industry with immense rapidity,

and it is not too much to say that it has been one of the factors that has made the present war possible.

When the manufacture of basic openhearth steel commenced in this country, a process for which many British ores are quite well adapted, the slag produced by it was forthwith discredited as a manurial agent, simply because it happens that slag produced by this process contains but little of its phosphoric acid in the citric soluble form. The reason assigned for this difference by Dr. J. E. Stead and others, is that whereas calcium phosphate is but slowly attacked by citric acid, the silico-phosphate is attacked readily.* Pig iron suitable for the basic Bessemer process must be relatively high in silicon and its treatment in the converter produces silico-phosphates, whereas for the basic openhearth process, pig iron is required to be as low as possible in silicon, so that practically the whole of the phosphorus is converted into calcium phosphate (tetracalcic phosphate, according to Dr. Stead). It should be noted that even this compound is slowly attacked by citric acid, hence the test introduced by Dr. Wagner—and, as above stated, generally accepted—consists of allowing a solution of citric acid of definite strength to act for an arbitrarily limited time upon the material under examination. It need hardly be pointed out that no such time factor exists when the slag is applied to the soil, and that the empirical test does not correspond to natural conditions.

This aspect of the subject is adequately discussed in a paper by Mr. G. S. Robertson, M.Sc., of the East Anglian Institute of Agriculture, which demonstrates how wholly fallacious is the citric solubility test, even from the purely chemical standpoint.

The matter is one of grave importance; thus in Great Britain the production for 1915 was as follows:—

Basic Bessemer Steel	479,816 tons.
Basic Openhearth Steel	2,958,968 tons.

The figures for Germany for 1911 are:—

Basic Bessemer Steel	8,169,183 tons.
Basic Openhearth Steel	5,946,215 tons.

so that whilst in Germany the production of basic Bessemer steel exceeds that of basic openhearth steel by more than one third, the make of the former in Britain is only one-sixth of that of the latter, and the great importance to this country of the proper recognition of the manurial value of openhearth basic slag becomes obvious. Roughly speaking, about 5 cwt. of slag are produced for every ton of basic openhearth steel made, so that the production of such slag in this country is about 750,000 tons annually, or say 100,000 tons of phosphoric acid, a large proportion of which is wasted every year, instead of being employed to fertilise our fields, mainly on account of insistence upon the empirical citric solubility test.

It is only within recent years that experiments have been conducted with the object of determining whether the citric soluble phosphoric acid has such greater manurial value than the insoluble phosphoric acid as has been ascribed to it by the Germans.

Trials conducted at Cockle Park, the Northumberland County Agricultural Experiment Station, from 1907 till 1915, on meadow hay and on temporary seeds mixtures for three years by one of the writers, show that in only one case out of five have slags with high citric solubility given the best results. The medium citric soluble slags gave the best results in one case out of two. The balance of results does not indicate that a high citric solubility gives either quicker or better results. The popular

belief that a high citric soluble slag means a quicker acting slag was not confirmed by these results. The results also indicated that a high content of lime in slags is advantageous, although the results as to this were somewhat contradictory. It was also shown that both Tunisian mineral phosphate and Belgian mineral phosphate, containing practically no citric soluble phosphates, gave quite satisfactory results, and the latter especially so when it had been calcined. In West Well Close pasture field, when equal amounts of phosphoric acid are applied in basic slag and in superphosphate, the results over many years are considerably better from basic slag. When cross dressings of lime were applied over the basic slag and superphosphate plots, the use of lime in addition to superphosphate made the results comparable with those from basic slag, whereas when lime was applied in addition to basic slag the pasture has only been slightly improved thereby.

Mr. James Knott, Close House, Wylam-on-Tyne, placed his park of about 31 acres at the disposal of Armstrong College in 1914 for trials of the effects of basic slag and of ground mineral phosphates on the improvement of pasture. The Park was then in poor condition and provided an excellent experimental area. The soil varies from a clay loam to a sandy loam. The plots were carefully inspected in July, 1916, about 2½ years after the application of the dressings. Basic slag (39% phosphate of lime), Belgian phosphate (38% phosphate of lime), and Algerian phosphate (67% phosphate of lime), were each applied at the rate of 200 lb. phosphoric acid per acre. In the basic slag 80% of the phosphates were citric soluble, but practically none of these were so in the other dressings. The fineness of grinding of the basic slag was 80% of the Belgian phosphate, 85% of the Algerian phosphate, 75% these being the amounts which passed through a mesh containing 10,000 holes to the square inch. All the treated areas showed a marked improvement over that untreated. Clovers, especially wild white clover, have been well developed by all three phosphatic manures, and the pasture is far more closely grazed and of a more nutritious character than on the untreated land. A close examination at the boundaries of the dressed plots failed to show any difference between the results of the three manures. Basic slag has effected the same characteristic improvement on poor pasture as at Cockle Park, and the two mineral phosphatic manures have given equally good results to the slag. The pasture on the untreated area was valued at 25s. an acre, and on the remaining areas at 45s. an acre. These striking results from mineral phosphatic manures, containing practically no citric soluble phosphates, show that the citric solubility test does not indicate the availability of phosphates for plant life, and that when mineral phosphates are as finely ground as basic slag the phosphates they contain can be equally effective.

In an address to the Illinois Farmers' Institute in 1916, Mr. C. G. Hopkins stated that at moderate prices, bone meal, superphosphate, basic slag, or finely-ground rock phosphate, may be used with profit, and that liberal applications of raw phosphate may well be used when high prices are charged for other phosphates.

Mr. G. S. Robertson, of Chelmsford, in a paper read to the Newcastle Section of this Society in February, 1916, after describing elaborate tests, came to the following conclusions:—

"1. The results clearly show that the citric acid test gives no true idea of the solubility of the phosphate in 'fluorspar slags' and affords no guide to its value to the plant.

"2. The use of fluorspar in the manufacture of steel by the openhearth process results in the production of a phosphatic slag with low citric solubility. Nevertheless the slag is completely soluble

* See paper by Dr. J. E. Stead on the "Relative Fertilising Value of Different Varieties of Basic Slag" in the Proceedings of the Cleveland Institution of Engineers, January, 1895.

in citric acid if sufficient time is spent on the extraction.

"3. The phosphate or phosphates which the slag contains do not appear to be in combination with silica and they seem to bear a very close resemblance to those contained in mineral phosphates."

In a second paper read at the same time Mr. Robertson stated that "With one exception calcining produced a marked decrease in the citric solubility of mineral phosphates. The longer the calcining continues the more insoluble does the phosphate become," and yet at Cockle Park the calcining of Belgian phosphate made this manure more effective! He also stated in the same paper: "The results judged as a whole confirm the conclusion arrived at as the result of a previous investigation, namely, the worthlessness of the citric acid test as a means of judging the relative value of phosphatic manures to the plant. Rock phosphates are quite as soluble in a $\frac{1}{4}$ % hydrochloric acid solution as the phosphates in basic slag, and there is just as much reason in favour of using a weak solution of a mineral acid for a solvent as there is for using a 2% citric acid solution."

In a paper on the "Availability of Mineral Phosphates for Plant Nutrition" in the Journal of Agricultural Research of the United States Department of Agriculture for 1916, Mr. W. L. Burlison, after experimenting with rock phosphates for cereals, clover, and lucerne, found that the crops tended to increase as the application of rock phosphate increased up to a certain point, and that the plants obtained their calcium from rock phosphate. Better results were not given when calcium carbonate was added to rock phosphate. "There was no particular relation between the citric-acid-soluble phosphorus and the availability of these phosphates for plants." To some extent the fineness of the rock phosphate determined its availability.

All the foregoing points to the conclusion that citric solubility is certainly not the only criterion, and is apparently not even a reliable criterion, of the value of phosphatic material as a manurial agent. It is therefore submitted that total phosphoric acid content is a far more reliable test of manurial value, and possesses the further advantage that it depends on the definite analytical determination of a substance, instead of being an empirical test liable to be affected by the conditions and methods of its application, and that it should therefore be authoritatively substituted for the citric solubility test throughout the country. This change would not only render available for the use of British agriculturists an annual amount which may reach up to one hundred thousand tons of phosphoric acid, most of which is now merely a troublesome waste product, but would at the same time render valuable assistance to the steel trade of the country, and would thus on both counts help this country in the forthcoming economic conflict with Germany, which is generally acknowledged to be impending.

Professor Hendrick, Aberdeen University, estimated that in 1906 the total world production of basic slag was nearly $2\frac{1}{2}$ million tons, of which Germany produced about $1\frac{1}{2}$ million tons, and the United Kingdom about 300,000 tons. Germany used nearly as much as she produced on her own land, whereas only about 167,000 tons were so used in the United Kingdom. As the total amount of basic slag now produced in this country is from 800,000 to 900,000 tons, and will certainly be increased in the near future, it can readily be recognised how much manuring by basic slag can be developed in this country.

At Cockle Park, on heavy loam soils of a poor character, a dressing of 10 cwt. an acre of high-grade basic slag, applied once in six years, has easily increased the seeds hay crops by 10 cwt. an acre in each of the three following years after its

application; oats have easily been increased by 10 bushels an acre in the fourth year thereafter, swedes by over 4 tons an acre in the fifth year thereafter, and barley by 4 bushels an acre in the sixth year thereafter. At pre-war prices, valuing hay at £3 a ton, oats at 3s. a bushel, swedes at 7s. 6d. a ton, and barley at 4s. a bushel, this gives a total of £8 2s. 6d. as the increased value of the crops for six years after the application of 10 cwt. high-grade basic slag, which at pre-war prices would cost about 25s.

On the sandy loam soils at the same centre, a dressing of 5 cwt. an acre of high grade basic slag has probably increased the following seeds hay crop by 10 cwt. an acre, the oats in the second year by 10 bushels an acre, the swedes in the third year by 3 tons an acre, and the barley in the fourth year by 4 bushels an acre. This gives an estimated return of £1 18s. 6d., from the application of 5 cwt. basic slag at a cost of about 12s. 6d.

In the Hanging Leaves fields at Cockle Park, where a pasture of the poorest character has been treated with basic slag alone, the increased gains made by the cattle and sheep during the past eleven years show a gain of about 7s. 6d. for each shilling spent on basic slag.

The foregoing estimates of increased crops from the application of basic slag are based on crop results at Cockle Park. It should be noted that the basic slag owes much of its effects to the inclusion of wild white clover in the seeds mixtures. This plant is enormously developed by basic slag, and the nitrogen collected by its roots is of the greatest help to the phosphatic residues of the slag in increasing the various crops.

The amount of basic slag now used annually for manurial purposes in this country may be between 200,000 and 300,000 tons. It has already been estimated that the total amount of basic slag produced in this country is now about 850,000 tons, but as much of this is of low grade, the total amount produced may be equal to about 600,000 tons of high-grade basic slag.

The total area under crops and grass in the United Kingdom (not including mountain and heath land) is under 47 million acres. Assuming that 250,000 tons of basic slag are now used for agricultural purposes in the United Kingdom, this would provide a dressing of 5 cwt. of basic slag per acre every fourth year for four million acres. If the total basic slag produced in this country were used for agricultural purposes, (estimated to be equal to 600,000 tons high-grade basic slag) the total area of land so treated would be increased to 9,600,000 acres, and it can be realised from the foregoing Cockle Park figures how enormously the food production of this country would be increased.

In this country there were produced annually before the war, from 820,000 to 850,000 tons of superphosphate, of which about 76,000 tons were exported. These figures give some idea of the relative amounts of superphosphate and basic slag used before the war for manurial purposes. Superphosphate is produced mainly from rock phosphates, of which nearly 600,000 tons were imported to this country in 1913.

A low-grade basic slag from the openhearth steel process, contains on the average only about 10% phosphoric acid, whereas high-grade basic slag contains from 17% to 20%. Before the war, various costs in producing high-grade and low-grade basic slags were probably about the following per ton:—

Grinding	6/-
Bags	3/- to 5/-
Putting on rail and other labour, say	3/-
Railway carriage, about 100 miles, say	8/6
	20/6 to 22/6

These costs amount to the same for slags of low-

grade as of high grade. It is therefore readily seen that a high-grade basic slag can be delivered at a distant railway station at a much less cost per unit of phosphoric acid, than is the case with a low grade basic slag. Actually railway rates to stations about 50 miles from Middlesbrough, amount to about 6s. per ton; and 100 miles distant to about 8s. 6d. per ton. A most valuable concession to agriculturists and to the producers of basic slag would be made by railway companies if low-grade basic slags were carried at reduced rates somewhat in proportion to their actual values.

Investigations are now being made with the object of ascertaining whether high-grade mineral phosphates (containing about 30% P_2O_5) can be added to the basic slag immediately it leaves the openhearth, say in about equal amounts of mineral phosphate and slag. If by doing so the mineral phosphates can be given practically the same character as those of basic slag, a high-grade basic slag will be produced which should reach the farmers' nearest railway stations at considerably less cost per unit of phosphoric acid, owing to the saving made in costs per unit of grinding, bagging, and railway carriage.

This subject is of the greatest importance to British agriculture and demands the best attention that can be given to it. At the present moment a vigorous campaign is being conducted throughout the country for the reclamation of available waste land with the object of increasing the area under cultivation. Whilst this is most desirable, there are far greater possibilities by increasing the output from the land now under cultivation, or laid away to pasture. With practically no increase in labour this can be obtained very largely by the judicious use of basic slag, which is now thrown aside as a waste product, one of the main reasons for this being insistence upon a test which gives results bearing no real relation to the manurial value of the material.

DISCUSSION (INCOMPLETE).

Mr. JOHN HUGHES said that if the citric acid test gave a low percentage of soluble phosphate in respect of the open-hearth slag as against a high percentage in the Bessemer slag it was a real practical illustration of the more insoluble character of the former, especially when it was borne in mind that in the case of the Bessemer slag practically the whole of the soluble phosphate was dissolved with the first extraction, whereas it was admitted that it required some four or five extractions before the whole of the phosphate was dissolved in the case of the open-hearth slag.

Dr. BERNARD DYER said that no doubt fine grinding was a matter of great importance as affecting the availability of water-insoluble phosphates, but fine grinding was not everything. A good deal would depend upon the kind of material ground. One would scarcely expect to get much efficacy, for instance, from the grinding of crystalline Canadian apatite, while on the other hand soft phosphates like some of the North African phosphates, when ground to a sufficiently fine state, become effective fertilisers. Any standardised citric acid test must in some sense be empirical. The validity of some of the experimental work on the basis of which Wagner evolved his solubility test had been some time ago brought into question, and, as a result, a meeting of representatives of all the German agricultural experiment stations remitted the whole subject for re-investigation. The result had been to confirm the conclusions originally arrived at, and it was decided, on the basis of this re-investigation, to retain the use of the citric acid solubility test for basic slag. Apart from experimental evidence, if a complex molecule like that of the phosphate in Bessemer basic slag could be readily broken down and brought into solution by a dilute solution of citric

acid, it would surely seem that it would be more likely to yield to the even gentler natural solvent processes in the soil than the phosphatic molecule of another form of slag which under similar conditions showed itself more resistant. The question, however, was one of experiment. He (Dr. Dyer) thought that more field experimental work remained to be done before general conclusions could be arrived at. It might be that open-hearth slag, if sufficiently finely ground, could do all that was claimed for it by its defenders, and if so it would become a further asset to agriculture. But its action should be tried on various kinds of soil, and there ought to be little difficulty in getting further experiments carried out with it under varying conditions. If it had anything like the properties of the better known basic slag, there was plenty of poor grass land on which its efficacy could be easily demonstrated.

Mr. G. S. ROBERTSON said that what was really wanted was a series of experiments in many parts of the country to test the value of open-hearth basic slags or fluorspar basic slags, compared with high citric soluble Bessemer basic slags. During the past two years he had been engaged in carrying out such experiments in Essex on various types of soil, and although the results were not yet sufficiently complete for definite conclusions to be drawn, still they indicated that the fluorspar basic slag was just as valuable as the highest citric soluble slags. The citric acid test did certainly seem to be very unfair to open-hearth basic slags and rock phosphates. There appeared to be no particular reason why one should use 5 grms. of phosphate in performing the test, or why the shaking should last for half an hour, or the volume of the solution be 500 c.c., or the strength of the citric acid 2%. If one gm. were used instead of 5, and the other conditions kept as usual, the order of solubility of the various phosphates was often completely altered. For example a particular sample of fluorspar basic slag had a solubility of 45% and a rock phosphate 38% according to the usual citric acid test, that was to say using 5 grms. When, however, the test was repeated using 1 gm. the solubility of the slag was only 68% whereas the solubility of the rock phosphate was 80%. That was not an isolated case: such results were continually being recorded, and they completely shattered any faith which could be put on the value of the citric acid test. The question of fineness of grinding which had been raised by the authors was, in his opinion, also of much greater importance than citric solubility. The difficulty in sowing such finely ground materials was not nearly so great as had been suggested in the discussion. The low citric solubility of open-hearth basic slags was due, not to the absence of silica, but to the fact that it was not in combination with the phosphate. Apparently the fluorspar used displaced the silica in combination. It was quite easy to reduce the citric solubility of a basic Bessemer slag to that of an open-hearth slag by heating it with a small amount of fluorspar in an ordinary furnace. The paper had been of great interest to him and he found himself in complete agreement with the conclusions drawn by Prof. Gilchrist and Prof. Louis.

Manchester Section.

EXPERIMENTS RELATING TO THE ACTIVATED SLUDGE PROCESS OF SEWAGE PURIFICATION.

BY WILLIAM T. LOCKETT, M.S.C.

Previous communications to this Society relating to the activated sludge system of sewage purification have been a series of papers under the title

"The Oxidation of Sewage Without the Aid of Filters,"¹ by E. Arden and the author, descriptive of experiments pertaining to the development of the activated sludge process which had been carried out with Manchester sewage, and a paper by S. E. Melling.²

A number of papers dealing with the subject have also appeared from time to time in various English and American journals, notably those by Fowler,³ Duckworth,⁴ Chalkley Hatton, of Milwaukee,⁵ and Bartow and others, of the University of Illinois.⁶

In the present communication it is proposed to give the results of a series of investigations carried out with the sewage of a manufacturing town, attention having been given to—

- (1) The volume of air required for the efficient working of the process;
- (2) Possible means of effecting economy of air;
- (3) Experiments relating to the maintenance of the activity of the sludge;
- (4) Enquiries into the bacteriological nature of effluents.

The sewage dealt with in these investigations may be classed as one of "average" strength, and contained, in common with other sewages of manufacturing towns, a variety of trade wastes, including those, inimical in character, discharged from chemical works concerned largely at the present time with the production of material for war purposes. The apparatus employed, in general, was similar to that used in the previous experiments with Manchester sewage and consisted essentially of a series of aerating vessels (capacity 3—4 litres) fitted with porous tiles for aeration purposes; each vessel being connected to a separate and controlled air supply.⁷

i. Volume of air required for the efficient working of the process.

In a previous study of the economics of the activated sludge process as applied to Manchester sewage, it was demonstrated that, with improved methods of aeration—diffused air—the minimum air supply necessary to maintain the maximum rate of oxidation of the sewage did not exceed the amount of air required for the adequate mixture and circulation of the sludge.

The early experiments with the sewage dealt with in the present investigations, indicated that purification of the sewage could be readily brought about by means of activated sludge and "diffused" air, and investigations were then made to determine the quantity of air required for the purification process. For this purpose it was necessary to determine, in the first instance, whether the above conclusion was applicable in this case also to the activated sludge process. Accordingly, a series of comparative experiments was carried out to ascertain the oxidation effected when using (a) quantities of air sufficient to obtain adequate mixture and circulation of the sludge and sewage, (b) air in excess. The following are the average results of these experiments:—

Results in parts per 100,000.

Raw sewage.	Effluent obtained with 2 hours' aeration using quantities of air:—		
	(a) sufficient for adequate mixture.	(b) in excess.	
Four hours' oxygen absorption	10.50	1.46	1.74
Free and saline ammonia	2.30	0.83	0.64
Albuminoid ammonia	0.99	0.115	0.15
Nitrite as NH ₃	—	0.06	0.08
Nitrate as NH ₃	—	0.71	0.94

Although the foregoing experiments showed that more highly nitrified effluents could be obtained in a given time by the use of excessive quantities of air, demonstrating that the conclusion arrived at in the Manchester experiments was not strictly applicable in this particular case, the question remained whether, in general, when dealing with the sewage employed in these investigations, it would really be advantageous to use more air than that required for adequate mixture and circulation. As a guide to the solution of this problem, the conditions which would obtain in large-scale operations were first considered. The use of large volumes of air in practical operations would tend to reduce tank capacity, as the periods of aeration would be short, but this advantage would not compensate for the increased cost of air unless the extent of the oxidation were reasonably proportionate to the volume of air used.

To obtain a decision on this question and thus provide a satisfactory basis to work upon, a series of comparative experiments was carefully carried out with mixtures of sludge and sewage in the proportions of 1:4, using air at the rate of (1) 6 cubic feet per hour per square foot, i.e., with just sufficient air under experimental conditions to produce adequate mixture, (2) 12 cubic feet per hour per square foot, and samples were taken after 1½ and 3 hours' aeration. In these experiments samples of strong sewage were used so that every opportunity was given for the beneficial effect of the larger volume of air to be shown. The following are the average results obtained:—

Results in parts per 100,000.

	Raw sewage.	Effluents obtained when using air at the rate of:—			
		6 cub. ft., etc., for		12 cub. ft., etc., for	
		1½ hrs.	3 hrs.	1½ hrs.	3 hrs.
Four hours' oxygen absorption	10.34	—	1.26	—	1.30
Free and saline ammonia	2.84	1.40	0.37	1.10	0.25
Albuminoid ammonia	1.30	—	0.13	—	0.13
Nitrite as NH ₃	—	0.08	0.07	0.08	0.05
Nitrate as NH ₃	—	0.59	1.39	0.78	1.52

From the foregoing results it will be seen that by the use of air at the rate of 12 cubic feet per hour, etc., the oxidation effected with 1½ hours, aeration was by no means equal to that obtained by the use of 6 cubic feet per hour, etc., for three hours—the extent of the oxidation not being reasonably proportionate to the volume of air used. Consequently, it was concluded that in the treatment of this sewage, no material advantage was to be obtained by the use of quantities of air in excess of that required for adequate mixture and circulation.

Purification effected, using suitable quantities of air and varying proportions of sludge.—Having arrived at a conclusion as to the quantity of air which could be most economically employed, a study was made of the purification effected when the sewage was aerated with that quantity of air, using 20 and 40 % by volume of activated sludge. To obtain average samples of the sewage over the 24 hours was practically impossible, and so to avoid misleading results experiments were conducted with samples of strong sewage obtainable from the afternoon flow.

In the following table, the average results are given of the series of experiments carried out under suitable temperature conditions, using

mixtures of sludge and sewage strictly in the proportions of 1 to 4 and 2 to 3. The quantity of air employed, which was carefully determined both prior to and during each experiment, was as nearly as possible throughout the whole series equivalent to 6 cubic feet per hour per square foot of the sectional area of the aeration vessel. Under these conditions well-oxidised effluents were obtained with the different proportions of sludge in 3 and 1½ hours respectively.

In the table, the average results of similar experiments carried out previously with average Manchester sewage under almost precisely the same experimental conditions are also given, for a purpose which will be seen later.

higher proportion of sludge to sewage, *e.g.*, 2 : 3, the volume of air should not exceed 1,200,000 cubic feet.

These conclusions, in view of the character of the sewage, indicate strongly the eminent practicability of the activated sludge process.

ii. Possible means of effecting economy of air.

The absolute minimum quantity of air requisite for the purification of any particular volume of sewage by means of activated sludge, apart from that required for agitation, depends upon the strength and nature of the sewage to be dealt with and the oxygen needed to maintain the vital

An estimate of the volume of air required for large scale operations.—By a comparison of the results obtained in the preceding experiments with those obtained previously in similar experiments with Manchester sewage, it will be seen that strong samples of the sewage in question can be purified in approximately three-quarters of the time required to purify average Manchester sewage. Taking into consideration the superiority of the effluents produced by the treatment of the sewage dealt with, in 3 hours (20% sludge) and 1½ hours (10% sludge) over those obtained in 4 and 2 hours respectively with Manchester sewage, and the fact, known but not previously referred to, that frequently the weaker samples of the former sewage can be completely nitrified with 2 hours, (20% sludge) and 1 hour (10% sludge) aeration, it may be concluded that the quantity of air required for the purification of the average sewage would be one-half to three-quarters of that required for the satisfactory purification of average Manchester sewage.

Accordingly, on the basis of an approximate estimate of the volume of air required for the purification of a definite volume of average Manchester sewage given in a previous paper,⁸ it would appear that the volume of air necessary for the satisfactory purification of 1,000,000 gallons of the sewage dealt with in these investigations, in tanks 6 feet deep, would be considerably less than 1,500,000 cubic feet allowing for the application of air at the rate of 15 cubic feet per hour per square foot of tank area (a quantity of air more than sufficient under these conditions to produce adequate mixture and circulation), using sludge and sewage in the proportions of 1 : 4. With a

processes of the sludge. In actual practice, the quantity of air required for the satisfactory working of the activated sludge process greatly exceeds the absolute minimum requirements, and thus it would appear that the introduction of more suitable means to bring about the circulation of the sludge and sewage would lead to appreciable economy of air.

In the opinion of many engineers, agitation can be more economically produced by the use of air than by the application of mechanical devices. Accordingly, to reduce the disparity between the large volumes of air required for the satisfactory working of the process and the absolute minimum requirements, improvements must be looked for in the methods of applying the air to the sewage, and the experiments described in the following relate to the possibility of effecting economy by applying air "intermittently" instead of "continuously" as hitherto.

That appreciable economy of air might be obtained by the adoption of intermittent aeration has been known for some time to those concerned with the development of the activated sludge process, although, I believe, the original suggestion is to be attributed to Mr. Makepeace, the Borough Engineer of Stoke-on-Trent. Without desiring to depreciate the merit of others who may be working on similar lines, I record the results of certain experiments which I have carried out in this particular line of enquiry, with a view to their possible usefulness in the mutual endeavour of sewage chemists and engineers to render the activated sludge process an economic success.

Intermittent aeration experiments.—In the first

series of experiments, the oxidation of sewage obtained by two hours' "continuous" aeration was compared with that obtained by two hours' "intermittent" aeration, excessive quantities of air being used in both cases.

At the outset, to the mixture of sludge and sewage to which intermittent aeration was applied, air was admitted continuously for 10 to 15 minutes to ensure a complete mixture of sewage and sludge; afterwards, in this particular series of experiments, excessive quantities of air were admitted for two out of every four minutes. Thus, during the total aeration period of two hours air was admitted for 68 minutes only. The following average results show the purification effected by the two methods of aeration:—

Results in parts per 100,000.

	Raw sewage.	Effluents obtained after two hours' aeration.	
		Air applied:—	
		Continuously.	Intermittently.
Four hours' oxygen absorption	14.21	2.34	2.36
Free and saline ammonia	2.57	1.16	1.22
Albuminoid ammonia	1.34	0.135	0.14
Nitrite in terms of NH_3	—	0.13	0.10
Nitrate in terms of NH_3	—	1.06	1.04

As the results of the foregoing experiments showed that with excessive quantities of air, the stoppage of aeration for short periods had little effect upon the purification process, the experiments were carried further to observe the effect when reasonable quantities of air were employed.

In these later experiments, in which air was applied at the rates of 12, 10, 8, and 6 cubic feet per hour, etc., it was found that as the rates at which the air was applied were reduced from 12 to 10, etc., it was necessary to increase gradually the total aeration period for the mixtures aerated intermittently in order to produce effluents equal in quality to those obtained by two hours' continuous aeration, and thus with the extension of the total aeration period the percentage saving of air was gradually reduced, until eventually, it became questionable whether intermittent aeration possessed a direct economic advantage over continuous aeration when the latter was applied in the most economical manner.

To obtain some definite information with regard to this question, a series of carefully controlled experiments was carried out as follows:—Two similar aerating vessels were taken, the air supply to each regulated to the requirements of the experiment, and the vessels filled with similar mixtures of sludge and sewage in the proportions of 1:4. In the one case, the mixture was aerated continuously for two hours in the most economical manner, i.e., with a quantity of air equivalent to 6 cubic feet per square foot per hour, known to be the minimum quantity of air which can be used satisfactorily for continuous aeration under the conditions of experiment. In the second case, the mixture was aerated intermittently throughout, the volume of air used being 3 to 4 cubic feet per square foot per hour, and the aeration of the mixture was continued until a quantity of air had passed equal to that used in the control experiment in two hours, viz., 12 cubic feet per square foot. Thus, in these

experiments the only altered factor was the means of applying the air, as ultimately each mixture received approximately the same volume.

During the short periods of time when air was admitted to the intermittently aerated mixture, the air was applied at the rate of 8 cubic feet per square foot per hour, a quantity of air found by experience to be the minimum amount possible under conditions of working to produce adequate mixing and stirring of the sludge and sewage within a short period of time.

Particular care was exercised to determine as accurately as possible the quantities of air used and, if anything, the tendency has been slightly to over-estimate rather than under-estimate the quantity of air applied intermittently, so that any advantage shown by intermittent aeration over continuous aeration in the following results may be taken as the minimum to be obtained by the use of the former.

The following are the average results of a series of experiments carried out as described:—

Results in parts per 100,000.

	Raw sewage.	Effluent obtained when air was applied:—	
		Continuously.	Intermittently.
Four hours' oxygen absorption	10.03	1.26	1.12
Free and saline ammonia	2.36	0.79	0.65
Albuminoid ammonia	0.98	0.10	0.075
Nitrite in terms of NH_3	—	0.06	0.07
Nitrate in terms of NH_3	—	0.83	0.87
Length of aeration period	—	2 hours.	3-3½ hours.

From the above results it will be seen that with intermittent aeration, effluents can be obtained distinctly superior to those produced by continuous aeration (applied in the most economical manner) using approximately the same quantity of air in each case. The direct economic advantage to be obtained by applying air intermittently appeared, however, from these experiments to be small.

It was thought that the above results could be considerably improved upon if the best method of applying air intermittently could be found, and accordingly a large number of experiments were carried out applying air intermittently in many different ways, by varying the length of the short aeration periods, etc. These experiments were not productive of results which could be considered a striking improvement upon those previously obtained; it appeared, however, that in the application of air intermittently to a mixture of sludge and sewage the following were matters of importance:—(1) That the periods of time for aeration should be sufficiently long or the amounts of air passed should be sufficiently great to produce adequate mixture. (2) That the periods of rest should be reasonably short, so that use may be made of any remaining momenta of the particles of sludge.

The following are the results of a series of experiments carried out under careful control, in which ample provision was made to fulfil these apparently requisite conditions for the satisfactory application of air intermittently. Short aeration periods of a few seconds' duration were employed and approximately equal volumes of air passed in each case.

Results in parts per 100,000.

Raw sewage.	Effluent obtained when air was applied:—	
	Continuously.	Intermittently.
Four hours' oxygen absorption	11.09	1.15
Free and saline ammonia	2.36	0.61
Albuminoid ammonia	1.22	0.14
Nitrite in terms of NH_3	—	0.02
Nitrate in terms of NH_3	—	0.71
Length of aeration period	—	2 hours. 3.31 hours.

The results obtained in these later experiments show some slight improvement upon the earlier ones and definitely establish the fact that sewage can be purified with reduced expenditure of air by intermittent aeration. On the other hand, the time required for the purification of any particular volume of sewage is materially increased.

On the basis of the foregoing results it would appear that the economy of air to be obtained by intermittent aeration, whilst appreciable, is not great, and in view of the increased tank capacity which would be required, it becomes a debatable point whether on a practical scale its adoption for general purposes would be productive of a substantial reduction in the cost of the purification of sewage. It is to be remembered that besides the increased capital cost a certain annual expenditure would be needed for the upkeep of the additional tiles, so that much would appear to depend upon the "life" of a porous tile and the cost of replacing it.

Consequently, whilst it is realised that the possibility of purifying sewage with a reduced expenditure of air by applying the air intermittently instead of continuously, may lead eventually to important practical developments, and further experiments are in progress with this object in view, it is felt that the evidence accumulated up to the present is not of sufficient strength to warrant a general recommendation of intermittent aeration.

The facts elicited by the foregoing investigations are of such a character, however, as to suggest that intermittent aeration may be of considerable practical value if its application to the activated sludge process is limited to certain occasions. For instance, the author considers that it would be particularly useful and would effect appreciable economy of air, if utilised for dealing with the night flow of sewage. Moreover, its use would be of considerable help in providing for the treatment of storm water.

With regard to the former it may be said that on the "fill and draw" system, it would be advantageous to treat the weak sewage and reduced flow which obtains during the night time by air applied intermittently, with a view to lengthening the period of aeration to obviate the loss of activity of sludge by standing and incidentally establish a check upon the consumption of air during the time of relaxed supervision. On the "continuous flow" system, intermittent aeration should be exceptionally useful. Under continuous aeration conditions presumably an equal amount of air would be passed during the night as through the day in order to maintain the circulation and mixing of the sludge and sewage, notwithstanding the fact that considerably less sewage, and that very much diluted, would be dealt with. Intermittent aeration might be applied in this case for 12 out of the 24 hours and would effect an appreciable saving of air.

In connection with the treatment of storm

water it is suggested that certain tanks might under dry weather conditions be operated on an intermittent aeration basis. In the time of storm, by changing the method of applying the air, i.e., to continuous aeration, an appreciable increase in tank capacity would result, as sewage could then be more rapidly purified.

iii. *Experiments relating to the maintenance of the activity of the sludge.*

It has been known from the outset of the investigations with regard to the activated sludge process that when a quantity of activated sludge is quiescent for some length of time certain changes take place and the sludge loses much of its activity.

The present investigations were carried out to ascertain what effect known periods of standing without aeration have upon the activity of the sludge, with a view to a knowledge of the conditions requisite to maintain the activated sludge process at its highest efficiency.

The following experiment illustrates the method of investigation adopted, and the results obtained are typical of those yielded by a number of experiments carefully carried out on similar lines.

A large volume of a recently aerated mixture of activated sludge and completely oxidised sewage was taken and allowed to settle for 20—30 minutes. At the end of this period, the supernatant liquor of oxidised sewage was decanted and the whole of the sludge remaining was collected, thoroughly mixed, and divided into several equal portions. A large volume of sewage was similarly divided. A mixture of one portion of sludge and one portion of the sewage was then made and immediately put on for aeration for a definite period of time, excessive quantities of air being used for aeration purposes. Samples were taken as required. Later, according to the time allowed for standing, a second portion of sludge was mixed with a second portion of sewage and aerated under similar conditions. Similarly with the third, fourth, etc., portions of sludge and sewage.

The following results show the nitrification effected with one and two hours' aeration, using fresh sludge and quantities of the same sludge after standing without aeration for periods of 4, 6, 8, and 10 hours respectively.

Results in parts per 100,000.

Sludge employed.	Composition of effluents after aeration for:			
	One hour.		Two hours.	
	Free and saline ammonia.	Nitrite and nitrate as NH_3 .	Free and saline ammonia.	Nitrite and nitrate as NH_3 .
1. Fresh sludge	1.13	0.71	0.33	1.33
2. Sludge after 4 hours' standing	1.23	0.39	0.41	1.12
3. Sludge after 6 hours' standing	1.33	0.34	0.67	0.87
4. Sludge after 8 hours' standing	1.50	0.25	0.86	0.80
5. Sludge after 10 hours' standing	1.73	0.22	1.01	0.63

Free and saline ammonia content of original raw sewage = 2.86.
Temperature of experiments 17°C .

The quantities of free ammonia remaining unoxidised and the quantities of nitrate produced in the several cases, after one and two hours' aeration, demonstrate the desirability of reducing to a minimum the period of non-aeration for sludge both in the "fill and draw" and "continuous flow" systems.

Experiments which have been carried out in connection with the changes taking place in the sludge during the periods of standing, indicate a rapid removal of the dissolved oxygen and nitrate present in the containing water of the sludge itself, accompanied by the formation of increasing quantities of free ammonia. From the following results it will be seen that appreciable quantities of ammonia are produced within short periods of time by the fermentation of the sludge whilst standing.

One litre of activated sludge yields:—0.97 mgrm. NH_3 in 2 hours, 2.06 mgrms. in 4 hours, 3.13 mgrms. in 6 hours, 4.10 mgrms. in 8 hours, and 10.40 mgrms. in 24 hours.

From a consideration of the whole of the facts ascertained with regard to the harmful effect of non-aeration upon sludge, it would appear that the activity of the oxidising bacteria contained in the sludge is not so seriously impaired as one would at first be inclined to think. The fact that sewage is not so perfectly purified by sludge which has been standing as by fresh sludge, is due to a large extent to the additional bacterial energy required to oxidise the accumulated products of the secondary fermentations. In this connection it may be interesting to state that the activity of activated sludge can be recovered by prolonged aeration even after standing several days. In one particular case a sludge which, when fresh, completely oxidised a sewage in 2 hours, after 48 hours' standing, completely oxidised a sample of sewage of similar character in 6 hours and subsequently rapidly improved, so that by the following day complete activity was regained and the sludge produced clear and well nitrified effluents with reasonable periods of aeration.

iv. Enquiries into the bacteriological nature of effluents.

A number of determinations of the bacterial content of effluents have been made during the course of the foregoing investigations, and from the results obtained it is evident that the purification of sewage by air and activated sludge is accompanied by an effective removal of bacteria.

From estimations of the number of organisms per cubic centimetre, contained in raw sewage, and in effluents obtained after 3 hours' aeration (20% sludge) and 1½ hours' aeration (10% sludge), it has been found that rather more than 99% of the organisms contained in the raw sewage are removed during the periods of aeration mentioned.

The following are the average results of a large number of estimations:—

Number of bacteria per c.c.

	Gelatin at 20° C.	Agar at 37° C.
Raw sewage	8,500,000	4,200,000
Effluent	66,000	30,000
Percentage removal.....	99.2	99.3

Experiments have also been made to determine the nature of the bacteria contained in the effluents, principally to ascertain whether the purification of sewage by aeration and activated sludge is accompanied by an effective removal of intestinal organisms. From a large number of determinations made it would appear that in general there is a high percentage removal of such organisms, although effluents of exceptional clarity and eminently satisfactory from a chemical point of view have been found to contain more than 1000 *B. coli* and more than 10 spores of *B. enteritidis*

sporogenes per c.c. It is to be remarked, however, that usually these high results for effluents were obtained when the original raw sewage gave a correspondingly high return for these particular organisms.

In these investigations extensive use was made of Klein's *B. enteritidis sporogenes* and the MacConkey bile salts tests although a number of effluents have been examined in greater detail. Below, the results are given of a detailed bacteriological examination—carried out on the lines suggested by Dr. Houston in the 2nd Royal Commission Report on Sewage Disposal—of a raw sewage and two corresponding effluents, obtained by the aeration of the sewage with (1) 20%, (2) 40% sludge for 3 and 1½ hours respectively. The results of a chemical examination of the sewage and effluents are also given.

Meeting held at Nottingham on Wednesday,
31st January, 1917.

DR. R. M. CAVEN IN THE CHAIR.

A MERCURIAL VISCOMETER.

BY F. M. LIDSTONE.

This viscometer (see fig.) was designed to meet the need often felt by the chemist for an instrument capable of accurately measuring the viscosity of an oil when only a very small quantity is available, as, for example, the mineral oil extracted from a blended oil or from a grease.

(One-third scale).

The tube, B E, is a fine capillary with a small bulb blown in it. The stopcock is opened and clean mercury sucked up to just above B, and the stopcock closed. A small measured quantity of the oil (just more than sufficient to fill the bulb) is then run into the cup, A B, where it is allowed to rest on the surface of the mercury, surrounded by the water jacket, for ten minutes, or sufficient time for the oil to acquire the exact temperature of the water, which is kept in constant agitation by means of the bellows, F.

When ready to take the reading, the stopcock is opened and the time occupied by the mercury level in falling from C to D is observed. The time reading is then converted into seconds (Redwood, or whatever other viscometer has been used for the calibration), by the equation

$$\frac{t}{d} \cdot K = R$$

where t is the time of running in seconds.

d is the sp. gr. of the oil at temperature of the running.

R is the time taken through the (Redwood) viscometer.

K is a constant for the instrument.

No allowance is made here for the variations in the head of oil, for although the volume is always the same if a definite measure be always used and the differences in specific gravity of the various oils ought strictly speaking to be taken into account, this correction is so small as to be negligible. Neither is any correction made for the varying time taken by the mercury itself apart from the oil. Both corrections are extremely minute, and with a moderately long capillary below the bulb the first correction is so small as to be negligible. However, as regards the second, namely, the time taken by the mercury, in the case of very mobile oils, if great accuracy be required, this time can be corrected for by the amended equation:—

$$\frac{tK}{d} \left\{ 1 - \left(\frac{t'}{t} \right)^3 \right\} = R$$

where t' time taken by mercury in flowing freely from C to D with no resistance from above to overcome (which of course includes the air friction in the capillary, B C): the other letters being the same as before.

This correction is arrived at thus:—

Let V' = mean velocity of mercury flowing freely.

V = mean velocity of mercury retarded by oil.

t' = time taken by mercury flowing freely.

t = time of running together with the oil.

m = mass of mercury.

Then $\frac{1}{2}m(V'^2 - V^2)$ represents work spent on the oil and $t' \frac{V^2}{V'^2}$ is time taken during the running

by the mercury in doing work on itself.

$$\text{But } V = \frac{V' t'}{t}$$

Therefore by substitution

$$t' \frac{V^2}{V'^2} = \frac{t'^3 V'^2}{t^2 V'^2} = \frac{t'^3}{t^2}$$

and this time has to be deducted from t , hence

$$t \left\{ 1 - \left(\frac{t'}{t} \right)^3 \right\} \text{ is the corrected time.}$$

The following readings taken when calibrating the instrument against Redwood's viscometer will show the accuracy obtainable when using an ordinary thermometer divided into one degree divisions, the temperature in each case being 60° F.

Oil used.	t	d	R	$K = \frac{Rd}{t}$
Typewriter	31.8	0.8838	195	5.12
Machine	91.8	0.9022	551.5	5.42
Heavy machine	187.5	0.9127	1116	5.43
Gas engine	387.2	0.9150	2293	5.42
Heavy engine	438	0.9312	2383	5.44

The particular instrument made by the author has the following approximate dimensions which may serve as a guide, as they have been found generally suitable for most purposes:—Diameter of capillary, 0.5 mm.; capacity of bulb, 0.18 c.c. The relative lengths of the capillary tubes and the proportions of the rest of the apparatus can be seen from the diagram, which is to scale.

Now taking Poiseuille's formula for absolute viscosity,

$$\eta = \frac{\pi g d h r^4 t}{8 V a}$$

The variations in the density, d , have been seen to be practically negligible in this case, and, as all the other factors except t cannot vary, the equation becomes $\eta = Kt$, also the correction for the kinetic energy of the oil usually reduced to a minimum by having a very long capillary, is here made

equally negligible by having the equivalent of an enormous "h."* The only significant correction (and that is a small one) is that already noticed for the mercury itself so that

$$\eta = \kappa t \left\{ 1 - \left(\frac{t'}{t} \right)^3 \right\}$$

Of course if the mercury pull were increased very much the velocity would in the case of thin oils reach the critical speed, sinuous motion would be set up, and the instrument would cease to be of any use. But the velocities obtained with a viscometer of the dimensions given above come well within the limits required by the formula found by Osborne Reynolds in order that a steady flow shall be produced.†

A viscometer made as above, but with a bulb 20 or 50 times the capacity, should be capable of giving very accurate determinations of η , although of course it would cease to fulfil the requirements for which the instrument was originally designed, namely, that of being able to work on very small volumes. However, a very small viscometer is only occasionally required, and it might be suggested that an instrument of this type be used as a standard instrument and specific viscosities be given in terms of water at 15.5° C. or 20° C., preferably the latter. Viscometry would thus be much simplified and worked on a more scientific basis.

The distinctive advantages which this viscometer possess may be summed up as follows:—

(1) There are no meniscus troubles, owing to the fineness of the capillary and the consequent speed with which the mercury passes the lines; errors due to parallax in reading are similarly reduced to a minimum.

(2) The volume of the oil run is exactly the same in all cases, as at the start the bulb is dry and at the finish full of oil. In viscometers where the reverse is the case, there is always a certain amount of oil left clinging to the sides of the vessel, which is greater in the case of thick oils than with thin ones.

(3) The capacity of the bulb can be made very small (the capillary being similarly reduced or else lengthened) without the instrument losing much in point of accuracy. There is, however, a drawback to an extremely fine capillary because of the almost certain presence either in the oil or mercury of tiny specks of dirt, which of course cause an obstruction and render the readings worthless.

(4) The whole of the working parts of the apparatus are surrounded by the water jacket with the exception of the small emergent stem of mercury, and here the error is solely one of expansion of the mercury and consequent lessening of the pull on the oil. But as the coefficient of expansion is only 0.00003 per degree it will be seen that errors due to all likely laboratory temperatures will not affect seriously even the most exact readings.

This feature, namely, the complete enclosure of the instrument by the water jacket, is more important than is generally thought, if the readings are to be at all reliable. The Ostwald type of viscometer is the only other one at all adapted to commercial uses which enjoys this freedom from external temperature influences. As the result of a large number of runnings from viscometers, having the exposed jet in laboratory temperatures as much as 10° F. above or below the temperature of the oil, the author can definitely state that this error can amount to as much as 3% on the time of efflux. It is obvious that if at the start of the running the jet is, say, 10° warmer than the oil, the first part of the running

will certainly be too short, and even after the oil has cooled the jet down to approximately its own temperature there is bound to be a flow of heat between the oil and the jet, although this is small as compared with the initial warming or cooling. This has been proved by taking half-way readings. There is also another disturbing influence which augments the error in the case of thick oils, and this is the immediate effect of the atmospheric temperature on the surface tension of the hanging drop, and when the head is small this error becomes appreciable. To get concordant runnings viscometers having an exposed jet must be used in a room the temperature of which is the same as that of the oil or else where the difference in temperature is always the same.

(5) The cost of the whole apparatus is trifling compared with that of most of the other viscometers, whereas in point of accuracy it compares favourably with the best of them.

This viscometer is at present in use at the Chemical Laboratory of the Midland Railway Co. at Derby, and my thanks are due to Mr. L. Archbutt for affording every facility and encouragement towards perfecting the instrument and for his helpful criticisms of it. My thanks are also due to my colleague, Mr. R. W. Lunn, for verifying the calculations and preparing the sketch.

DISCUSSION.

Mr. ARCHBUTT said that those who had to deal with the analysis of lubricants had often felt the want of a handy viscometer capable of measuring accurately the viscosity of the small quantities of oil separated from mixtures in the process of analysis. Mr. Lidstone had done more than design an instrument of that kind; his viscometer was not only convenient to use but distinctly novel in design, and either in its present form or in a modified form he believed it might eventually replace for ordinary work some of the commercial instruments at present in use. It was very desirable that viscosity values should be expressed in absolute measure, and he had suggested to Mr. Lidstone that he should calibrate his viscometer with liquids of known viscosity with this object in view. Mr. Deeley and he (the speaker) in their book on "Lubricants" had shown how this could be done with mixtures of glycerol and water, and Professor Dunstan had more recently suggested calibration by the addition of phenol in which the temperatures had been accurately determined. In commercial work, however, one had to wait until the business man had learned to appreciate the advantages of the scientific method, and at the present time all countries were content to make use of so-called standard viscometers with exposed jets and use the times of efflux as measures of viscosity. All such instruments suffered from imperfections and serious faults in design. In those with tubes of wide diameter, such as the Redwood and Engler viscometers, there was a slope in temperature of the liquid from the outside to the centre of the tube which could not be corrected for, especially when working at high temperature, but, as Mr. Lidstone had pointed out, the temperature of the liquid in the exposed jet was dependent upon that of the room in which the experiment was being conducted. Mr. Lidstone's viscometer resembled the Ostwald type in being free from these defects, and it was superior to the Ostwald in simplicity and rapidity of action.

Mr. H. DROOP RICHMOND said that he was much impressed with the simplicity of the viscometer; the viscosity in absolute units could be obtained by this instrument with a very much nearer approach to accuracy than with most commercial viscometers. He quite agreed with what Mr. Archbutt had said about some of the commercial

* Archbutt and Deeley's "Lubrication and Lubricants," 3rd Edition, p. 28.

† Phil. Trans., 1895, page 149.

forms, but he thought it followed that such types did not measure the viscosity; they measured a sort of compromise between viscosity and surface tension, and were affected by errors due to varying temperature and varying quantities running out. Now in Mr. Liddstone's instrument the other things which were measured were to a very large extent eliminated, or if not quite eliminated, to a very great extent controlled. One thing of which he did not approve in Mr. Liddstone's viscometer was the variable head; as it was a head of mercury, not a head of oil, the oil hardly counted at all; it was the head of mercury that counted. He thought that could be eliminated. He suggested that the tube should be bent at the point marked D at a right angle and at the point marked C, or a little above those points respectively, so as to reduce the variation in the head. He thought that with such a slight modification the instrument would give the viscosity in absolute units with a much nearer approach to accuracy. Mr. Liddstone had said that the ratio between the efflux of his instrument and that of the Redwood only varied between 5.42 and 5.44, and he was surprised, seeing the errors of the Redwood, that there was not a greater variation in the constant. The simplest viscometer he had used, which unfortunately was not generally available, was one in which a long tube was filled with liquid and the viscosity determined by the rate of fall of a small sphere. After a very short interval of time the motion of the small sphere in the liquid would approach almost to constancy, and if the size of this small sphere were known, viscosity could be deduced from the rate of fall, which could be measured with a high degree of accuracy. In that form of viscometer there were no disturbing factors so long as the size of the sphere were such that it did not move too fast. But what prevented that form of viscometer being of general use was that it was very difficult to get a suitable sphere which would not move too fast except in liquids of very high viscosity. In theory he thought that the next best approach to accuracy was to have a revolving cylinder or disc, preferably a hollow cylinder, which could be rotated by means of a constant force. If that force were suitably chosen, and the shape of the rotating body were also suitably chosen, there was quite a simple relation between the time of rotation and the viscosity expressed in absolute units. But the two instruments he had mentioned, though giving very accurate results, lacked the very important advantages that Mr. Liddstone's apparatus possessed. The important advantage, to his mind, was that it could be used with a small quantity of material, that it was very simple, cheap, and very easy to use.

Mr. LIDSTONE, in reply, said, with regard to Mr. Archbutt's remark as to the exposed jet, that all viscometers, except his own, had fixed jets and could not be adjusted, but Mr. Archbutt's was the only one in which the jet was moved and could be pushed up into the liquid. He did not point that out in the paper. In reference to Mr. Droop Richmond's criticisms, as to the variable head of mercury, he did not see how putting the bulb horizontally would be any advantage at all, for only the head varied from the top line to the bottom. It was the main head which counted. It did not make any difference in the calibration. The Redwood and all other viscometers gave viscosities very nearly in proportion to the absolute viscosity. It was only with thin oils that there was any large degree of departure in ratio, and that was why the 5.42 to 5.44 was in very good agreement. He thought that the American rotating disc viscometer had not been found to give very good results, and he believed it was rather difficult to work.

SOLUBLE FILTERS AND FILTERING MEDIA.

BY JOHN M. WILKIE, B.Sc., F.I.C., AND H. S. ANDERSON.

A filter may be regarded as consisting of a medium, a support for the medium, and the containing vessel. When a filter paper is used in a funnel, the paper plays the double rôle of medium and medium support, and the same is true of paper or cloth used in frames or presses. When asbestos or similar material is used with a filter paper, the paper then more strictly functions as the "medium support." In the disc filters so largely used, the medium support may be attached to the containing vessel as in the Buchner type. In the Gooch crucible the rôle of the upper disc is largely protective, though it may be classed as a support. When the precipitate has to be removed quantitatively from the filter, it is sometimes useful to employ a filter in which both medium and medium support are soluble in some arbitrarily selected liquid. A filter satisfying these conditions we term a "soluble filter." So far as we are aware, such filters have not been previously described, although a soluble medium (anthracene) has been used in conjunction with a Gooch crucible. (We are indebted to Mr. Droop Richmond for drawing our attention to this use of anthracene, which had not come under our notice.)

It is, of course, essential that the medium or medium support should not be appreciably soluble in the liquid to be filtered, while it must be readily soluble in some other liquid. In some cases the insolubility of the medium does not require to be absolute provided solubility during filtration is so limited that mechanical destruction of the filter does not occur.

The most general case would be where the medium and support were insoluble in water and soluble in some other liquids. Such substances are numerous—calcium carbonate is of one type, and anthracene of another. Another important case would be where the medium and support are insoluble in alcohol but soluble in water. Probably all types are included in the following classification:—

- (1) Insoluble in neutral or alkaline liquids, but soluble in aqueous acids.
- (2) Insoluble in aqueous solutions; soluble in organic liquids.
- (3) Insoluble in organic liquids; soluble in inorganic liquids.
- (4) Insoluble in aqueous liquids and soluble in organic liquids, at the same time being volatile without decomposing at moderate temperatures.

In connection with some work on the separation of potash soaps from strong alcoholic mother liquors, the advantages of a soluble filter became apparent. Briefly, we wished to filter such solutions, decompose the soaps with aqueous acid, and shake out the fatty acids with ether. If filtration could be effected by means of a filter in which the medium and support were soluble in water and insoluble or practically insoluble in alcohol, we hoped to be able to carry out the whole process in a stoppered separator with a considerable saving of time and manipulations. The use of a separator solved any question that might have arisen as to the shape of the containing vessel. The medium support would occupy the tubular portion above the stopcock—a circumstance that made its selection comparatively simple.

Practically any crystalline inorganic salt of the alkalis or alkaline earths is available. Ammonium chloride was first used. The fibrous salt has considerable mechanical strength. The tubular neck of the separator was filled with fragments of such a size that they packed down easily but did not fall through the stopcock bore, but potassium nitrate was found to be as good. For filtering medium the selection in any particular

case is limited by density, and that indefinable property "texture." Powdered ammonium chloride and potassium nitrate possess the required features in a marked degree. Even in very fine powder they feel markedly granular when rubbed between the finger and thumb.

Filters made on the above lines were found to answer admirably when used with suction. They did not block and they retained the precipitated soap completely.

Our experience with filters of this type has been limited almost entirely to one in which crystalline and powdered potassium nitrate are used as support and medium respectively for alcoholic solutions. In use continuously during the last eight years, it has worked admirably. At a later date we hope to describe further work with the other types of soluble filters referred to above.

For the separation of precipitates from alcoholic solutions the filter is prepared as follows:—A separator is selected with well-marked tubular portion between bulb and stopcock, special potassium nitrate crystals are introduced so as to give a column nearly filling the tube and then 3–5 grms. of powdered potassium nitrate (rubbed down smooth between paper just previous to using, is added through a funnel. The separator is finally tapped on the bench to consolidate the filter. The filter is then ready for use, and with alcoholic soap solutions (of type used here) no precautions are required other than seeing that the added liquor does not unduly disturb the surface of the potassium nitrate powder. The above directions refer to an ordinary pear-shaped separator of 150–200 c.c. capacity. With larger separators the amount of powdered potassium nitrate needed require to be increased.

This investigation was carried out in the analytical laboratory of Messrs. Boots Pure Drug Co., Ltd., to whom our thanks are due.

NOTE.

Dr. W. R. E. HODGKINSON has suggested that the material known as "meal nitre," obtained by rapidly cooling and agitating a hot solution of potassium nitrate, is more suitable as a filtering medium than powdered crystals. Most substances can be obtained in this "meal" form by suitable rapid cooling and agitation of a hot, nearly saturated solution.

RAPID DETERMINATION OF OIL IN MALT AND COD LIVER OIL PREPARATIONS.

BY H. DROOP RICHMOND, F.I.C., AND F. G. HITCHMAN.

The method employed is based on the fact that while the density of cod liver oil is less than that of water, averaging 0.925, that of malt extract is considerably greater, and further that the density of a 50% solution of malt extract (a convenient strength for the determination of density) is, within small limits of error, proportional to the refractive index of the malt extract itself. It has also been observed that small solid particles or small globules of oil do not affect the refractive index; the solid particles either obstruct a portion of the light, or deflect it outside the pencil of emergent rays, while spherical globules either let the light pass through without deflection, deflect them right away, or allow rays to pass through in equal amounts in opposite directions; the result is that there is a slight diminution in the light and sharpness of reading, but the refractive index of malt extract is unaltered whether determined on the malt extract, or after emulsification with a considerable proportion of cod liver oil. On these observations the following rapid method for the estimation of oil in malt and cod liver oil preparations has been founded.

Equal weighed quantities of the sample to be examined and distilled water are mixed thoroughly and the density determined at 20° C. by means of a delicate hydrometer; if the temperature is not exactly 20°, the density may be corrected by adding 0.0006 for each 1° above. The refractive index is determined at 20°, preferably by the Abbe refractometer, correcting the reading, if necessary, for small differences of temperature by adding 0.00018 for each 1° above. The percentage of oil is calculated by the following formula:—

$$(n_D - 1.3332) \times 549.6 - \left(\frac{d-1}{d} \right) \times 584.8$$

The following figures give a few of the results obtained:—

	Oil found.	Oil calculated.
	%	%
1.....	9.8	9.6
2.....	14.5	14.5
3.....	18.1	18.4
4.....	29.4	29.8

This investigation was carried out in the Analytical Laboratory of Messrs. Boots Pure Drug Co., Ltd., to whom our thanks are due.

THE ESTIMATION OF SMALL QUANTITIES OF COBALT.

BY A. D. POWELL.

The solubility of cobalt ammonium thiocyanate in amyl alcohol, with formation of an intense blue coloration, was first made use of by Vogel as a means for the qualitative detection of cobalt in nickel salts, and has since been applied to quantitative separation of these metals (Rosenheim and Hildschinsky, this Journal, 1901, 810). The test, as described by Treadwell, consists of the addition of a concentrated solution of ammonium thiocyanate to the solution to be tested, followed by extraction with amyl alcohol. In the presence of cobalt, the amyl alcohol is coloured blue; if ferric iron be present, however, the blue colour is masked by the red colour of the ferric thiocyanate, and the solution is then shaken again after the addition of sodium hydroxide or carbonate to destroy the ferric salt, when the blue colour of the cobalt salt becomes apparent.

In using this test for the estimation of cobalt in samples of pyrolusite containing 2% or more of iron oxide, it was found that, unless a certain concentration of ammonium thiocyanate was maintained throughout, the cobalt either was not extracted by the amyl alcohol, or else, after extraction along with the iron, the addition of sodium carbonate, and consequent reduction in the concentration of the ammonium thiocyanate, caused part of the cobalt to be re-extracted into the aqueous solution.

On making further experiments it was found that the minimum concentration of ammonium thiocyanate necessary for complete extraction of the cobalt was 25%, and in all succeeding tests a concentration of 30% was maintained, two extractions from a solution of this strength removing practically all the cobalt. In making comparative tests, a known amount of cobalt was added to a solution containing about the same quantities of iron and manganese as were present in the solution under examination, and the extractions were made under the same conditions, the matching being carried out in Nessler cylinders, in a volume of 50 c.c. It was found impossible to filter the amyl alcohol extract through paper before matching, owing to absorption of the coloured salt by the paper, the first few c.c.s. coming through almost

colourless. As the separated extracts, even after long standing, always held in suspension sufficient ferric hydroxide to render the colour greenish and difficult to match correctly, sodium carbonate was discarded as a reagent for removing the iron, and sodium pyrophosphate, recommended by Romijn for suppressing ferric iron (see this J., 1911, 1471), was substituted. With this alteration the difficulty entirely disappeared, the ferric pyrophosphate formed dissolving in the excess of sodium pyrophosphate. In fact, except in cases where the amount of manganese present formed too much precipitate with pyrophosphate to make extraction possible, half a gram or so of sodium pyrophosphate added to the solution before extraction, entirely prevented the iron reacting with the thiocyanate, and the cobalt could be extracted directly, the test thus taking only a very short time to carry out.

Another advantage of sodium pyrophosphate is that it ensures a very uniform colour being obtained. In the earlier experiments very varying colours were obtained according to the acidity or the alkalinity of the solution from which the cobalt was extracted. The control tests also when kept for some time for the purpose of comparison with future tests, became slightly acid, and changed from light blue to violet blue. When kept over a little solid sodium pyrophosphate, however, the control solution retains its colour unchanged in tint and density for many months. The quantity of substance taken was usually arranged to give a coloration not exceeding that produced by 0.5 mgrm. of cobalt, as this quantity gives a sufficiently deep coloration for matching. A far smaller amount of cobalt may be matched, the colour being visible when only 0.02 mgrm. of cobalt is present.

This investigation was carried out in the Analytical Laboratory of Messrs. Boots Pure Drug Co., Ltd., to whom my thanks are due.

Communications.

PRELIMINARY NOTE ON THE NATURAL COAGULATION OF THE LATEX OF *HEVEA BRASILIENSIS*.

BY L. E. CAMPBELL, B.Sc., F.I.C.

(1) In 1913, Whitby* advanced the hypothesis that four agencies are responsible for the changes that take place in the latex of cultivated *Hevea brasiliensis*—namely, a coagulating enzyme, an oxidase, anaerobic putrefaction, and aerobic putrefaction.

In the present paper we are concerned only with the coagulating enzyme. Whitby's conclusion that spontaneous coagulation of latex is probably due to a coagulating enzyme was founded on observations which showed that heating prevents such coagulation. The present author has carried out a series of investigations on this subject, and is able to support Whitby's theory. He has, in addition, determined to some extent the nature of the enzyme in question.

The natural coagulation of latex bears a superficial resemblance to the clotting of blood. It is known that blood contains a coagulating enzyme—thrombin or fibrin ferment, and that lime salts, e.g., calcium chloride, exert a particularly favourable influence on the rapidity with which the clotting of blood takes place. On the other hand, if blood be collected in a solution of alkali oxalate it does not clot, owing to the precipitation of the calcium as oxalate. Again, the presence of calcium

salts plays some part in the coagulation of milk by rennin.

Coagulating enzymes (the photo-chymases) are known to occur in certain plants, and some of these are known to require the presence of calcium salts for their action.

In view of all these considerations it was apparent that a study of the influence of calcium salts on the natural coagulation of *Hevea* latex might throw some light on the nature of the enzyme present.

Two sets of experiments were carried out—

(1) On the influence of the addition of calcium chloride; and

(2) On the influence of the addition of precipitants of calcium.

Calcium chloride.—In the first experiment, various amounts of a 10% solution of calcium chloride were added to equal quantities (1 litre) of normal latex containing 30–35% dry rubber. Without calcium chloride solution and with 1 c.c. small clots formed in three hours. With 5, 10, or 25 c.c. clotting occurred within half an hour.

Further experiments were then carried out in order to compare the action of barium chloride and calcium chloride. These substances were added in the form of 1% solutions. When 1 c.c. or 5 c.c. of calcium chloride solution was added to one litre of latex, no effect was observed within 3 hours. With 10 c.c. small clots formed in 20 minutes, with 25 c.c. coagulation started in 10 minutes, and 50 c.c. caused coagulation to start immediately. Addition of 1, 5, 10, or 25 c.c. of 1% barium chloride solution to the latex produced no effect within 3 hours; when 50 c.c. was added, the latex started coagulating in 10 minutes.

In the next experiment, the effects of manganese sulphate, calcium chloride, and magnesium sulphate were compared. The addition of from 5 to 50 c.c. of 1% manganese sulphate solution to 1 litre of latex produced no effect; 100 c.c. produced coagulation within one hour.* Quantities of 1% magnesium sulphate from 5 to 100 c.c. had no effect on 1 litre of latex, neither was any effect produced by 2 or 5 c.c. of 1% calcium chloride solution, but 10 c.c. produced coagulation within one hour and 25 c.c. produced coagulation very rapidly.

Further experiments were then carried out with the object of ascertaining the smallest amount of calcium chloride which will produce a marked effect in hastening natural coagulation.

The various sets of experiments were carried out on different days with one litre of latex from the same trees. In the first experiment 5 c.c. of 1% solution produced a marked effect within 1 hour, and 10 c.c. within 1/4 hour; with 25 c.c. the latex was thickly clotted in 10 minutes, and with 50 c.c. the majority coagulated in 10 minutes, whilst with 100 c.c. a solid coagulum formed in 10 minutes. In the second experiment, 5, 10, and 15 c.c. produced no visible effects after 1 hour; with 20 c.c. the latex started coagulating in 1 hour, and with 30 c.c. in 1/4 hour. In the third experiment no effect was produced by 5 c.c. within 1 1/2 hours; with 10 c.c. the latex commenced to coagulate in 1 1/2 hours, and with 25 c.c. within 10 minutes. In the fourth experiment, no visible effect was produced by 5 or 10 c.c. in three hours; with 15 c.c. an effect was observable within 1 1/2 hours, and with 20 c.c. within 1 hour. In the fifth series, 5 and 7.5 c.c. had no effect; 10 c.c. produced a marked effect within 2 hours, and 15 c.c. within 1 hour.

The effect of adding neutral, or faintly acid, potassium oxalate was then ascertained, a 10% solution of this salt being added to one litre of normal latex over a series of days. In each case

* India Rubber Journal, 1913, 45, 941.

* The coagulating effect in the case of barium chloride and manganese sulphate is attributable to a purely electrolytic reaction.

the clots of rubber were weighed after 18 hours, the weights being given in grammes of dry rubber.

10 % Potassium oxalate solution. c.c.	Weight in grms. of rubber coagulated after 18 hours.					Next morn- ing.
	A.	B.	C.	D.	E.	
0	280	350	300	400	360	400
5	185	200	200	320	—	—
10	—	40	150	160	280	230
20	—	30	—	—	—	—
25	10	—	—	80	200	14
30	—	30	—	—	—	—
50	20	—	0	110	110	28
100	70	—	—	160	170	0

In all these cases it is apparent that neutral potassium oxalate has a considerable inhibiting effect on the natural coagulation of *Hevea* latex. In order to confirm this conclusion, experiments were made with another precipitant of calcium, namely, sodium fluoride. This substance was added in the form of an approximately 5% solution, the reaction of which was rendered neutral or faintly acid with hydrofluoric acid. The results obtained are given in the following table, one litre of latex being used in each case:—

5% sodium fluoride solution added. c.c.	Weight in grms. of rubber coagulated after 18 hours.			
	A.	B.	C.	D.
0	400	310	400	310
5	370	—	—	—
10	110	170	200	230
25	0	130	—	14
50	0	15	0	28
100	—	—	0	0
200	—	—	0	—

These experiments show that an amount of sodium fluoride equivalent to from 0.125 to 0.250 % of the latex is capable of almost totally inhibiting spontaneous coagulation for 18 hours after tapping. Sodium sulphate was found to have a slight inhibiting effect.

It is to be noted that latex when rendered alkaline with the hydroxides of sodium, potassium, or barium did not coagulate at all. It is therefore probable that the coagulating enzyme of *Hevea* latex requires an acid medium for its action. It was for this reason that particular care was taken to ensure that the solutions of sodium fluoride and potassium oxalate were not alkaline in reaction. Had this not been the case, the retarding action of the salts in question on the natural coagulation of the latex might fairly be assumed to be due to their alkalinity rather than to their calcium-precipitating properties.

Conclusions.

The natural clotting of *Hevea* latex is aided by the addition of calcium chloride.

So far, salts of other metals have not been found to produce an equal effect. This natural clotting is, on the other hand, retarded or inhibited by:— (1) Heating; (2) addition of neutral or faintly acid solutions of precipitants of calcium, namely, potassium oxalate and sodium fluoride; (3) rendering the latex alkaline in reaction; (4) formalin.

In the case of (4) it may be noted that the phenomena are somewhat complicated by the fact that by the prolonged action of formalin on latex, a peculiar condition of the latex is produced. It retains its superficial appearance but is in reality a suspension of flakes of coagulated rubber in a clear serum, the Brownian movement of the particles having ceased. The factors concerned in the "natural" coagulation of latex are, like those concerned in the coagulation of blood, somewhat complex. In the latter case it is not yet clear how the coagulation is effected.

Nolf has stated that it consists in the interaction of three colloidal proteins, thrombogen, thrombozyme, and fibrinogen, in the presence of calcium salts.

According to Morawitz, the thrombogen in the circulating blood is converted by a thrombokinase, which is present in the tissues, into prothrombase which is changed by the action of calcium ions into the active form of the coagulating enzyme thrombase.

According to Pekelharing, thrombin is the calcium compound of prothrombin, the nucleo-protein which occurs in blood-plasma.

In view of the uncertainty as to the mechanism of the coagulation of blood it is not proposed here to offer explanations as to the mechanism of the coagulation of latex. From the evidence obtained, however, it is fair to assume that:—

(1) The natural coagulation of latex depends upon the action of an enzyme.

(2) The action of this enzyme is encouraged by the presence of calcium ions.

(3) The enzyme does not act in an alkaline medium, and

(4) according to Whitby the coagulation can take place in the absence of air.

Speculations as to the reason why latex does not coagulate in the latex vessels of the tree under normal conditions would no doubt prove as interesting as similar speculations as to the non-coagulation of blood in the blood vessels of the body.

It has frequently been stated by various investigators that latex as it emerges from the latex-vessels is alkaline in reaction, afterwards becoming acid on exposure to air. It is possible that the coagulating enzyme is enabled to act only on the development of this acidity.

In the experiments quoted above, the addition of a given amount of calcium chloride to a given amount of latex on one day did not produce the same effect as an equal amount of calcium chloride on the same amount of latex on another day. The same remark applies to the action of potassium oxalate and of sodium fluoride.

This difference is probably due not to the fact that the latices on the 2 days contained different amounts of enzyme, but rather to the fact that the latices had been examined at different times after collection. The action of the enzyme had already proceeded to a greater extent in one case than in the other.

It is to be noted that latex contains a carbohydrate, *l*-methylinosite.

Many enzymes appear to be combinations of protein and carbohydrate, and it is possible that *l*-methylinosite may prove to be part of the enzyme of *Hevea* latex.

Serum from pure latex contains up to 4% of solid matter.

This work is being continued, but it is thought that the results already obtained are of sufficient interest to justify the publication of this preliminary note.

The thanks of the author are due to Messrs. K. C. Browning and C. T. Symons of the Government Analysts' Department, Ceylon, for suggestions and assistance.

STEAM DISTILLATION.

BY F. J. TROMP.

In a series of experiments in which the author had to distil large amounts of aniline in the laboratory he was led to devise a condensing apparatus which considerably shortened the time usually taken for such distillations.

The liquor which is to be distilled is contained in the vessel, A. Steam enters at B, passes out at C, and is led by means of D below the surface of some water in E. The water in E is cooled by means of a cooling coil. As the liquor collects in E, it may be siphoned off. Once the air has escaped from A, there appears to be practically no limit to the rate at which the steam can be passed. Condensation is complete so long as the liquor in E is below the boiling point. It is possible to heat the liquid in the cooling coil to above 80° C. and still have efficient condensation.

If a number of vessels similar to E were connected in series by means of siphons and cooling coils, the apparatus would serve as a rapid and efficient condenser, and would be very suitable on the large scale for utilising the heat from the condensed vapours.

Faraday Society.

THE TRAINING AND WORK OF THE CHEMICAL ENGINEER.

A general discussion on the above subject was held at the Faraday Society on March 6th.

The President of the Society, Sir ROBERT HADFIELD, in opening the discussion, said that each important branch of industry demanded its own special type of chemist, and no course of training could cover all the requisite ground; thus a chemist suitable for the chemical industry would probably not shine as a chemist in the industry of ferrous metallurgy, for the ferrous metallurgist had to deal with a large range of high temperatures, up to and exceeding 3000° C., in addition to the much lower "treatment temperatures" and those used in tempering work. It would be advisable if somewhat early in his training the student could more or less branch to a special study of the line of work with which he expects later to be associated. He felt that, in some respects, a chemist of the first rank was born and not made. It was most desirable that increased facilities should be given to training chemists to meet those conditions which would arise after the war.

Sir Robert then alluded to the benefits which the world had derived from the discoveries of

British chemists, and also referred to the State organisation of scientific research, expressing the hope that the efforts of the Advisory Council would bear good fruit. He mentioned that in 1914 there were 69 agricultural colleges in America, with an annual income of £7,000,000, and instructing 60,000 students, and also that the Bureau of Standards expended annually about £125,000 on research work.

Sir Robert concluded with an appeal for support for the Ramsay Memorial Fund, one of the objects of which was to establish a laboratory for dealing with engineering chemistry.

In the course of his introductory address, Sir GEORGE BELLBY pointed out the danger that the present war conditions might encourage the development of unbalanced proposals for the training of the future leaders and workers in industry, and that it was desirable to make the general relation of chemical engineering to industrial chemistry as a whole more clear. He had always considered chemical engineering to have as its function the design and construction of apparatus required for carrying out chemical processes on a manufacturing scale. In the future the control of processes in the factory must pass more and more into the hands of trained chemists, but no amount of purely scientific training would produce the right type of man for this purpose. A man might easily be over-trained if left too long amidst purely academical surroundings. Laboratory training tended to produce a narrow individualism which might be a serious disqualification for the work of the factory. He strongly recommended a certain amount of engineering training in the education of the industrial chemist in the majority of cases; the heads of the engineering department could select from the chemical students those who showed special mechanical aptitude, and these could then be given further training in engineering. The training of the industrial chemist should consist of a sound and practical three years' course in chemistry and chemical physics, at the end of which the student should be advised in what direction to specialise; average students with no special bent should complete their four years' course by general advanced studies, but those fitted to become chemical engineers, research chemists, and specialists in other branches should devote one or two years to higher post-graduate study.

To fulfil his proper functions the chemical engineer must have a great deal of knowledge and experience quite outside the range of the ordinary engineer, and must know from within the chemist's as well as the engineer's point of view. Since the chemist's views of matter and energy were much further removed from every-day notions and conceptions than are those of the engineer, it was wiser first to imbue the mind of the future chemical engineer thoroughly with the chemical point of view.

Prof. F. G. DONNAN, in the course of a paper on "The Training of the Chemical Student for work in the Factory," said that there were three broad lines upon which to train a man for future work in connection with chemical processes in the factory, viz., (1) thorough and extensive chemical training, with a certain amount of training in engineering; (2) a pretty extensive training in both chemistry and engineering; (3) a further study of chemistry for those who have received or are receiving a thorough training in engineering. Method (1) produces the chemist (research chemist), method (2) the engineer-chemist, and method (3) the chemical engineer. The research chemist should possess a good knowledge of physics and physical chemistry with some idea of engineering science. Engineer-chemists, who are required in

very large numbers, must receive a very considerable amount of engineering training, and should possess sound "horse" sense, cool quick judgment, power to control workmen, and courage in the face of danger. The training of both these types must include research, which, in the case of the engineer-chemist, should take the form of an investigation of the conditions which determine how a given chemical process can best be carried out on a technical scale. The essential for men of class (3) is that they are thoroughly trained engineers. In chemical engineering there lies the greatest and most lucrative field of development for engineering science, and schools of chemical engineering should be founded without delay.

Mr. W. R. COOPER, in "A Plea for the Forgotten Factor in Chemical Training," urged that the financial side of chemistry should not be neglected during the training of the chemical student. He should appreciate the fact that manufacturing cost is only a part of the total, and that the cost of selling, depreciation of plant, etc., must be considered. Further, costs must be divided into "overhead" and running costs. The commercial efficiency of plant is also of importance; for instance, it may be worth while to have a lower technical efficiency if this increases the utility factor, *e.g.*, the ratio of the quantity of material actually produced in a given time in a discontinuous process to the quantity produced if the plant were working continuously under the best conditions. The speed of reaction is another point to be considered. He suggested that three months might be devoted to this part of the subject at the conclusion of the technical course.

Mr. CHARLES R. DARLING read a paper on "The Training of the Works Chemist in Physics," in which he described the course of instruction in physics at the City and Guilds Technical College, Finsbury, in which students receive a training to fit them to enter works as chemists. He said that physico-chemical subjects, such as electro-chemistry, osmotic pressure, etc., are dealt with in the Chemical Department, either following or parallel with instruction in sound, light, heat, and electricity in the Applied Physics Department. During the three years' course the student received about 120 lectures in purely physical subjects, and spent about 200 hours in the Laboratories. Instruction in light includes a description of, and practical work with, the optical instruments used in industries, whilst the course on heat includes fuels, electrical heat production, fusion, pyrometry, heat insulation, etc.

Mr. J. W. HINCILEY, describing "The Work of the Imperial College in the Training of Chemical Engineers," said that the Department of Chemical Technology was inaugurated in 1912. The students here obtain practical acquaintance with experimental units of filter-presses, reaction towers, stills, grinding mills, etc., they make original designs of simple plant for a given output of product, and finally study the process on a suitable scale. They design the plant, prepare specifications and estimates, and determine the cost of production, and also devise a system of factory records for controlling the plant and plan a factory for the manufacture.

Sir ARTHUR DUCKHAM thought that the engineer-chemist should not try to go too deeply into engineering, but should simply be able to think as an engineer and appreciate engineering problems. He agreed that the chemical engineer, the engineer who could think as a chemist, was essential. He emphasised the value of practical training, and said that it was necessary to introduce the practical work of the factory into the college, where it should be taught by practical men. The questions

of fuel economy and fuel utilisation were of the highest importance, and must always be kept in view by the engineer-chemist and the chemical engineer.

Prof. A. K. HUNTINGTON agreed with Mr. Cooper as to the necessity of teaching the student to think of a problem from a financial point of view. It must be borne in mind that because a process cannot be economically worked to-day, it did not follow that it would not pay a year or two hence, since knowledge was increasing at such a vast rate. He mentioned that the Haber ammonia process could be worked at a pressure of 200 atmospheres, which would have been impossible a few years ago. Referring to the deficient nature of the technical education in this country, he attributed it to the fact that the student came to college altogether inadequately equipped in mathematics. He thought the scientific man was rather to blame for the antagonism which had existed between scientific and practical men in the past. The theories of the scientific man did not always work out in practice, owing to the fact that he did not get into touch with practical work, and was therefore apt to overlook certain important factors in a problem.

Mr. A. P. M. FLEMING expressed it as his opinion that engineering experience, which was necessary to every chemist, should partly be obtained in the works. In that way the chemist would get to understand men, and that might do away with the inherent antipathy to the chemist which existed in many English works. It was essential for every chemist to get into early touch with the works, so as to get some grip of manufacturing processes. He was trying a scheme in which his chemists were put for a year into the shops before they came into the laboratory. He was of the opinion that post-graduate courses might with great advantage be spent in the works. Finally, he urged the necessity of employers using every means to attract to engineering and chemistry the best brains in the country.

Dr. W. ROSENTHAL said that in training students it was necessary to encourage breadth of view. A man trained solely as a chemist or solely as an engineer tended to lack that breadth of view, and probably much better results would be obtained by a course of training as outlined by Prof. Donnan. The antagonism between theory and practice, alluded to by Prof. Huntington, arose from the complexity of industrial problems. In the laboratory the conditions of a problem could be simplified to a large extent by isolating the factors, but in a works the problems had to be dealt with by methods of approximation and frequently by insight, which could only be acquired by those possessing the necessary breadth of view and reasoning power. His own experience was that the most useful man for elucidating practical problems was one who had changed his opinions half way, or better, one who had been trained in one direction, and had been later impelled to take up another line of study. A man expert in one subject and in nothing else was always liable to be in trouble when he got out of his own groove.

Dr. R. ROBERTSON said that the necessity for engineer-chemists had been brought home to them by recent events. A course of engineering should be introduced into the training of every chemist, because, apart from the fact that it would be of direct benefit to the student, it might enable the professor to differentiate between students fitted for purely research work and those adapted to applied science. He agreed with what had been said as to the value of contact with the reality of works practice, and mentioned that in the nitro-glycerin works at which he had been engaged, chemists who were to take charge of a process had

to go into the works and perform the duty of each of the men attached to that process. Post-graduate students might be set a practical problem not necessarily a novel one—but a specific problem to solve with certain facilities and in his own way. A man who had shown himself capable of tackling such a problem would be very useful in a chemical works.

Mr. W. MACNAB thought that the teaching institutions were to some extent to blame for the lack of engineering chemists in this country. It was true that some chemists received very small salaries, but they were often not worth more. The chemist now had ample opportunity of showing his value, and engineering training must take a part in his education. The exchange of views which was now taking place between manufacturers would be of the greatest benefit to the nation at large.

Prof. E. G. COKER thought that the scheme of putting students to solve problems in the works would to a large extent overcome the difficulty in placing young engineers in suitable positions. He agreed that chemists should receive some training in engineering, but considered that it should be a training of a special kind, so as not to deal with subjects which would be of no ultimate value to the student.

The PRESIDENT, speaking of competition, said that it was the life-blood of trade, and we did not fear fair competition of the type we looked for from America; the type which was difficult to meet was the so-called peaceful penetration system of Germany.

Lieut. GREENWOOD said that it was lamentable that in many chemical works the design and erection of the factory was entrusted entirely to the engineer, with the result that the chemist often took little interest in the matter afterwards. The remedy was to be sought in our educational system, and students who intended to go into industrial work should receive a training in applied physics and engineering. Great prominence should also be given to physico-chemical subjects, since the modern process tended more to involve physical methods for its control and less to depend on analysis.

Mr. C. S. GARLAND agreed as to the value for chemists of some training in engineering. The chemist must be induced to take up the most important chemical work in this country, viz., manufacture.

Dr. E. F. ARMSTRONG said that his experience had been that there had been no difficulty in getting men of the type described by Prof. Donnan as engineer-chemists. He agreed that research chemists were of great value, and the aim of teaching institutions must be to produce well-trained chemists first of all; at a later stage of training the professor could select those with mechanical aptitude and those suitable for research work, with a view to suggesting specialisation. It would also be a great advantage if the Universities were to get into closer touch with industry by inducing manufacturers to become members of their academic councils. The management of a works, with its commercial and other problems, soon lost touch with science, and must depend very largely on chemists. Industries had been revolutionised by men who had specialised in certain branches of science, such as the phase rule and colloid chemistry. He believed that if a hundred leading chemists engaged in industry were asked what was their deficiency as the result of their training, they would agree that it was a lack of greater knowledge of chemistry. He mentioned that of the three really great achievements of industrial chemistry in recent years, viz., synthetic ammonia, artificial silk, and fat hardening, the two last had been worked out entirely in this country, although fat

hardening had actually been discovered by a German. Synthetic ammonia was a German process, but it had not appealed to us because we had plentiful supplies of cheap ammonia.

Mr. W. GATHORNE YOUNG agreed with Prof. Donnan as to the training of the engineer-chemist, and considered that it should consist of a three years' scientific course at a University, including elementary instruction in engineering, followed by a two years' post-graduate course in general chemical engineering; during this latter course systematic visits to chemical works should be arranged, and the student should work at these factories during his vacations. He was sure that manufacturers would be willing to co-operate with Universities in the matter, as it would give them opportunities of securing useful additions to their staff. He thought British chemical industry had done remarkably well during the last 30 years, considering the poor inducement that chemists had been offered.

Mr. T. G. ELLIOTT agreed as to the necessity of better secondary education, particularly in regard to a course of physics. He thought that the system followed by our northern Universities of specialising in the industries of the district, was an admirable one.

Written communications were received from Mr. F. H. Carr, Dr. P. E. Spielmann, Mr. H. L. Heathcote, Dr. E. B. R. Pridaux, and Mr. G. S. Albright.

Industrial Notes.

CHEMISTS IN WAR.

Under the above title the Registrar of the Institute of Chemistry has written an interesting account of the part chemists have played in the present war, from which the following passages are taken:—

Owing to the conditions of modern warfare chemists have been more than ever in request. The Government has secured the guidance of chemists and other men of science to assist in the investigation of suggestions and inventions and to bring their knowledge and experience to bear on measures and devices of offence and defence, while apart from those acting in an advisory capacity, chemists have been called for service in the field as well as in the factory. In such times there is a demand for the solution of problems of an unusual character which can only be entrusted to men of the highest scientific training, with initiative and foresight.

So much had we come to rely on foreign sources of supply for many of our needs, that means had to be found for dealing promptly and efficiently with difficulties some of which, unless overcome, threatened serious disaster. The chemists of the country have not been found wanting.

The laboratories of our universities and colleges have become small factories for the preparation of drugs and medicaments, and many institutions have been entrusted with the examination of materials used in the manufacture of explosives. The measures taken in this emergency secured uniformity in method and the standardisation of processes which would otherwise have been difficult to attain. Under the supervision of their professors, students unfit for service with the colours have been helping the country and at the same time gaining useful experience.

Several hundred chemists have been engaged for assistance in the laboratories and in the works of Government and controlled establishments supplying armaments, munitions, and other materials of war. In cases where the number of

men having technical experience in some branches was limited, the authorities have made arrangements for probationary training, so that their services should be available when required in new factories.

The staffs of the chemical departments of Woolwich Arsenal and other Government factories have been considerably augmented, as also that of the Government Laboratory, which, as the recently published report shows, has been largely responsible for the examination of foodstuffs and many other requirements of the Expeditionary Forces.

In previous wars the authorities have considered officers of the R.A.M.C. sufficiently trained for all necessary military duties involving chemical knowledge, but in the present conflict, with an unprecedented demand for medical men, qualified chemists have volunteered in such numbers as to give practical force to the suggestion that they should be engaged for the purification and examination of water supplies and for dealing with matters of hygiene requiring chemical knowledge. As a result many have been appointed to commissions and engaged for scientific work, not only with the R.A.M.C., but also with the A.S.C., A.O.D., and other units. Attached to various forces at home, with the armies on the Continent and in Africa, chemists have thus rendered valuable service.

In consequence of methods of offence initiated by the enemy, such as the employment of poisonous gases, there arose a further demand for men with training in chemistry for service in the field. For the duties involved the authorities deemed it expedient to enlist men with such training, rather than entrust them to men without any scientific knowledge, and the unit thus formed is a fighting force. With the assistance of the universities and technical colleges and the various bodies interested in chemistry, an entirely new force was brought into existence. At that time there was no question of compulsion, yet it was raised with little difficulty, being subsequently augmented by the addition of other troops. The men went voluntarily, and were sent abroad at very short notice, and after short training went into action. The officers were mainly selected from chemists who already held commissions, while sergeants and corporals with knowledge of chemistry were transferred from other units. That they did their work well is shown by the dispatches of Lord French and Sir Douglas Haig, dated October 15th, 1915, and May 19th and December 23rd, 1916.

High qualifications were unnecessary for the work of the rank and file, but many very competent men joined, and it may be mentioned incidentally that it was remarked on an early occasion that generally speaking the best qualified chemists proved the best soldiers. The majority of the university graduates and men possessing recognised diplomas, who originally enlisted as corporals, subsequently received commissions, and when the force was more completely organised a considerable number were withdrawn and transferred to the Ministry of Munitions in order that their services might be available in work of a more scientific character.

Mention should also be made of the fact that during the campaign against the rebels in South Africa and the Germans in South-West Africa chemists were attached, on the personal order of General Botha, to the different brigades and rendered valuable service.

From the experience gained in the campaign it is clearly advisable that the State should have control of such an organization of professional chemists as to ensure at any time their efficient service in the many requirements of the naval, military and air forces. In addition to competent chemical advisers of undoubted standing, the following appear to be essential:—

Chemists to control the manufacture of munitions explosives, metals, leather, rubber, oils, gases, food, drugs.

Chemists for the analysis of all such materials and for research.

Chemists, on active service, to assist in the control of water supplies, in the detection of poison in streams, in the analysis of water and food, in the disposal of sewage, and in other hygienic matters.

Chemists, both at home and on active service, to assist in devising safeguards against enemy contrivances of a scientific nature, and methods of offence to meet the same, as well as for the instruction of troops in such matters.

To sum the matter up, chemists have met the situation with a spirit of true patriotism and have been promptly organised for the service required of them. It is not too much to hope that, as the discoveries of science have been applied to the destruction of humanity, they may be devoted more and more to the furtherance of the arts of peace, to the uplifting of civilisation and the pacification of the world.

During the war, in spite of the shortage of labour, considerable additions have been made to the large manufacturing concerns throughout the country in the extension of factories, both for the production of things hitherto obtained from abroad and for the requirements of the war.

One important lesson which on no account must be lost sight of is that the country must be self-supporting in all such requirements.

The chemists engaged in connection with the production of materials of war include a large number who were previously occupied in works which have passed under Government control. Most of these were members of the Institute or graduates in science and many were teachers, who thus obtained an insight into operations on a manufacturing scale. If they return to teaching, this experience will have broadened their views, but many will no doubt prefer to remain in industry. Of those with the forces, probably the majority will return to their former work. In any case, many good British chemists should be available for the furtherance of British industry.

THE FOOD SUPPLY OF THE UNITED KINGDOM.

At the request of the President of the Board of Trade, a Committee was appointed by the Royal Society in 1916 to report upon the food supply of the United Kingdom. The Committee comprised Prof. A. D. Waller, F.R.S. (Chairman), Prof. W. J. Ashley, Mr. A. W. Flux, Mr. A. D. Hall, F.R.S., Prof. F. G. Hopkins, F.R.S., Mr. T. H. Middleton, Prof. D. Noel Paton, Prof. W. H. Thompson, and Prof. T. B. Wood.

The first part of the report of this Committee [Cd. 8421] deals with the food supply of this country in the period before the war. The quantities of the various food materials available for human consumption in the five years before the war (1909-1913) are given in tabular form; the statistics of home-grown foods are admittedly liable to error, but as considerably more than half of our food supply is imported and the import statistics are on the whole sufficiently accurate, the ultimate error in the figures given is much reduced.

The subjoined table shows the average quantities of food materials (imported and home produced) available for the United Kingdom during the five years, 1909-1913, inclusive, together with the amounts of protein, fat, and carbohydrate present and the energy value. The average population is taken as having been 45·2 millions.

	Amounts.	Protein.	Fat.	Carbo- hydrate.	Energy value. Millions of Calories.
	Metric tons.	Metric tons.	Metric tons.	Metric tons.	
Cereals	4,865,000	549,000	63,000	3,628,000	17,712,000
Meat	2,685,000	356,000	799,000	—	8,890,000
Poultry and eggs, game and rabbits	331,000	42,000	31,000	—	461,000
Fish	848,400	91,000	17,000	—	531,000
Dairy produce (including lard and margarine)	5,231,800	199,000	686,000	258,000	8,253,000
Fruit	1,271,000	9,000	14,000	222,000	1,077,000
Vegetables	5,482,000	120,000	10,000	1,031,000	4,812,000
Sugar, including cocoa and chocolate	1,657,000	5,000	18,000	1,572,000	6,633,000
Cottage and farm produce not included above	—	67,000	13,000	551,000	2,655,000
Total	—	1,438,000	1,651,000	7,262,000	51,024,000
Per head per day	—	grms. 87	grms. 100	grms. 440	3,091 Calories
Per "man"† per day	—	113	130	571	4,009 ..

* Negligible quantity.

† A "man" is an average workman doing an average day's work. One hundred of the total population (men, women and children) are reckoned as equal to 77 "men."

As a result of a full consideration of the dietary requirements of a nation for the most part engaged in active work, the Committee is convinced that these requirements cannot be satisfactorily met on a less supply of food, as purchased, than 100 grms. of protein, 100 grms. of fat, and 500 grms. of carbohydrate, representing approximately 3400 calories, per "man" per day. This has been adopted as the minimum standard. From the figures for available food supply and the minimum standard it is calculated that there has been either wasted or consumed in excess of requirements 11—14% of protein, 25—30% of fat, and 10—14% of carbohydrates.

In Part II. of the Report, the food supply during 1916 is considered, on the assumption that the pre-war supply is maintained. The total population is estimated at 46·5 million, of which four million were our fighting forces at home and abroad; this leaves a civil population of 42·5 million, equal to 31·8 million men. The food requirements for the fighting forces is calculated from the Army Rations, and the calculations show that, on the pre-war basis of supply, the food available for the civil population would be more than sufficient, both as regards the supply of protein and of energy. From the information available to the Committee it is believed that the available amount of protein, fat, and carbohydrate per "man" has been maintained at about the normal level, but the needs of our armies, the decreased yield of the harvest at home in 1916, and the possible interference with imported foods, may reduce the supply in the future below this level.

Up to the present the supply of food has provided a general margin of about 5% above the minimum necessary for proper nutrition, and rather more as regards the supply of energy, so that a reduction could be borne without serious consequences provided the available food were equitably distributed. It is pointed out that if the rising prices curtail for any class of the community its accustomed supply of food, its output of work will be reduced, and that a slight reduction of food below the necessary amount causes a large diminution in working efficiency.

Part III. of the Report deals with certain suggestions as to possible means for increasing or economising our available food supply. (1) *Better recovery of flour in milling.* Under present conditions millers obtain on the average about 70% of flour from cleaned wheat, but many mills could readily be adjusted to recover 80%

of the wheat as flour, and this 80% flour makes wholesome and palatable bread. It is calculated that the gain for human consumption which might result from raising the milling standard from 70% to 80% (after making allowance for the reduced digestibility of the 80% flour and for the decrease in production of pig meat due to removal of 10% of offals from the market) would be 31,000 metric tons of protein and 866,000 million calories. (2) *More economical meat production* is possible in several directions, e.g., slaughtering cattle when 17 months old instead of at 2½ years, discontinuing fattening when no increase in weight is shown, and feeding animals which are good "converters" of fodder into energy. (3) By adopting *cheese-making* as a general practice in place of butter-making it is calculated that an annual saving of 55,000 tons of protein would be effected. (4) The economy which might be effected by the *prohibition of brewing* was dealt with in the last issue of this Journal (p. 198).

Note.—It will be observed on reference to page 301 of this issue that it is now compulsory on all millers to extract from wheat not less than 81% of flour.

MINERAL PRODUCTION OF THE UNITED KINGDOM IN 1915.

THE subjoined table, showing the mineral produce of the United Kingdom, is taken from the Report on Mines and Quarries, Part III. [Cd. 8441].

The average price of coal in 1915 was 12s. 5·60d. per ton in 1915 as compared with 9s. 11·79d. in 1914. The quantity of coal exported, exclusive of coke and manufactured fuel and of coal shipped for the use of steamers engaged in foreign trade, was 13,534,560 tons. France received over 17½ million tons, Italy over 5½ million tons, Denmark over 3 million tons, Sweden over 2½ million tons, Norway over 2½ million tons, the Netherlands over 1½ million tons, the Argentine over 1½ million tons, Spain over 1½ million tons, and Egypt over 1½ million tons. Adding the 2,786,401 tons exported in the form of coke and manufactured fuel, and the 13,630,961 tons shipped for the use of British and foreign steamers engaged in foreign trade, the total quantity of coal which left the country was 59,951,925 tons, as against 80,993,890 tons in 1914. The amount of coal remaining for home consumption was 193,254,156 tons, or 4·193 tons per head of the population. 37,284,600 tons was used in the manufacture of coke and briquettes,

* Exclusive of 400 tons of micaceous iron ore, used for paint, and placed under the heading "Ochre, Umber, &c."

† " 312 " " " "

and 2,509,456 tons of coal with 9,746,743 tons of coke (equal to 16,244,572 tons of coal) in the blast furnaces for the manufacture of pig iron, as against 36,289,010 tons and 18,381,106* tons respectively in the previous year. 20,059,140 tons of coke

was obtained in 1915, valued at £18,270,018. 16,574 coking ovens were in use during the year. 1,697,541 tons of briquettes was produced, valued at £1,755,406.

During 1915 the output of iron ores was 11,235,012 tons, yielding 4,567,351 tons of iron, or more than half of the total quantity of pig iron made in this country.

* Previous to 1915 the actual quantity of coke used was not furnished. This figure therefore represents the coal used and the equivalent in coal, or coke used.

Journal and Patent Literature.

PATENT SPECIFICATIONS may be obtained by post by remitting as follows:—

English.—6d. each, to the Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C.

United States.—1s. each, to the Secretary of the Society, who has to furnish the U.S. Patent Office with the following data:—Patent number, date, name of patentee, and title of invention.

French.—1 fr. 05 c. each, as follows: Patents dated 1902 to 1907 inclusive, Behn et Cie., 56 Rue Ferou 8 Paris (3e) Patents from 1908 to date, L'Imprimerie Nationale, 87, Rue Vieille du Temple, Paris.

I.—GENERAL; PLANT; MACHINERY.

PATENTS.

Regenerator. L. Bergfeld, Durlach. Ger. Pat. 295,436. July 1, 1913.

A SERIES of glass balls passes first through the hot, escaping gases or liquid, and then through the gas or liquid which it is desired to heat. The balls travel in the opposite direction to the gas or liquid.—A. B. S.

Catalytic reactions; Method of carrying out. J. Walter. Geneva, Switzerland. Ger. Pat. 295,507, Apr. 20, 1913.

MECHANICAL agitation of the catalyst is effected by the application of a magnetic field. If the catalyst itself is not magnetic it is supported on a magnetic body. By rapidly making and breaking the circuit forming the magnetic field, fresh parts of the catalyst can continually be brought into contact with the reacting substances and the catalyst can be moved to different parts of the

apparatus. For reactions with gases the catalyst is supported preferably on nets or perforated plates, and a magnetic field is maintained permanently near the outlet to cause the settling of any material carried along by the gas.—J. N. P.

Distilling and rectifying columns. Metallwerke Neheim A.-G. Ger. Pat. 291,781, July 11, 1911.

The spaces between the perforated plates of a vertical column are each divided into two compartments by a

partition, *B*, provided with an overflow pipe, *C*. The vapour ascending the column takes the path shown by arrows and the is brought repeatedly in contact with the condensed liquid, but does not bubble through the latter. Pieces of wire gauze, *G*, may be provided to effect better

distribution of the vapour. Radial or concentric partitions may be used in place of the transverse partitions, *B*, and the spaces may be so connected that the vapour is forced to bubble through a layer of the condensed liquid.

Lead linings of vessels; Increasing the resisting power against mechanical shocks of —. F. Schüller, Frankfurt. Ger. Pats. (A) 295,556, Oct. 7, 1915, and (B) 295,557, Nov. 9, 1915. (A) Addition to Ger. Pat. 288,571 (this J., 1916, 365).

(A) After applying the small pieces of metal harder than lead, as described previously (*loc. cit.*), the lead is heated to its melting point; or the pieces of hard metal may be embedded in the lead after heating the latter to the melting point, or may be added to molten lead and the latter then cast in position. (B) Effective hardening of the lead is brought about by heating and at the same time subjecting to mechanical working such as kneading, pressing, and rolling.—J. N. P.

Centrifugal dryer. K. and A. Ward, Stockholm, Sweden. U.S. Pat. 1,213,983, Jan. 30, 1917. Date of appl. Apr. 30, 1914.

See Eng. Pat. 10,783 of 1914; this J., 1911, 1192.

Separation of colloids from mixtures by electro-osmotic action. Ger. Pat. 295,666. See XI.

IIA.—FUEL; GAS; MINERAL OILS AND WAXES.

Coke production in the United Kingdom in 1915.

PART III. of the General Report on Mines and Quarries for 1915 [Cd. 8114] contains full particulars as to the quantity of coke produced. The figures show that 35,690,342 tons of coal was carbonised producing 20,059,140 tons of coke, valued at £18,270,018. Gas works produced 8,150,200 tons and coke ovens 11,908,919 tons. All these figures are higher than those for 1911. The total number of coke ovens in operation during 1915 showed a decrease as compared with the preceding year, the figures being 16,571 and 17,025 respectively. It is

satisfactory to note, however, a considerable reduction in the number of beehive ovens used, viz., from 9210 to 7521, whilst the by-product ovens increased from 7815 to 9053. Increased numbers of Simon-Carvès, Otto-Hilgenstock, Semet-Solvay, Koppers, Simplex, Huessener, and Collins ovens are noted, whilst fewer Coppée ovens were in use.

Scottish shale industry: Appointment of Committees on the —.

THE Minister of Munitions, after consultation with the Admiralty and the Home Office, has appointed the following Committees to deal with certain problems connected with the Scottish shale industry:—

Owners' Committee.—Mr. John Wishart (Chairman); Mr. J. C. Clarke, Admiralty; Mr. A. H. Thrichton; Mr. H. Fraser; Mr. A. Kerr; and Mr. William Love.

Workmen's Committee.—Mr. John Byrne; Mr. Robert Hood, President, Shale Miners' Association; Mr. John Kilday; Mr. Michael O'Hagan, General Secretary, Oil Works Association; Mr. Robert Simpson, General Secretary, Shale Miners' Association; and Mr. H. Walker, H.M. Divisional Inspector of Mines.

The Minister has appointed Professor John Cadman to represent the Ministry of Munitions in connection with this subject, and to act as Chairman of the two Committees on any occasion on which they meet in joint session. Sir George Beilby will act as technical adviser on the questions within the purview of the Committees, and Mr. Hugh Johnstone has been appointed to be a member of, and to act as Secretary to, the Committees.

Wood charcoal; Heat of combustion of —. N. I. Nikitin, J. Russ. Phys.-Chem. Soc., 1916, 48, 51–75.

VARIOUS methods of drying charcoal to constant weight have been investigated. Satisfactory results are obtained by drying in a desiccator over sulphuric acid, and with charcoal which has been stored in the air for a year or more the dry weight obtained in this way is almost exactly the same as that given by five hours' heating in an oven at 103° C., whilst a further heating for three hours at this temperature is without appreciable influence. On the other hand, charcoal which has been recently prepared exhibits progressive increase in weight when heated at 103° C., probably owing to oxidation, which also occurs, although slowly, at the ordinary temperature. Eighteen samples of charcoal prepared from different kinds of wood by carbonising, some in heaps and others in retorts, have been analysed and investigated as to calorific value. The percentage of carbon varied from 73.01 to 92.11 and was always higher in heap charcoal than in retort charcoal; the proportion of hydrogen varied from 0.64 to 1.71%. The values for the heats of combustion, calculated by means of either Dulong's or Mendeléev's formula, were always less than the experimental values, and in general the divergence increased with the proportion of oxygen and nitrogen taken together, although the introduction into these expressions of a correcting term was not found possible. Calculation from the author's experimental results shows that the number of calories generated by the combustion of 1 gram of charcoal is given very closely by the expression, $80.51 C + 273.4 H$, *C* and *H* representing the percentages of carbon and hydrogen in the dry charcoal. The errors of the values calculated from this formula lie between the limits, $\pm 0.63\%$ and $\pm 0.17\%$, and, for a sample of brown charcoal

and dividing each by the number n of oxygen atoms necessary for complete combustion, values of H/n are obtained which are remarkably constant. This is shown in a graph in which the measured heats of combustion of 121 compounds (hydrocarbons, halogen compounds, ethers and acetals, alcohols, aldehydes and ketones, acids and anhydrides, esters, mercaptans and other sulphur compounds, cyanogen compounds, nitro-compounds, and amines) are plotted against the oxygen atoms per molecule required for complete combustion in each case. Many of the points practically coincide, and a straight line drawn from the farthest to zero touches 55 of them. The heat of combustion is therefore, as a first approximation, proportional to the number of oxygen atoms which combine with a molecule of combustible gas, irrespective of molecular complexity and of whether carbon or hydrogen is burnt, and is equal to $53n$ kilo-calories per gram-molecule. This suggests, as the essential feature of combustion, that oxygen is first sensitised by contact with the source of ignition and becomes an immensely active agent, atoms of which are able to seize upon and tear apart the almost unresisting hydrocarbon molecule. The heat of the reaction, being all translational energy, is the result of the speed with which the oxygen atoms rush into combination, and is therefore proportional only to their number. This is capable of interpretation, in many instances, in terms of the regular occurrence of the CH_2 radicle; but it also suggests that the heat of combustion of carbon being twice that of hydrogen may not be altogether accidental, but may be an example of this general relation from which the value for CH_2 is itself derived. If the combined oxygen in nitro-compounds be regarded as used in their combustion, a much higher value for H/n is obtained; thus the value for nitromethane, which requires only 1½ atoms of oxygen per molecule, is 120.5. But if the combined oxygen be regarded as not used in the combustion, nitromethane would require 3½ atoms of oxygen per molecule, in which case the value of H/n would be 51.7 and in line with that of other organic compounds. This opens a question as to the part played by combined oxygen in explosives. From the relation, $H=53n$, the quantity of air required for the complete combustion of any hydrocarbon of unknown composition, such as

million galls. The tendency has also been in the direction of the production of pure compounds, probably 80% of the present production being worked up into pure benzene and toluene. The future field for benzol products includes industrial blasting explosives, paints, varnishes, grease and fat extraction, solvents for rubber, cleaning processes, manufacture of artificial leather and insulating material, gas enrichment, and motor spirit. The use of benzol for gas enrichment is dying out, but the field for benzol as a motor spirit is very extensive. The present output of benzol in the United States only represents 25 galls. per car per annum, whilst if all the coke were made in by-product ovens recovering benzol, this figure would reach 55 galls. The majority of benzol recovery plants in the United States are of the Koppers type, the wash oil used being a petroleum product, "straw oil," of which at least 90% distils between 250° and 350° C. A good absorbing oil should have a specific gravity of less than 0.88 at 15° C. and be readily fluid at 4° C. In practice the amount of benzol absorbed by the oil should be kept between 2 and 3%. Heavy tar oils, as used in Europe, may find increasing application in the United States. These should contain less than 7% naphthalene, and 90% should distil between 200° and 300° C. Cost of manufacture should not include items involved in the manufacture of gas, but only the extraction of the benzol, and subsequent purification, the total figure for these being between 3 and 4 cents (1½—2d.) per gallon. The author anticipates under normal conditions a substantial profit in the production and sale of 90% purified benzol at prices competing with those of gasoline. From figures given by Shaeffer (this J., 1916, 1209) the author estimates a reduction in heating value of the gas corresponding to 8% of the normal value of the benzol recovered, based on gasoline prices, or about 3.83 cents (1-9d.) per ton of coal. —J. E. C.

Mineral oil exports from the United States. Oil, Paint, and Drug Reps., Feb. 5, 1917.

Exports of mineral oils from the United States during 1916 showed a gain of about 275,000,000 gallons over the exports of 1915, the figures being as follows:

	1915.	1916.		
	Gallons.	Dollars.	Gallons.	Dollars.
Crude oil	154,704,318	4,175,011	168,358,167	6,832,001
Illuminating	835,219,438	43,787,216	852,765,091	55,861,298
Lubricating and paraffins	247,660,120	32,001,289	258,993,634	42,601,575
Naphthalene, gasoline, etc.	273,906,978	33,081,274	349,721,727	67,562,520
Residuum, gas oil, fuel oil, etc.	808,343,638	21,956,813	953,199,204	26,772,057
Total	2,900,766,792	131,001,603	2,581,047,822	199,630,471

a petrol substitute, can be found when the heat of combustion and the vapour density are known; and in the same way the calorific value of any liquid or gaseous fuel can be determined by finding by explosion the volume of air required to burn completely a measured volume of the vapour of known density.—W. E. F. P.

Benzol recovery after the war. F. W. Sperry, jun., Amer. Inst. Chem. Eng., Jan., 1917. Gas J., 1917, 137, 295—296.

The total production of benzol products in the United States in 1915 was over 22 million galls., being more than twice the amount recovered in 1911. Allowing for enlargements and new plants, it is estimated that the amount will rise to 50

Petroleum: Irreversible adsorption of the "carbonaceous substances" of —. M. A. Rakuzin, J. Russ. Phys.-Chem. Soc., 1916, 48, 720—724. (See this J., 1915, 859.)

The adsorption of a 1% solution of petroleum in benzene by animal charcoal and by calcined kaolin has been investigated. The "carbonaceous substances," that is, those which cause polarimetric opacity, are adsorbed less rapidly by kaolin than by animal charcoal, but their adsorption is complete if the carbonisation constant (coefficient of polarimetric opacity) is not less than 18%. The adsorption is irreversible, neither boiling light petroleum nor boiling water extracting anything from the adsorbent after use. Other conclusions drawn from the results obtained

are: (1) The qualitative and quantitative results of adsorption depend on the character and proportion of the adsorbent, but not on the mode of its application. (2) The velocity of adsorption is very high, since with a suitable concentration of the solution, filtration of the latter through a layer of adsorbent 2.5 cm. in thickness is accompanied by adsorption. (3) The adsorbent used as filtering layer for petroleum may be regenerated by ignition. The bearing of these results on the natural filtration-distillation processes of petroleum is discussed.—T. H. P.

Gasoline; Construction and operation of a single tube cracking furnace for making —. C. P. Bowie. U.S. Bureau of Mines, Tech. Paper 161, 1916. 16 pages.

IN operating the Rittman vapour-phase cracking process (this J., 1916, 1003), with furnaces containing several tubes, *e.g.*, ten, an even temperature is difficult to maintain and the single tube furnace is now preferred. The tube is of steel and lap welded, 13—13½ feet long over all, 13—14 inches outside diameter, and with walls about 1 inch thick. It is connected to a tar pot from which carbon and tar can be easily removed when necessary. In the inside of the tube, at the top, is a cast steel basket which serves as a bearing for the stirring rod (which occupies the centre of the tube and prevents its choking by deposited carbon) and as a receptacle for steel balls or other pieces of metal over which the oil passes before entering the tube. Vaporisation is, however, more suitably effected by means of a spray nozzle. The stirring rod is made from 3-inch extra strong pipe, to which are fastened four vertical rows of chains 3 inches apart. The rod enters a stuffing-box and gland which are placed in the tar pot. On the lower part of the stirring rod is a cast-iron paddle, to prevent carbon from accumulating on the stuffing-box and choking the neck of the tar pot. Before entering the tube the oil is strained and heated to about 100° C. From the preheater the oil passes through another strainer, a meter, and a needle valve for regulating flow, into the cracking tube. By means of a pressure reducing valve condensation of the cracked products takes place at practically atmospheric pressure in the ordinary box type of condenser. The cost of the plant, exclusive of a building or other protective covering, and condenser box, is about \$3000. After the best working conditions have been determined, temperature and pressure control should be based on the specific gravity of the crude oil produced. After removal of gasoline from the cracked oil by distillation, the residuum may again be cracked but should not be mixed with the original oil, as "once cracked oil" may require somewhat different temperatures and pressures for re-cracking, and may yield a distillate of a different specific gravity from that of the cracked oil originally obtained. The paper is illustrated by 10 plates.—F. C.

Ichthyol oils; Chemical constituents of sulphur-containing, bituminous tar oils. —. H. Scheibler. Ber., 1916, 49, 2595—2600.

SULPHUR plays an essential part in the formation of asphaltic oils from petroleum, and some light is thrown on the method of their formation by the production of asphaltic substances when a solution of sulphur in petroleum is subjected to distillation. The sulphur-containing non-volatile product appears to contain thiophene derivatives, and its formation involves both polymerisation and dehydrogenation, which is accompanied by liberation of hydrogen sulphide. The presence of this gas is a well-known feature of many asphalt-producing districts.—G. F. M.

PATENTS.

Washing or sorting coal and other minerals; Apparatus for —. P. Habets, Montegnée, and A. France, Liège, Belgium. Eng. Pat. 100,967, June 30, 1914. Under Int. Conv., July 26, 1913. (Appl. No. 10,417 of 1916.) (See also Eng. Pats. 22,655 of 1912, 17,011 of 1913, and 15,689 of 1914; this J., 1913, 471; 1916, 957.)

IN apparatus for washing coal and other minerals, in which the material is passed along a trough having transverse slots in the bottom, longitudinal slots are also provided, the bars separating the slots being of a form adapted to tilt flat pieces of mineral to facilitate separation.—J. E. C.

Briquetting porous materials, as small coke, peat, sawdust, &c. R. Behr, Kolberg. Ger. Pat. 295,491, Aug. 20, 1915.

THE binder, such as pitch, resin, starch, tale, gums, animal or vegetable albumin, casein, glue, &c., is used in the form of vapour, dust, or atomised liquid, which is blown into an exhausted chamber containing the fuel to be briquetted. Under these conditions, very little binder is needed. Moist fuels are dried automatically on the introduction of the binder.—A. B. S.

Coke ovens or the like; Regenerators for —. A. Roberts, Chicago, U.S.A. Eng. Pat. 103,321, Jan. 18, 1916. (Appl. No. 816 of 1916.)

IN connection with coke ovens or the like a pair of regenerators is located away from the oven heating walls, spent gases passing through one regenerator and air through the other. On reversing by means of valves, dampers, or the like, air is conducted through the first regenerator in a direction at right angles to that of the gases previously passing through, spent gases being conducted into the second regenerator also in a changed direction. The heated air passes through a recuperator between adjacent heating walls of the oven prior to reaching the burners.—J. E. C.

Retort-setting for gas and coke manufacture. H. Koppers, Essen. Ger. Pat. 295,321, June 7, 1914.

THE retorts are arranged in groups of four, one above another, with heating flues between them and regenerators below, so as to secure a uniform heating of their contents, to enable any groups to be set in and out of action without difficulty, and to recover as much as possible of the heat produced by the gas used in heating the retorts. The arrangement of the retorts is more compact than usual and there is no limit to the number in a bench.—A. B. S.

Gas retorts; Charging mechanism for —. Riter-Conley Manufacturing Co., H. A. Carpenter, and A. W. Warner, Leedsdale, Pa., U.S.A. Eng. Pat. 103,494, Jan. 19, 1916. (Appl. No. 856 of 1916.) Addition to Eng. Pat. 17,855, Aug. 1, 1912.

Treating materials; Process of —. [Production of water-gas.] J. W. Hornsey, Summit, N.J., Assignor to General Reduction Gas and By-Products Co. U.S. Pat. 1,211,161, Jan. 30, 1917. Date of appl. July 15, 1910. Renewed June 24, 1916.

SEE Eng. Pat. 19,101 of 1912; this J., 1913, 1000.

Petroleum; Process of treating crude —. C. B. Forward, Urbana, Ohio, U.S.A. Eng. Pat. 103,572, Apr. 7, 1916. (Appl. No. 5126 of 1916.)

SEE U.S. Pat. 1,189,083 of 1916; this J., 1916, 883.

Process for improving the fertilising value of the ammoniacal liquor produced in the manufacture of gas or coke. Ger. Pat. 292,145. See XVI.

Preparation of fertiliser from lignite ash. Ger. Pat. 294,858. See XVI.

IIb.—DESTRUCTIVE DISTILLATION; HEATING; LIGHTING.

Heat of combustion of wood charcoal. Nikitin. See IIa.

PATENTS.

Separation of volatile products from solid carbonaceous material. W. W. White, London. Eng. Pat. 14,800, Oct. 19, 1915.

SOLID carbonaceous material is carried by a conveyor through a heated chamber the temperature of which increases progressively from the inlet to the outlet, the vapours being conducted from various portions of this retort into a substantially parallel condensing tube. The vapours in the condensing tube flow in the opposite direction to the solid material, so that vapours given off at higher temperatures are condensed by contact with successively cooler vapours.—J. E. C.

Charcoal kilns. W. J. Mellersh-Jackson, London. From G. H. Dale, Cape of Good Hope. Eng. Pat. 103,321, Jan. 19, 1916. (Appl. No. 875 of 1916.)

The kiln consists of detachable sections capable of being readily assembled to form a structure of circular or polygonal cross-section. The sections are secured to each other by stops and latches so as to form inner and outer walls kept apart by distance pieces. The space between these walls is filled with sand or similar material. A double-walled roof constructed of radial sections also filled with sand and supporting a feed drum with movable cap, is provided.—J. E. C.

Flotation process of concentrating ores. U.S. Pat. 1,124,130. See X.

III.—TAR AND TAR PRODUCTS.

Benzene; Action of ammonia and calcium on —. A. V. Dumanski and A. V. Zvereva. J. Russ. Phys.-Chem. Soc., 1916, 48, 994–996.

WHEN dry ammonia is passed through benzene containing shavings of calcium, the following reactions take place: $\text{Ca} + 4\text{NH}_3 \rightarrow \text{Ca}(\text{NH}_2)_2 + 2\text{H}_2$; $\text{Ca} + 2\text{NH}_3 \rightarrow \text{Ca}(\text{NH})_2 + \text{H}_2$; and $\text{C}_6\text{H}_6 + \text{H}_2 \rightarrow \text{C}_6\text{H}_8$. —T. H. P.

Benzophenone; Basic derivatives of —. Tertiary aminobenzyl alcohols and their derivatives. V. J. von Braum. Ber., 1916, 49, 2605–2608.

BASIC diphenylmethane derivatives containing methyl- or dimethyl-amino groups in the ortho position to the methylene group cannot be oxidised directly to the benzophenone derivative with chloranil, but the oxidation is effected by chromic acid if the $-\text{N}(\text{CH}_3)_2$ groups are first converted into $-\text{N}(\text{CN})\text{CH}_3$ groups. The cyanogen group may then be removed by saponification with formation of a monomethylamino group, and from the latter on methylation the dimethylamino group is regenerated.—G. F. M.

Dihydroindole bases; Substituted —. Fission of the reduced indole and quinoline rings by reduction. III. J. von Braum, K. Heider, and L. Neumann. Ber., 1916, 49, 2613–2624.

THE dihydroindole ring is reduced in three different directions when the indole base in the form of the quaternary methyl chloride compound is treated with sodium amalgam, viz., with the formation of an N-methyldihydroindole, an o-alkyldimethylaniline, and a 3-phenylalkyldimethylamine. The relative proportions of these products vary greatly according to the substituents present in the pyrrole ring. Thus whilst dihydroindole itself gave 75% of tertiary cyclic base, 8% of aromatic base, and 17% of aliphatic base, α-methyldihydroindole gave 40%, 40%, and 20% respectively, and β-methyldihydroindole (dihydroskatole) gave but traces of the aniline base, and as much as 21% of 3-phenylpropyldimethylamine. Substitution in both α and β positions gave results intermediate between the above extremes.—G. F. M.

Benzol recovery after the war. Sperr. See IIa.

PATENTS.

o-Chlorotoluene; Process of preparing —. Badische Anilin u. Soda Fabr. Ger. Pat. 291,638, July 5, 1914.

TOLUENE-p-SULPHONIC acid, or its chloride or amide, is dissolved in sulphuric acid, the solution treated with chlorine, and the sulpho group removed from the resulting o-chlorotoluenesulphonic acid, e.g., by heating it in a current of steam. —C. A. M.

Arylamides of 2-hydroxynaphthalene-3-carboxylic acid; Process of preparing —. Farb. vorm. Meister, Lucius, u. Brünning. Ger. Pat. 294,799, Apr. 30, 1914.

A MIXTURE of 2-hydroxynaphthalene-3-carboxylic acid with a large excess of an aromatic amine is treated with phosphorus chloride, whereby the hydroxynaphthoic acid chloride first formed, reacts with the amine to form the arylamide. The yield is approximately quantitative.—C. A. M.

2,3-Hydroxynaphthoic acid and its derivatives; Process of preparing —. Farb. vorm. Meister, Lucius, u. Brünning. Ger. Pat. 295,183, Oct. 23, 1913.

AN acyl-2,3-hydroxynaphthoic acid is heated until an intermediate product of the nature of an anhydride is formed, and this is treated with ammonia or with bases capable of yielding acyl-derivatives.—C. A. M.

Tar; Continuous distillation of —. J. Artmann, Essen, Germany. U.S. Pat. 1,214,259, Jan. 30, 1917. Date of appl., Oct. 14, 1909.

SEE Fr. Pat. 407,906 of 1909; this J., 1910, 552.

IV.—COLOURING MATTERS AND DYES.

Hydroxyquercetin; Synthesis of —. M. Nierenstein. Chem. Soc. Trans., 1917, 111, 4–10.

THE synthesis of hydroxyquercetin from 1,2,3,5-tetrahydroxybenzene was undertaken to establish the correctness of the formula of this substance, which had previously (Ber., 1911, 44, 3187) been obtained from quercetin by oxidation and subsequent reduction. Tetrahydroxybenzene was con-

verted into 2,3,4,6-tetrahydroxyacetophenone by the action of acetic acid and zinc chloride; this on methylation under suitable conditions gave a trimethyl ether, m.pt. 125°—126° C., which condensed with veratraldehyde to give 2-hydroxy-3,4,6-trimethoxyphenyl-3,4-dimethoxystyryl ketone, m.pt. 143° C. The latter in presence of hydrochloric acid was converted, with ring formation, into 5,7,8,3',4'-pentamethoxyflavanone, which through its 3-isonitroso-derivative gave the corresponding flavonol, m.pt. 147°—149° C. The demethylation of this compound gave a substance identical with the hydroxyquercetin previously obtained.—G. F. M.

PATENTS.

Triarylmethane dyestuffs fast to light: Manufacture of—. Farbw. vorm. Meister, Lucius, und Brünig. Ger. Pat. 295,495, Mar. 5, 1915. Addition to Ger. Pat. 290,065 (this J., 1916, 531).

IN addition to the diarylindyl dyestuffs which contain a halogen atom in the *para* position to the methane carbon atom as claimed in the original patent, similarly constituted bodies having an amino, sulphonic, or oxy group, either in the form of an ether or ester, in the place of the halogen, may be treated with aromatic amines.—J. F. B.

Copper-containing pigments. Ger. Pat. 295,794. See XIII.

V.—FIBRES; TEXTILES; CELLULOSE; PAPER.

Vegetable fibres: Purification of—. G. L. Stadnikov. J. Russ. Phys.-Chem. Soc., 1916, 48, 301—302.

THE purification of vegetable fibres (cotton, flax) to be used in the study of adsorption in general and that of colouring matters in particular, may be effected as follows. The fibre is boiled with water, which is changed each day after boiling for eight hours, this procedure being followed until 250 c.c. of the filtered water after use leaves no residue on evaporation. The extracted fibre is left for three days covered with alcohol, which is then replaced by a fresh quantity. After another period of three days, the fibre is removed from the alcohol and washed with ether, alcohol, and water successively. The complete displacement of the alcohol by water is effected only very slowly at the ordinary temperature, since even after eight months a fresh quantity of water was found to contain alcohol after being in contact with the fibre for a few days. The process takes place far more rapidly when the fibre is boiled with successive quantities of water.—T. H. P.

Paper-yarn textiles, and dyeing and impregnating them. A. Kertesz. Ver. deut. Textilveredlungsbund., Düsseldorf, Dec. 9, 1916. Chem.-Zeit., 1917, 41, 43—44.

THE manufacture of paper-yarn textiles in Germany has been stimulated in an extraordinary degree by the war. The industry may be considered under two branches: the manufacture of substitutes for jute sacking and the manufacture of textiles for ordinary use. Very great progress has been made in a technical sense in the manufacture of jute substitutes; the satisfaction of the requirements as regards high tensile strength presented considerable difficulty, on account of the shortness of the paper fibre, but improved results have been attained by certain after-treat-

ments, notably by suitable impregnation. This branch of the trade is essentially a war industry, the material being employed mainly for sand bags, and the question of its continuation after the war remains more or less open. Nevertheless, it is hoped that the substitution of the entirely home-manufactured product for the imported material may be permanently established after the war, more especially since it is shown that the price of jute increased 120% during the twenty years from 1893 to 1913. Other materials have advanced in much lower ratio, e.g., cotton 47%, wool 43%, raw silk 2%, flax 30%. The quantity of raw jute imported into Germany in 1913 was 162,063 tons, and even as compared with 1910, the price showed an advance of 76%. The manufacture of the finer grades of paper textiles for general purposes shows even better prospects for the future; the technical progress made during the period of the war is most striking when products of the present day are compared with those of three years ago. Yarns of different character are required for this branch of the trade; the cotton manufacturer requires yarns and fabrics of greater softness. It has been found that a textile finished by calendering from a weakly alkaline soda or soap bath becomes much softer and more pliable. It is expected that public taste will be trained by the present scarcity of the standard textile fibres to take these new materials into favour for decorative printed goods and wearing apparel and that the demand will go on increasing after the war. As regards the impregnation of paper yarns to increase their strength and resistance to moisture, it has been found that the treatment with aluminium soaps as practised with cotton goods does not give such satisfactory results in this case. The best treatment is by impregnation in two baths: (1) passage through a glue, tannin, and silicate bath at 50° C. without drying, and (2) passage through a cold basic aluminium formate bath of 6° B. (sp. gr. 1.01), and drying. The first bath is made by steeping 80 grms. of glue in cold water for several hours and then melting. In a separate vessel 1.5 grms. of tannin is dissolved in hot water and 1.5 grms. of water-glass of 36° B. (sp. gr. 1.31) is added. The glue solution, heated to 50° C., is then treated with the tannin-silicate solution, while stirring, and the whole made up to 1 litre. The impregnated yarn shows an increase of over 10% in dry tensile strength and about 30% in wet strength. The dyeing of paper yarns and fabrics is done exactly on the same principles as that of cotton. Substantive, sulphur, and vat dyestuffs are employed, but greater care is required in turning and handling the goods. Dyeing machines are preferable to hand dipping on this account, and for the same reason the baths must not be too strongly alkaline and the temperature must be kept below the boiling point, preferably at 50° to 60° C.—J. F. B.

Economic sources of polish and wool fat in S. Australia. Winterbottom. See VII.

PATENTS.

Yarn: Conditioning or moistening of—, and apparatus therefor. The Fine Cotton Spinners' and Doublers' Assoc., Ltd., H. Brooks, Manchester, and A. Stafford, Bolton. Eng. Pat. 103,923, Feb. 23, 1916. (Appl. No. 2683 of 1916.)

IN the process of singeing, doubling, and winding or spinning yarn, the latter, as it leaves the bowls of the singeing machine, is humidified by passing in front of a nozzle through which a blast of air and spray of water is caused to issue and impinge upon the yarn. A wind shield or receiver is placed so as to stop the blast or spray, collect the surplus water, and convey it to a tank.—J. F. B.

Cotton yarns and fabrics: Manufacture or treatment of — [to produce woolly effects]. Tootal Broadhurst Lee Co., Ltd., and H. Lester, Manchester. Eng. Pat. 103,057, May 4, 1916. (Appl. No. 6373 of 1916.)

TEXTILES having the appearance and "feel" of wool are produced from yarns spun from mixtures of dyed and undyed cotton or of different shades or colours of dyed or undyed cotton, the yarns or the fabrics made from them being subsequently shrunk by treatment with caustic soda or sulphuric acid.—J. F. B.

Celluloid: Process of treating —. E. Josephson, Assignor to Pantasote Leather Co., Passaic, N.J. U.S. Pat. 1,211,588, Jan. 9, 1917. Date of appl., Feb. 2, 1914. Renewed Aug. 19, 1916.

FINELY powdered celluloid is treated with water and the camphor is distilled off with steam.—J. F. B.

Cellulose: Manufacture of —. C. N. Waite (C. B. Magonn, administratrix) and J. E. Hedin, Wilmington, Del., Assignors to W. H. Sharp, Philadelphia, Pa. U.S. Pat. 1,212,158, Jan. 9, 1917. Date of appl., Oct. 1, 1915.

A RAW material containing cellulose is digested with caustic soda which has been treated with a small quantity of sulphur so that the amount of sodium sulphide present is less than 0.5%. This small quantity of sulphide is sufficient to neutralise the effect of the free oxygen present and thus prevent the formation of oxycellulose, but is insufficient to exert an appreciable digesting action.—J. F. B.

Pulp or paper stock: Method and apparatus for indicating and regulating the consistency of —. E. J. Trimbley, Glens Falls, N.Y., U.S.A. Eng. Pat. 17,811, Dec. 20, 1915.

THE apparatus comprises a constant-level chamber having a discharge orifice maintained under a constant head of pulp, and a variable-level chamber arranged to receive the pulp discharged from the constant-level chamber and provided with an outlet pipe of suitable size and shape to cause a frictional resistance in the flow of pulp, thus maintaining a head of pulp varying with its consistency and frictional resistance. The variable-level chamber may be supported by an arm and counter-weights so that variations in the level are indicated on a scale. The variations in the level are caused to operate a rod controlling a supply of diluting water through a ratchet wheel operated by a double reciprocating pawl, with means for throwing the pawl into and out of engagement, the movement of the ratchet wheel in one or the other direction causing an increase or decrease in the supply of diluting water as required.—J. F. B.

Paper stock: Apparatus for the treatment [steeping] of —. W. G. Fiske, Purfleet, Essex, Eng. Pat. 103,376, Mar. 2, 1916. (Appl. No. 3160 of 1916.)

MATERIAL, such as wood pulp, waste paper, or the like, is fed continuously along with liquid into one end of a revolving drum, the internal periphery of which is divided up by a helical partition into an open channel winding from one end of the drum to the other, so that the material with the liquid travels with a rolling motion through all the convolutions, being discharged at the further end in a thoroughly steeped and partially disintegrated condition, without the use of positive mechanical tearing devices. At inter-

vals in the channel are placed variously shaped obstructions, such as gates, serrated plates, strainer bars, etc., which impede the passage of the more resistant portions of material and cause them to remain for a longer period under treatment. The material caught on these obstructions is carried round to the top of the drum and then drops off, and the edge or lip is so constructed that the humps fall into the preceding and not into the succeeding convolutions of the channel.

Preparation of a gutta-percha substitute from paper impregnated with waterproof substances. Ger. Pat. 295,121. See XIV.

VI.—BLEACHING; DYEING; PRINTING; FINISHING.

Cotton yarns: Action of two different processes of bleaching on American —. F. P. Jecusco. J. Soc. Dyers and Col., 1917, 33, 34—38.

FOR the control of the cotton yarn bleaching process, three skeins of yarn are taken from the batch and tested in the grey state for tensile strength, elasticity, and weight; they are marked, returned to the batch, and one skein is withdrawn after the boiling, one after the "chemic" and sour, and one after finishing. The results are recorded and any departure from normal conditions can be located and investigated. The standard process through which the yarn is passed consists of the following operations:—Boiling under a pressure of 15 lb. in an injector kier with 2% of "sulphated oil" and 3% of caustic soda for 8 hours; washing in kier, upwards for 1 hour and downwards for 1 hour; chemicking with calcium hypochlorite of 1°—2° Tw. (sp. gr. 1.005—1.010) for $\frac{1}{2}$ —2 hours according to the count of yarn; washing for half an hour; souring with sulphuric acid of 1—2 Tw. (sp. gr. 1.005—1.010) for half an hour; washing for half an hour; soaping and neutralising (soap 1—2%, borax 0.25%) for half an hour; blueing and softening. In order to test the quality of the bleach, two skeins are taken after the neutralising, one of them is steamed in a small laboratory kier for one hour and compared as to colour with the other one; if there is any yellowing the bleaching should be repeated. The softening agent is an ammoniacal emulsion of stearic acid and coconut oil. In a normal bleach, the effect on the mechanical properties of the yarn is represented by the following figures which are the average of twelve different records:—Boiling out, gain in strength 22.8 and in elasticity 6.95, loss in weight 6.15%; bleaching, gain in strength 25.9 and in elasticity 0.79, loss in weight 7.3%; finishing, gain in strength 19.2 and in elasticity 0.61, loss in weight 6.2%, all calculated on the grey. These numbers are liable to variations according to the relative work performed by the boil-out and by chemicking respectively; if the boil-out be thorough, the chemicking would reduce the strength of the yarn slightly as compared with the boiled yarn, but in all cases the sum total of the bleaching operations is a substantial gain in strength and elasticity over the grey, owing to the more intimate contact of the fibres produced by the removal of the impurities. On the other hand, when the boiling process is so restricted as to necessitate a very much more severe hypochlorite treatment, the total effect of the bleach may result in a loss of strength. For instance, a batch of yarn boiled for 8 hours with 1% of soap and 5% of soda ash, required 2 hours in hypochlorite of 2° Tw. (sp. gr. 1.01), and showed a total loss in weight of 7.1% and loss in strength of 4.7%.

Paper-yarn textiles, and dyeing and impregnating them. Kertesz. See V.

PATENTS.

Cotton fabrics; Manufacture of—. [*Production of transparent and wool-like effects.*] Akt.-Ges. Cilander, Herisau, Switzerland. Eng. Pat. 103,432, July 6, 1916. Under Int. Conv., Feb. 9, 1916. (Appl. No. 9516 of 1916.)

Transparent effects on cotton fabrics, whether mercerised or not, are produced by treatment with sulphuric acid of less than 50% B. (sp. gr. 1.497), cooled to at least -4° C., and subsequently mercerising with caustic soda. Wool-like effects are produced on non-mercerised cotton fabrics by immersing for 5–10 mins. in sulphuric acid of similar concentration and temperature. Patterns may be produced by local action.

—J. F. B.

Size [for yarns]; Heating of—. J. Brandwood, Bury. Eng. Pat. 103,431, July 6, 1916. (Appl. No. 9514 of 1916.)

SIZE in the size-beck or size-box is heated, and its temperature maintained by blowing a current of hot compressed air directly through the size, thus avoiding the dilution arising from the use of live steam and evaporating off any moisture introduced by the passage of damp yarns.—J. F. B.

Dyeing; Impts. in—. Surpass Chemical Co., Assignees of H. B. and I. J. Smith, Albany, N.Y., U.S.A. Eng. Pat. 103,445, July 31, 1916. Under Int. Conv., Mar. 21, 1916. (Appl. No. 10,788 of 1916.)

VII.—ACIDS; ALKALIS; SALTS; NON-METALLIC ELEMENTS.

Potash and wool fat in South Australia; An investigation into the economic sources of—. D. C. Winterbottom. S. A. Dept. Chem., Bull. No 2, 1916. 1–34.

The imports of potash salts into Australia for the year 1913 are returned as follows: Potash alum, alum, and aluminium sulphate, 3285 cwt.; potash and pearlash, caustic potash, 2499 cwt.; potassium chloride and sulphate, 88,113 cwt.; potassium and sodium cyanides and bromides, 40,400 cwt. Of these, very small amounts were imported direct to South Australia. The possible sources of potash salts in the State are discussed under eight heads. The production of potash from the ashes of land plants does not appear to offer any considerable prospect for industrial enterprise. An investigation of four species of local seaweeds indicated that the kelps from these varieties were too poor in potassium and too rich in sodium to have any commercial value; two of them, however, contained appreciable quantities of iodine. As regards the wool-scouring industry, about 3500 tons of wool is scoured annually in S. Australia, equivalent to about 157.5 tons of potassium carbonate and 700 tons of wool fat. It would

not be possible to recover the whole of these by-products, but a simple method for collecting some of the potash is suggested which would be commercially advantageous. The wool should receive a preliminary steep or wash in water before the application of chemicals, for which purpose an ordinary wash-bowl or Malard steeping machine would be suitable. The steep-water should be allowed to attain a conveniently high concentration, then evaporated in open vats, and the residue incinerated in pans. It is estimated that a plant for treating 3000 tons of wool, including 3 steeping bowls and a small Porion evaporator, would cost £1700 and would yield £863 profit on a working expenditure of £1501, at normal prices. The recovery of potassium salts from sea water has not been closely investigated under Australian conditions. Another possible commercial source of potash is from the mineral alunite, two distinct deposits of which occur in S. Australia, with potash contents of 10.5 and 9.0% (as K₂O) respectively. By various known methods of treatment it would be possible to carry out the manufacture either of potash alum or potassium sulphate for the Australian market, but for export it would be more profitable to ship the crude alunite. The fume condensed from cement kilns is capable of yielding commercial quantities of potassium salts. The recovery of potash from beet sugar manufacture is of no interest in the present discussion. Felspar rocks may serve as a source of potash when they contain not less than 12% K₂O. A very rich variety containing 14.04% is found at the yelta mine but not in commercial quantities; a large deposit of felspar occurs at Kangaroo Island but it contains only 7% K₂O. The recovery of the unsaponifiable portions of wool fat from the wool-scouring industry is capable of profitable development, especially when combined with the recovery of potash. In Australian wool washing, no soap is employed, only sodium carbonate, and the unsaponified grease may be skimmed off the surface of the liquor in the wash-bowls and submitted to some simple refining treatment. It is melted, strained, and kept melted for half an hour in presence of wood-charcoal as a deodoriser. The melted fat is washed by boiling with water for about one hour four times in succession, then cooled and kneaded with cold water until no further colouring matter is removed. The hydrated fat is then melted and separated from the enclosed water, at the same time it is treated again with wood charcoal and a little bone charcoal, and subsequently filtered. The yield can only be roughly estimated, but the 3500 tons of wool scoured in S. Australia might be expected to yield 50 tons of lanolin at a cost for treatment of not more than £15 per ton. The treatment of the scour-liquors by the acid process would hardly be profitable unless chamber-acid could be obtained at not more than £2 per ton.—J. F. B.

Metabisulphites of potassium and of sodium. P. Carles. Rep. Pharm., 1917, 28, 33. Pharm. J., 1917, 98, 161.

SINCE the war, and the consequent scarcity of potassium metabisulphite, considerable attention has been directed to the corresponding sodium salt. This is richer in sulphurous anhydride, containing, when pure, 67.2%, and it should, for many reasons, be preferable to the potassium salt. Sodium metabisulphite does not readily crystallise, and it is placed on the market in powder, or in compressed tablets. Hence it does not keep so well as the crystals of potassium metabisulphite. A more serious defect is the frequent presence of notable quantities of iron as an impurity. Frequently samples are met with containing sufficient

iron to impart a distinct yellow colour to the powder. This defect is specially harmful when the product is used as a preservative for wines and dietetic preparations. When these contain tannin, they ultimately develop a dark or even black shade when treated with the iron-contaminated preservative. This undesirable result is not at once evident, since the sulphurous acid at first present keeps the iron in the ferrous condition. As, however, the reducing acid is volatilised or oxidised, so the dark tint develops. It is, therefore, necessary that all sodium metabisulphite used as a preservative should be reasonably free from iron.

Magnesium [in limestone]; Rapid method for the determination of —. N. Busvold. *Chem.-Zeit.*, 1917, 41, 42.

As a rapid method for the determination of magnesium, suitable for industrial laboratories, the following procedure is recommended:—5–10 grms. of the limestone containing magnesium is calcined in an electric crucible furnace and dissolved in the smallest possible quantity of dilute hydrochloric acid (1:1). The solution is boiled for a few minutes with an excess of pure calcium carbonate, which precipitates the metals of the third group, then poured on a folded filter, and the residue washed. The filtrate is treated with 20 c.c. of a 6% suspension of pure lime, boiled for just sufficient time to produce a granular precipitate, easy to filter, cooled, filtered, and the precipitate washed with water containing a little milk of lime. The precipitate with the filter is placed in an Erlenmeyer flask of 1 litre capacity and treated with about 300 c.c. of water and 40 c.c. of *N/1* oxalic acid solution. The liquid is boiled for 5 mins. or sufficiently long to convert all the calcium into oxalate, filtered hot, and the precipitate washed with boiling water. The filtrate contains the excess of free oxalic acid and the magnesium oxalate in solution. It is cooled and titrated with *N/5* sodium hydroxide in presence of methyl red as indicator; 25 c.c. of sulphuric acid (1:5) is added, the solution heated to 70° C. and the total oxalic acid titrated with *N/5* permanganate. The difference between the total and the free oxalic acid is calculated as magnesium oxalate; 1 c.c. of *N/5* oxalic acid = 0.001306 gm. MgO. The whole operation takes about two hours.—J. F. B.

Dialysis of the chlorides of ferric iron, chromium, and aluminium; Hot — and rapid preparation of their colloidal hydrous oxides. M. Neidle and J. Barab. *J. Amer. Chem. Soc.*, 1917, 39, 71–81.

THE membranes used were of parchment paper and were prepared by moistening discs of 38 cm. diam., folding into a bag, and tying to the flanged end of a glass tube, 15 cm. long and 2 cm. in diameter. Commercial C.P. chlorides were employed in all except a few experiments, in which specially prepared green chromic chloride was used. It was found that the yield of colloidal hydrous oxide obtained by dialysis of solutions of aluminium and ferric chlorides is far greater in hot solutions than in cold ones, and that for a given volume of chloride solution, the percentage yield of colloid decreases with increasing concentration. Colloidal aluminium and chromium hydrous oxides can be prepared by dissolving the freshly precipitated hydrous oxide in the chloride and dialysing at 70° to 80° C. To prepare the clear brownish-red colloidal hydrous ferric oxide, it is necessary to dialyse first in the cold, until no more iron passes through the membrane. For example, 25 grms. of ferric chloride was dissolved in 250 c.c. of water, and 127 c.c. of 1.365 *N* ammonia solution, sufficient to react with 92.5% of the ferric chloride, was added. After shaking vigorously, the mixture was

allowed to stand several hours or over night. The perfectly clear brownish-red solution obtained, was diluted to 400 c.c. and dialysed in the cold for 23½ hours, and then for 23½ hours at 75°–80°. The yield of colloid was 89.9%. To prepare the purest hydrosol in the shortest time, the lightest (30 lb.) paper must be employed, and the dialysis should be carried out at the boiling temperature. Operating in this manner, colloidal sols can be obtained in 10 hours of a purity equal to that obtainable only after dialysis for several months by the older methods.—J. B. C. K.

Platinum sulphide; New method of precipitating — and analysis of platinised asbestos. V. N. Ivanov. *J. Russ. Phys.-Chem. Soc.*, 1916, 48, 527–529.

THE addition of mercuric chloride to a platinum solution prior to precipitation of the metal as sulphide facilitates the estimation of platinum and allows of accurate results being obtained (see Gaze, this J., 1913, 48), but the bulk of the precipitate is greatly increased and injurious mercury vapour is liberated when the precipitate is ignited. The incomplete precipitation of platinum sulphide under ordinary conditions depends on the formation of a stable colloidal solution of the sulphide, and the author finds that the hydrosol is converted into the insoluble hydrogel if magnesium chloride is present in the solution. The method employed is as follows: A weighed quantity of about 5 grms. of platinum chloride is dissolved in water in a 250 c.c. flask, the solution being made up to volume and mixed. Twenty-five c.c. of this liquid is diluted to about 200 c.c. in a 250–300 c.c. beaker and then treated with a few drops of hydrochloric acid and about 5 grms. of magnesium chloride, either in solution or as crystals, per 100 c.c. of liquid. A rapid current of hydrogen sulphide is then passed through the solution until the latter is saturated, the precipitate adhering to the gas-delivery tube being removed by a piece of filter paper and the latter dropped into the liquid, which is then boiled until all odour of hydrogen sulphide has disappeared. The platinum sulphide is washed twice by decantation and several times on the filter with water acidified with one or two drops of hydrochloric acid, the wet filter being then charred in a covered platinum crucible and finally ignited in a blowpipe flame. This method gives results in very close agreement with those obtained electrolytically.

In the case of platinised asbestos, this is treated with *aqua regia*, which dissolves the platinum and also sufficient magnesium salts from the asbestos to render subsequent addition of magnesium chloride superfluous. Ten grms. of the asbestos is heated in a large beaker with excess of *aqua regia* (2 parts of hydrochloric and 1 part of nitric acid) on a water-bath until all the black particles disappear from the asbestos and the liquid assumes an orange-yellow colour. The contents of the beaker are carefully poured into a porcelain funnel, the asbestos, which serves as a filtering medium, being washed free from platinum. The filtrate is made up to a litre in a measuring flask and 100 c.c. of the solution evaporated three times to dryness with hydrochloric acid on a water-bath. The residue is dissolved in 50 c.c. of hot water containing 5 c.c. of hydrochloric acid, and the silica and any fibres of asbestos filtered off. The filtrate is diluted with water to about 250 c.c., and the platinum precipitated as sulphide, the subsequent procedure being as described above. With a particular sample of platinised asbestos, five estimations of the percentage of platinum present gave results varying from 7.72 to 7.75 by the electrolytic method and from 7.75 to 7.77 by the above hydrogen sulphide method.

—T. H. P.

Carbonyl chloride; Preparation of—V. A. Plotnikov, J. Russ. Phys.-Chem. Soc., 1916, 48, 457—458.

THE catalytic effect of salts is often attributable to the formation of complexes containing the catalyst and the substances reacting under its influence. Such complexes then undergo decomposition, which is induced either by temperature conditions or by the presence of compounds causing a diminution in the stability of the complexes. In this connection, interest attaches to the compounds of aluminium chloride and carbonyl chloride obtained by Baud (Comptes rend., 1905, 140, 1688). Experiments by the author and Salatkó-Petrishitsche show that carbonyl chloride is formed when carbon monoxide and chlorine are passed through a tube containing pieces of aluminium chloride at 36°–35° C., or, still better, if the gaseous mixture is passed through a saturated solution of aluminium chloride in chloroform; subsequent treatment of the chloroform solution with water yields a considerable quantity of carbon dioxide.—T. H. P.

Heterogeneous catalysis. [Decomposition of carbon bisulphide.] Gurvitsch. See XX.

PATENTS.

Tin oxides; Method and means [electric furnace] for producing—C. H. Thompson, Stourbridge, and E. K. Scott, Edgbaston, Eng. Pat. 103,415, May 22, 1916. (Appl. No. 7254 of 1916.)

TIN is admitted to a fuel-heated furnace by means of a hopper. A short channel at the base of the hearth leads to the bath of an adjacent electric furnace and enables the molten tin in this bath to be kept at a constant level. The electric furnace is covered with a domed roof through which three equidistant electrodes are admitted and adjusted to meet in the centre of the furnace. The electrodes, which are of carbon or of iron with an arrangement for water cooling, allow of the formation of an arc above the surface of the molten tin. A short pipe is fitted vertically in the centre of the roof, and a stream of air or oxygen blown through this impinges on the centre of the arc and causes it to strike on the surface of the tin. The volatilised metal is immediately oxidised, and the tin oxide passes into a third chamber which is fitted with baffles and serves to collect the product.—J. N. P.

Apparatus for the electrolytic decomposition of water. U.S. Pat. 1,211,687. See XI.

VIII.—GLASS; CERAMICS.

PATENTS.

Graduations on glass ware; Method of producing burned-in—C. Fiege, Cassel, Ger. Pat. 295,552, May 5, 1916.

THE graduations are marked on the glass by means of a fusible stain which is afterwards burnt in. The surface of the glass is then covered with oil by means of a roller and dusted over with a transparent and readily fusible glass. The articles are heated first to volatilise the oil and then to fuse the vitreous coating. The graduations are thus covered with a vitreous coating which prevents the colour in them from being removed when cleaning them.—A. B. S.

Clays; Reducing the plasticity of—Dr. North, Kommanditges., Hanover, Ger. Pat. 295,719, May 30, 1915.

HIGHLY plastic clays contain notable proportions of fatty substances which can be removed by the

customary methods of fat extraction. On removing these, a dry, friable material is produced which is excellent as a diluent for other clays or a substitute for grog. The fat-free clay resembles Scotch fireclays, and it may be used for the manufacture of articles without the addition of any non-plastic material.—A. B. S.

Enamels; Manufacture of—H. Wade, London, From R. Koepf und Co., Oestrich, Germany. Eng. Pat. 101,221, Aug. 16, 1916. (Appl. No. 11,586 of 1916.)

ENAMELS are clouded or rendered opaque by the addition of zirconium borate supersaturated with zirconia, e.g., by a product of the composition $ZrO_2 \cdot 2B_2O_3 - 1ZrO_2$. Cryolite or other suitable alkali fluoride and an oxidising agent may advantageously be added. For example, 70 parts of raw zirconia, 30 parts of boric acid, 20 parts of cryolite, and 50 parts of sodium nitrate are mixed together, fused, and the product ground to a very fine powder. This material has a much greater covering power than ordinary zirconium borate and does not cause the enamels to become spotty and dull. The nitrate converts the brown zirconia into a bright borate which produces a white clouding.—A. B. S.

Coatings with a metallic appearance and the durability of enamels; Production of—on metallic articles. Gebr. Jacob, Zwickau, Ger. Pat. 295,627, Feb. 13, 1911.

IN order to produce the appearance of brass, copper, tin, and other metals on enamelled ware, the appropriate metallic mixture is painted or sprayed on to the enamelled surface of the article to be decorated, and afterwards fused. For copper and brass effects, the enamel should be grey and for steel it should be blue, so that the colour of the ground coat adds to the intensity of the effect desired, thereby enabling a minimum thickness of metallic mixture to be used. The metallic mixture is made by suspending or dissolving the desired metal, with or without the addition of bismuth and borax as fluxes, soot and kaolin as clouding agents, and suitable oils. By the use of a mixture of metal and bismuth oxide, mercurous or mercuric oxide, patina and other antique metallic effects are produced.—A. B. S.

IX.—BUILDING MATERIALS.

Cement; Behaviour of—in water containing sulphuric acid. H. Nitzsche, Armierter Beton. 1916, 9, 167—172. Z. angew. Chem., 1917, 30, Ref., 16.

SHORT cones were made from two Portland cements, an iron Portland cement, a mixed cement, and five blast-furnace slag cements respectively, both from the neat cements and from mixtures with sand in the proportion of 1:2.5. After 36 days storage under water, in air, and again under water, the test pieces were kept for 14 days in water containing 1% free sulphuric acid, then, for the same time, in a solution of 1.2%, and finally for three months in a 1.5% solution of sulphuric acid. The Portland cement test-pieces blistered, owing to the formation of gypsum; the cement-sand mixtures swelled badly, and some of them were badly cracked. The presence of trass or blast-furnace slag cements only delayed the destructive action of the acid. Test-pieces made with blast-furnace slag cements were more resistant to the acid. After 1 month, the pieces of pure cement were covered with a smooth, white, hard coating of gypsum, which protected the interior, and the cement-sand test-pieces retained

their form and structure fairly well. The iron Portland cements were more strongly attacked than the others. The author admits that the acid solutions used were stronger than those likely to come into contact with concrete under ordinary conditions, but considers that these tests show that blast-furnace slag cements have a greater resistance to acids than Portland and iron Portland cements.—A. B. S.

Rapid method for the determination of magnesium [in limestone]. Busvold. See VII.

PATENTS.

Preservation of wood; Process for waterproofing and —, D. P. Schröder, Hamburg, Ger. Pat. 295,053, June 16, 1911.

Wood is treated with an alkaline extract of lignite, with or without the addition of water-glass, and afterwards with acids or oxidising materials, such as chromic acid or peroxides, and is finally subjected to the action of hot air.—F. C. T.

Dust; Removal of — from the waste gases from cement-kilns. G. Polysius, Dessau, Ger. Pat. 295,490, Jan. 25, 1916.

The gases are washed by passing them through the slurry tanks, wherein they are cleaned much more effectively than in ordinary wet scrubbers. — A. B. S.

Stones; Covering natural and artificial — with a metallic coating. E. Abeles, Vienna, Ger. Pat. 295,607, June 19, 1915.

COPPER or other metal, in powder, is mixed with water-glass or other solution of a silicate and applied to the surface to be coated. After each application, the articles are dried rapidly at 200–300° C. and then immersed in a bath of dilute acid. The process is particularly applicable to the production of roofing tiles of asbestos and cement which have the appearance of being made wholly of metal. The coating is insensitive to changes in temperature, weather-resisting, and more durable than coatings produced by the customary methods of bronzing.—A. B. S.

X.—METALS; METALLURGY, INCLUDING ELECTRO-METALLURGY.

Ironsand; Titanium, phosphorus, and vanadium in Taranaki —, W. Donovan, N. L. Wright, and R. P. Wilson. 49th Annual Report, Dominion Laboratory, New Zealand. 5 pages.

SIX representative samples of Taranaki ironsand were analysed. Samples 1–3 were obtained from the coast at Patea, samples 4–6 from New Plymouth.

Sample.	Fe.	TiO ₂ .	P.	V.
1.....	21.03	3.8	0.16	0.08
2.....	57.12	10.6	0.16	0.16
3.....	35.42	6.0	0.25	0.14
4.....	49.56	9.2	0.28	0.34
5.....	50.92	10.6	0.29	0.26
6.....	36.62	6.2	0.27	0.16

Concentration by means of a horse-shoe magnet showed that vanadium and titanium remained with the iron, the titanium content being slightly

increased relatively in the concentrate; the relative phosphorus content was not decreased appreciably by concentration. The concentrates assayed 50–60% of iron.—W. R. S.

Manganese in high speed steels; Determination of —, C. T. Nesbitt. Chem. News, 1917, 115, 61–62.

ON account of the difficulty in obtaining bromine at the present time, an investigation was made of methods which do not involve the use of this element in estimating manganese in high-speed steels. These steels contain tungsten and chromium, together in some cases with vanadium and molybdenum. The method which was found to be the most advantageous is based on the oxidation of manganese to permanganate by means of sodium bismuthate and titrating with ferrous sulphate. The steel (1.1 grms.) is dissolved in 12 c.c. of hydrochloric acid, 5 c.c. of nitric acid is added so as thoroughly to oxidise the tungsten, and the liquid evaporated to a syrupy consistency. Sulphuric acid (7 c.c.) is then added and the mixture heated to fuming to decompose all chlorides, cooled, treated with dilute nitric acid (30 c.c. of acid of sp.gr. 1.2 and 20 c.c. of water), boiled, and the tungsten oxide filtered off. The filtrate is treated with 15 c.c. of concentrated nitric acid, and a very small quantity of bismuthate, and chromium is then reduced by sulphurous acid (10 c.c.), the excess of which is removed by boiling. More sodium bismuthate (0.2 grm.) is added and the liquid after filtering is titrated with N/10 ferrous sulphate until all the permanganate colour is discharged, and then with N/10 permanganate until a permanent pink tint is obtained; 1 c.c. N/10 ferrous sulphate = 0.1% Mn. — J. N. P.

Gold; New method of precipitating — from cyanide solutions by zinc. H. R. Conklin. Eng. and Min. J., 1917, 103, 195–196.

A REVOLVING cylinder, 10½ in. × 16 ft., inclined at 30°, with an inner cast-zinc lining and a central spiral rib acting on the principle of an Archimedean screw, is used. The inner space is filled with zinc balls and small zinc fragments. As the cylinder revolves, the zinc balls travel upwards, and at the end of the spiral they drop into a small central pipe and travel again to the bottom of the machine. The cyanide solution, flowing through the tube, and the rolling of the zinc, remove the precipitate from the surface of the metal. The separation of the precipitate from the exhausted solution takes place in a steep conical zinc-lined tank. Iron cannot be used, as zinc in contact with iron does not precipitate silver from cyanide solutions. The advantages of the device are that zinc is used in its cheapest form; no excess of zinc is used; clean precipitate is produced which can be melted with fluxes without intermediate acid-treatment or roasting.—W. R. S.

Zinc; Velocity of solution of — in acids. M. Centnerschwer. J. Russ. Phys.-Chem. Soc., 1916, 48, 170–521. (See this J., 1915, 965.)

ETCHED zinc dissolves in hydrochloric acid more rapidly than zinc with a polished surface. The metal, which reaches its maximum velocity of dissolution in 2N-hydrochloric acid, dissolves in fresh acid with a continually diminishing velocity, and the process of solution follows Boguski's law. Sulphuric acid dissolves zinc appreciably more slowly than hydrochloric acid with an equal concentration of hydrogen ions. Zinc sheets from one and the same melt dissolve with different velocities, owing to variations in the crystalline structure of the metal, but with rolled zinc sheets concordant

results are obtained. Zinc which has been treated with emery dissolves more rapidly than polished zinc, and zinc plates subjected to the action of iodine solution more rapidly than fresh plates. The velocity of dissolution of the metal increases more rapidly than the concentration of the acid, and the black precipitate which forms at the surface of the metal during the action accelerates dissolution, removal of this precipitate resulting in the loss of the former activity of the metal. In distilled water zinc retains its activity for a long time, but in the air the metal partially loses its activity. When rapidly cooled, zinc exhibits a more pronounced induction period than when slowly cooled, but if its surface is subsequently etched, its velocity of dissolution is the same as in the latter case. Prolonged heating at 400° C. of zinc which has been rapidly cooled increases its period of induction. The potential of active zinc is somewhat higher than that of passive zinc. In order to explain the phenomena observed, the supposition is made that ordinary (chemically pure) zinc is in a passive condition, increase of the velocity of dissolution during the period of induction being explained by transformation of the metal from the passive to the active state.

An attempt is made to explain the passivity of iron and other metals in accordance with Helmholtz's theory of the electric double layer and it is shown that such a representation is capable of furnishing explanations of: the influence of foreign metals on the solution of zinc (De la Rive's theory), the influence of mechanical and chemical treatment of the surface of the zinc, the period of induction, periodic phenomena in the dissolution of metals, the passivification of metals by means of oxidising agents and polarisation, rusting of iron and other metals (compare Walker, Cederholm, and Bent, this J., 1907, 1051; Cushman, this J., 1907, 1201), the activation of metals by hydrogen (compare Grave, this J., 1911, 1120), the specific influence of different electrolytes on the condition of metals, etc.—T. H. P.

Tin concentrate; Hcl assay of —. H. W. Hutchin. Bull. 149. Inst. Min. and Met. [Advance proof.] 27 pages.

VERY serious errors may be introduced in crushing the sample, agate being the only material unaffected by cassiterite. A sample crushed in different mortars was assayed for tin with the following results: unpowdered, 75.1; in agate, 75.1; in steel, 74.0; in Wedgwood mortars (3 different types) 73.35, 73.65, and 72.95%. The colour of the powdered material from the steel mortar was much darker than that crushed in agate. For reducing the solution prior to iodine titration, it is recommended to add 5 grms. of pure powdered zinc after nearly neutralising the excess of acid; 50 c.c. of hydrochloric acid is then added, a nickel coil is inserted, and the solution boiled for 10 minutes. The solution is cooled in an atmosphere of carbon dioxide and titrated. Ores containing tungsten, arsenic, or copper should be treated with acid before fusion. Titanium was not found to interfere when the ore was decomposed with lime (this J., 1914, 262) and zinc-nickel used for reduction.—W. R. S.

Stibnite ores; Flotation of —. J. Daniels and C. R. Corey. Eng. and Min. J., 1917, 103, 185—187. (See also this J., 1916, 1222.)

EXPERIMENTS were made on material from tailing dumps resulting from the hand-sorting of stibnite ore in the Fairbanks district, Alaska. The material contained Sb 35.8%, and Au 0.14 oz., and Ag 2.0 oz. per ton; it was tested in a Case experimental machine with a view to recovering

antimony, disregarding gold and silver. The best conditions were found to be: Size of ore, —100-mesh (aperture 0.0058 in.); pulp ratio, 1:5; peripheral speed of agitator, 1200 ft. per min.; temperature, 26° C.; time of agitation, 15 min.; concentrated sulphuric acid and creosote oil, 0.44 and 0.60% respectively of the weight of ore. The recovery for all tests was 54—92%, the tailings carrying 8—20% of antimony. Re-treatment of combined tailing samples gave a 70% recovery.—W. R. S.

Potassium permanganate; Action of — with metals. W. Foster. Chem. News, 1917, 115, 75.

It was found that dilute solutions of potassium permanganate, when either acid or neutral, are reduced by finely divided metals, including platinum and gold. The reduction appears to be accompanied by the formation of oxygen, potassium hydroxide, and hydrated manganese dioxide, in accordance with the equations:—

In the case of certain metals, e.g., mercury, the oxygen converts the metal into an oxide, but such inactive metals as gold and platinum serve merely as catalytic agents in decomposing the permanganate. In some cases, green potassium manganate is formed as an intermediate product of decomposition.—J. N. P.

Metals; Thermo-electric properties of certain polymorphous —. P. A. Laschitschenko, S. F. Bukov, and S. V. Eremov. J. Russ. Phys.-Chem. Soc., 1916, 48, 279—296.

MEASUREMENTS have been made at different temperatures of the thermo-potentials of a number of pairs of metals, one metal in each case being capable of existing in polymorphous modifications; the numerical results are given and also the curves showing the connection between electromotive force and temperature. The Ni-Pt curve shows a characteristic bend in its early part but no break, and the temperature coefficient of the thermo-electric force (dE/dt) exhibits a minimum at about 400° C. With Fe-Pt, dE/dt has minima at 475° and 1025° and a maximum at 850° C., the last temperature corresponding nearly with the transformation of β into γ -iron (compare Broniewski, this J., 1913, 290). With Zn-Pt, Zn-Pd, Zn-Au, and Zn-Fe, the results obtained bear little relation to allotropic change of the zinc. With Zn-Cu, however, this change is sharply shown, the neutral point at which the thermo-electric force is a maximum, being at about 240° C.; at 310° C., the curve again assumes its regular parabolic form, this temperature being regarded as that of the transformation of zinc. The Sn-Pt curve shows no peculiarity, but the Sn-Ni curve consists of two branches meeting at a very slight angle at 160°—165° C. (compare Degens, this J., 1909, 1041; Werner, this J., 1913, 1113). The influence of the allotropy of thallium on the thermo-electric properties of the metal appears, from a study of Tl-Pt, Tl-Cu, and Tl-Ni, to be only slight (Werner, *loc. cit.*). Investigation has been made of aluminium paired with platinum, palladium, silver, and constantan, the aluminium employed containing 1.30% Si, 0.85% Fe, and traces of copper. In all these cases the curves exhibit changes in direction at temperatures lying within the limits 570°—590° C., which are in agreement with those observed by other investigators in other ways.—T. H. P.

Physico-chemical force of attraction. III. [Formation of colloidal solutions of metals.] L. G. Gurvitch. J. Russ. Phys.-Chem. Soc., 1916, 48, 856—861.

THE phenomenon of the auto-disintegration of

floridin which occurs in various liquids necessitates the assumption that the force of physico-chemical attraction which tears off small particles from the surfaces of the floridin granules is capable of similar behaviour at the surfaces of other substances, such as metals. Experiment shows, indeed, that metals do undergo pulverisation when shaken in the form of granules or small pieces with various liquids at the ordinary temperature. Between the degree of disintegration of the metal and the residual chemical energy of the liquid as measured by the heat of adsorption, perfect parallelism exists, and the conclusion is drawn that the pulverisation is caused by the physico-chemical attractive force between the metal and the liquid. This force alone is insufficient to dislodge particles from the compact surface of the metal, but becomes able to do so when the impacts of the metallic fragments loosen the surface layers. The agitation of certain liquids of especially great residual energy, such as water, methyl alcohol, acetone, etc., with metals may even lead to the formation of colloidal solutions of the metals of very considerable concentration and marked stability. The maximum percentage concentrations of the colloidal solutions obtainable on shaking 100 grms. of granulated lead with 120—130 c.c. of various liquids are: water, 0.098; methyl alcohol, 0.132; ethyl alcohol, 0.0131; amyl alcohol, traces; acetone, 0.0115; pinene, 0.0088; and aniline, 0.0071. In methyl alcohol, colloidal solutions of the following percentage concentrations are obtainable: cadmium, 0.052; zinc, 0.0028; bismuth, 0.059; mercury, 0.032; and tin, 0.0031. This procedure furnishes a very simple method for obtaining colloidal metal solutions, but it is attended with some uncertainty, which appears to be due to insufficient cleanness of the surface of the vessel in which the shaking takes place. The best results are obtained if the vessel is washed successively with chromic-sulphuric acid mixture, water, alcohol, and several times with the liquid to be employed; it should then be charged at once and closed. Excessive shaking may result in the complete deposition of the metal from the colloidal solution.

Preparation of collargol [colloidal silver]. Gerashimov. See XX.

PATENTS.

Iron alloy. F. C. T. Daniels, Natick, Mass. U.S. Pat. 1,211,826, Jan. 9, 1917. Date of appl., Apr. 3, 1916.

A WHITE iron alloy for casting contains silicon 1.0—5.0, manganese 1.0—2.75, carbon 1.25—3.5, nickel 1.0—3.5%, and sulphur and phosphorus. The relative proportions of the ingredients are maintained so as to produce white iron.—W. R. S.

Steel and tin plates: Process for heating —. V. C. Smith, Whentland, Pa. U.S. Pat. 1,211,635, Jan. 9, 1917. Date of appl., Oct. 1, 1915.

To prevent scaling, welding, and sticking, the articles are heated in a furnace in which an oxygen-free atmosphere is obtained by boiling a soft metal such as lead in the hotter part of the furnace (e.g., near the fire-bridge).—W. R. S.

Coatings of fusible substances [metals]: Process for making —. G. Stolle, Berlin-Schöneberg, Germany. Eng. Pat. 23,289, Oct. 15, 1913. Under Int. Conv., Oct. 21, 1912.

THE fusible material, such as metal, is wholly or mainly volatilised, and then caused to impinge on the work by means of a blast of compressed

inert gas, without using a closed chamber. The blast may be passed through a highly-heated superheater, preferably of quartz, so arranged that the superheated blast impinges on the surface of the object, the latter being placed close to the outlet of the superheater.—B. N.

[Lead] smelting furnaces. A. S. Moses, New York. Eng. Pat. 103,205, Mar. 4, 1916. (Appl. No. 3271 of 1916.)

A FURNACE of the Scotch hearth type has an annular hearth supported so that it can be rotated. All the operations (supply of ore, fuel, blast, and cooling-water, tapping for metal, catching fume) can be carried out while the hearth is in motion. Automatic compound-movement poking and levelling devices operate along the hearth, the levelling devices moving in an inclined path with respect to it. A slag seal between the basin and the receiving trough prevents discharge of slag along with the metal.—W. R. S.

Welding a protective covering of copper to an iron or steel body: Method of —. J. Kirby, Pittsburgh, Pa. U.S. Pat. 1,211,715, Jan. 9, 1917. Date of appl., Dec. 8, 1915.

A SOLID copper body, e.g., a copper plate, is placed in position within the moulding cavity of the mould, and the iron or steel, at 2400° to 2600° F. (1300—1400° C.), is then supplied to the moulding cavity so as gradually to make contact with the inner face of the copper and soften it. The metal is allowed to cool, and the copper is thus welded to the solid iron or steel.—B. N.

Amalgamator. R. F. Lounsberry, Assignor to Mid-Continent Machinery Co., Sheridan, Wyo. U.S. Pat. 1,211,729, Jan. 9, 1917. Date of appl., July 11, 1913.

THE receptacle of the amalgamator, designed to contain mercury, is provided with means for agitating the metal and drawing off the amalgam formed, and with an inclined platform at the delivery end for the supply of ore and water. The top of the platform is provided with a series of riffles, each of which is composed of a vertical front portion and a rear portion inclined in a downward direction towards the delivery end. A water receptacle below the inclined platform is divided into compartments, each of which is supplied with water under pressure, and each compartment is provided with water openings discharging in an upward direction parallel to the inclined side of each riffle. Openings also discharge water, in a horizontal direction, from the lowest compartment over the top of the mercury in the mercury chamber.—B. N.

Smelting ores: Process and apparatus for —. G. W. Wright, Deming, N. Mex. U.S. Pat. 1,211,805, Jan. 9, 1917. Date of appl., July 25, 1916.

THE apparatus comprises a retort from which air can be excluded and provided with an agitator extending through one of its walls in an air-tight manner. The retort has an inlet, a reciprocating and revolving feeder to which a closure for the inlet is attached, and a housing closely fitted to the feeder. The feeder is supplied outside the retort with material from a hopper.—W. R. S.

Flotation process of concentrating [ores]. G. H. Clevenger, Palo Alto, Cal. U.S. Pat. 1,212,130, Jan. 9, 1917. Date of appl., June 13, 1916.

THE distillate from the destructive distillation of sage is utilised as a floatative agent. (See also this J., 1916, 1020.)—W. R. S.

Lead alloys; Manufacture of—F. C. Frary, Niagara Falls, N.Y., and S. N. Temple, St. Paul, Minn., U.S.A. Eng. Pat. 101,025, July 19, 1916. Under Int. Conv., July 26, 1915. (Appl. No. 10,151 of 1916.)

[Electric storage] battery cells. W. L. Walker, Boston, Mass., U.S.A. Eng. Pat. 100,176, Mar. 2, 1916. Under Int. Conv., Mar. 17, 1915. (Appl. No. 3161 of 1916.)

THE battery cell is composed of an outer jar of an acid-resisting alloy of lead and antimony, and an inner jar of an acid-resisting non-conducting material, such as vulcanised rubber, fitting snugly in the outer jar. A removable cover is supported within the cell on an enlarged portion at the top of the inner jar, and is held in place by bolts, bearing against the cover, carried by locking strips engaging in lugs on opposite sides of the outer jar.—B. N.

Batteries; Electric—R. S. Baxter, Tayport, Fife, Eng. Pat. 103,020, Feb. 15, 1916. (Appl. No. 2256 of 1916.)

THE negative element of the battery, cell, or voltaic couple, is formed from a plate of tin, with a layer of sulphur on one side of it, so that a sulphide of the positive metal, such as zinc, is formed during the electrochemical action. The electrolyte is composed of a solution of one or more alkali or alkaline-earth chlorides; the precipitated zinc sulphide may be recovered subsequently by filtration, or barium chloride may be used as the electrolyte and a precipitant stirred in with it, so as to form barium sulphate which is collected jointly with the zinc sulphide.—B. N.

Electrode; Protected—and process of making the same. E. H. Becker, Washington, D.C., Assignor to Kinetic Electric Co., Norfolk, Va. U.S. Pat. 1,211,388, Jan. 9, 1917. Date of appl., Oct. 18, 1916.

A NEGATIVE electrode, for galvanic cells, is composed of an intimate and uniform mixture of cuprous and cupric oxides, having its surface coated with copper, and the coating then amalgamated with mercury.—B. N.

Electrolytic decomposition of water; Apparatus for the—A. Dohmen, Cologne, Germany. U.S. Pat. 1,211,687, Jan. 9, 1917. Date of appl., Oct. 20, 1913.

AN electrolytic apparatus, of the filter-press type, is composed of a series of cells, each comprising a thin quadrilateral wrought iron frame having a single central opening, and with two passages through the top of the frame. A detachable sheet metal electrode is secured in the opening of the frame, and the top of the latter is also provided

with two gas-separating chambers, one at each end. The chambers extend laterally in a downward direction to the active faces of the electrode, for conducting the gases from opposite sides to the two passages.—B. N.

Resistance material; Electrical—M. A. Hunter, Troy, N.Y. U.S. Pat. 1,211,913, Jan. 9, 1917. Date of appl., Aug. 9, 1916.

THE resistance material is formed from an iron alloy portion containing 75 to 25% of iron and 25 to 75% of a metal having the properties of nickel or cobalt, 100 parts of this alloy being combined with 10 to 30 parts of a metal of the chromium group.—B. N.

Colloids; Separation of—from mixtures by electro-osmotic action. Elektro-Osmose A.-G. (Graf Schwerin Ges.), Berlin. Ger. Pat. 295,666, Jan. 26, 1915. Addition to Ger. Pat. 291,672 (see Eng. Pat. 11,823 of 1914; this J., 1915, 877).

IN carrying out the process described in the original patent (*loc. cit.*), the mixture is stirred so that feebly charged particles may be brought into the sphere of action of the strongly charged diaphragm. Stirring also prevents the formation on or near the diaphragm of layers which impede the migration of certain colloids.—J. N. P.

Bipolar-electrode electrolyser. G. G. Hepburn, Manchester. U.S. Pat. 1,213,871, Jan. 30, 1917. Date of appl., Aug. 26, 1916.

SEE Eng. Pat. 12,730 of 1915; this J., 1916, 1120.

Method and means [electric furnace] for producing tin oxides. Eng. Pat. 103,415. See VII.

XII.—FATS; OILS; WAXES.

Vegetable oils; Influence of climatic conditions on the composition of—G. V. Pigulevski. J. Russ. Phys.-Chem. Soc., 1916, 48, 324–341.

EVIDENCE is adduced showing that among plants belonging to one and the same sub-family, the iodine value of the essential oil increases as the geographical distribution of the plant extends further towards the north. Plants of the families *Rosaceæ*, *Ericaceæ* and *Pinaceæ* yield fatty oils containing the same acids. In the case of oleic acid, for which a number of isomerides are possible with different positions of the double linking, the natural acid is practically always the Δ^6 acid and the existence of this acid is doubtless related to its activity, since the activity varies considerably with the position of the double linking in the carbon chain. The iodine value of an oil, characterising the degree of unsaturation, depends on the percentage of the triglycerides of unsaturated acids, and may be expressed by the formula, $A_m = a_1x/100 + a_2y/100 + a_3z/100$, where A_m is the iodine value, x , y , and z are the percentages of the triglycerides of oleic, linolic, and linolenic acids respectively, and a_1 , a_2 , and a_3 the corresponding iodine values of the triglycerides, have the respective values, 86.2, 173.58, and 262.15. By means of this formula a table has been constructed which shows how, for one and the same iodine value, the proportions of the three glycerides may vary.

—T. H. P.

Soap; Determination of free alkali hydroxide in—V. A. Izmailski. J. Russ. Phys.-Chem. Soc., 1916, 48, 411–432.

FOR the determination of the free alkali hydroxide

in soap neither the alcohol method nor the barium chloride method yields results which are accurate or reproducible by different workers. The errors of the alcohol method are due principally to the capability of colloidal soap in an alcoholic medium of adsorbing free alkali, and the difficult solubility in alcohol of the "alkali soap" thus formed and its marked retention of the filtrate. When barium chloride is used, special precautions are necessary to prevent hydrolysis of the soap itself. From the results of experiments made by the author the following method has been devised. A portion of the soap is freshly cut from the interior and *a* (about 10) grms. is weighed into a flask of about 400 c.c. capacity fitted with a rubber stopper, and dissolved in 20*a* c.c. of boiling distilled water. To the hot solution is gradually added 2 *a* c.c. of neutralised (towards phenolphthalein) barium chloride solution containing 30 grms. of the salt to 100 grms. of water, the liquid being rotated and boiled for a short time as long as the precipitate does not settle. During the dissolution and boiling, the flask is loosely closed with the stopper. When the precipitate settles the flask is cooled under the tap and tightly stoppered, the cold liquid being immediately filtered through a rapid filter into a conical flask and the filter washed with cold boiled water. Any precipitate remaining in the original flask is washed with three portions of boiled and cooled water, amounting to 19 *a* c.c., in the closed flask. The liquid is titrated with *N* 10 acid in presence of phenolphthalein. The values thus obtained, which the author terms the "alkali numbers," are characteristic for different types of soap. —T. H. P.

Economic sources of polish and wool fat in S. Australia. Winterbottom. See VII.

XIII.—PAINTS; PIGMENTS; VARNISHES; RESINS.

PATENTS.

Artificial ochre: Preparation of— from iron mordant liquors and clay. C. E. Sachse, Elberfeld. Ger. Pat. 295,209, Mar. 11, 1914.

AN ochre of even grain and colour is obtained by evaporating to dryness a mixture of iron mordanting liquor and clay and roasting the resulting mass with access of air.—B. V. S.

Lampblack: Production of—. Gebr. Siemens und Co., Berlin-Lichtenberg. Ger. Pat. 295,517, Aug. 25, 1914.

IN a continuous process for the production of lampblack, the soot-containing gases are strongly cooled and led into settling chambers of sheet lead. The cooling may be done by passing the gases through a system of tubes extending upwards from the burning oven and then downwards to the lead chamber, the tubes being slightly or not at all cooled at the inlet and strongly cooled, e.g., by cold water, at the outlet.—B. V. S.

Copper-containing pigments. Siegwirk Chem. Lab. Ges. m. b. H., Siegburg. Ger. Pat. 295,794, Mar. 3, 1914. Addition to Ger. Pat. 287,149 (this J., 1916, 368).

COPPER is introduced into suitable pigment colours and organic lakes (e.g., the barium, calcium, and other lakes of Diamine Pure Blue) by the action of a neutral solution of a copper salt and a substance which will neutralise the acid formed in the reaction.—B. V. S.

Substitute for drying oils as a medium for paints, varnishes, and impregnating agents for fabrics, wood, etc. O. Rohm, Ger. Pat. 295,340, June 5, 1915.

A SOLUTION of a polymerised acrylic acid ester, in acetone, lower fatty esters, or other solvents, is claimed for the purposes mentioned in the title. The acrylic esters may be prepared from allyl alcohol, glycerin, lactic acid, etc. When exposed to sunlight or artificial ultra-violet light, they are transformed into a colourless, transparent, very elastic (not gelatinous) tough mass, which is soluble in the solvents for oils. Alternatively the ester may be mixed with a solvent, and the mixture polymerised. The polymerised ester dries rapidly, resists many chemical agents, and is not readily affected by exposure to weather.—C. A. M.

Printing inks. V. Friedrich, Berlin-Schöneberg. Ger. Pat. 295,489, Nov. 28, 1915.

PRINTING inks with about half the normal content of linseed oil, turpentine, drying oils, and the like are obtained by dilution of the usual printing inks with water mixed with wool-fat, and the addition of more colouring matter to compensate for the dilution.—B. V. S.

Lead oxide: Apparatus for carbonating—. F. H. Sharpe, Liverpool. U.S. Pat. 1,214,222, Jan. 30, 1917. Date of appl. May 31, 1916.

SEE Eng. Pat. 9486 of 1915; this J., 1916, 933.

XIV.—INDIA-RUBBER; GUTTA-PERCHA.

Vulcanisation: Studies on—. A. Dubosc, Caout. et Gutta-Percha, 1917, 14, 9109—9115.

THE author puts forward the view that in order to bring about vulcanisation sulphur must be present in the colloidal form. In ordinary practice colloidal sulphur is formed *in situ* by the interaction of hydrogen sulphide and sulphur dioxide, the former produced by the action of ordinary sulphur (S_8) upon the rubber resins, or upon the protein, or upon the caoutchouc itself, the latter by the interaction of ordinary sulphur with the oxygen-containing insoluble constituents, or with some added substance such as a metallic oxide:— $e.g., 16PbO + 3S_8 = 16PbS + 8SO_2$. The results obtained by Stevens (this J., 1914, 268) are readily explained on this hypothesis. Rubber freed both from insoluble constituents and from resins shows little tendency to vulcanise, and this is also true of rubber from which only the insoluble constituents have been removed. The removal of the resins only, however, has not the same effect. Rubber containing an excess of insoluble constituents is readily vulcanised to a high coefficient. Owing to the fact that the ease with which they are decomposed by heat varies, all resins are not equally active. Thus Jelutong resins have not as great an effect as colophony, or as the original resin, when added to de-resinified rubber.—E. W. L.

Vulcanisation: Coefficient of— as a check on the state of cure. O. de Vries. India Rubber J., 1917, 53, 101—103.

ALTHOUGH he has not met with so wide a range of values for vulcanisation coefficient at "correct cure" as that quoted by Schidrowitz and Goldsbrough, viz., 2.03—1.86% (compare this J., 1915, 842; 1916, 550), the author agrees with the view that the chemical process of combination of rubber and sulphur is in itself independent of the physical process determining the position of the stress-strain curve. In support of this view it is shown

that it is possible to bring the rubber to the "correct" or other standard cure (as judged by the curve) with other and quite arbitrary coefficients of vulcanisation. Below 80° C. the percentage of combined sulphur does not increase with time (cf. Spence, *Koll. Zeits.*, 10, 299; Hinrichsen, *ibid.*, 8, 245; Rubber Industry, 1911, 306; this J., 1911, 699; 1912, 651), although the curve shifts its position. Thus in the case of a crêpe mixing (rubber, 92.5; sulphur, 7.5%), vulcanised for 105 minutes at 148° C., and tested at various intervals after vulcanisation, the breaking strain increased from 1.285 kilos. per sq. mm. at 2 hours to 1.39 kilos. at 20 hrs., the length at break fell from 1058 to 1033, and the length at 1.30 kilos. load from 1060 to 1018; whereas the combined sulphur varied only between 1.59 and 4.69%, variations which may be ascribed to experimental error. Similar results were obtained in a shorter time when the vulcanised samples were kept at 70°–75° C., instead of at the ordinary temperature. In the case of one particular sample, at 148° C., vulcanisation for 115 minutes was necessary to reach the standard curve (elongation of 990% at 1.30 kilo.) and a coefficient of 5.50% was obtained; nearly the same position of the curve was reached, with a vulcanisation coefficient of only 4.45%, by vulcanising at 148° C. for 95 minutes and heating at 70° C. for 36 hours. In another case the same position of the curve was reached by vulcanising at 148° C. for 60 minutes, and afterwards heating at 70° C. for 66 hours, as by vulcanising at 148° C. for 100 minutes; but in the former case the coefficient of vulcanisation was only 2.85%, whereas in the latter it was 4.40%. It is pointed out, however, that a parallelism—really accidental—exists between the state of cure and the coefficient of vulcanisation, within the limits of 0.5% of combined sulphur, under ordinary fixed conditions of vulcanisation.—E. W. L.

Polymerisation of α -phenyl- Δ^2 -butadiene, Lebedev and Ivanov. See XX.

PATENTS.

Drying materials [pulverised reclaimed rubber]; Method of—, R. B. Price, New York, Assignor to Rubber Regenerating Co. U.S. Pat. 1,209,643, Dec. 19, 1916. Date of appl. Feb. 3, 1913.

IN order to prevent its oxidation and spontaneous combustion during the process of drying, pulverised reclaimed rubber is agitated in a heated, non-oxidising vapour atmosphere maintained for a part of the treatment below the saturation point, and for another part of the treatment above the saturation point.—E. W. L.

Rubber articles: Manufacture of hollow—, R. B. Price, New York, Assignor to Rubber Regenerating Co. U.S. Pat. 1,209,644, Dec. 19, 1916. Date of appl., Apr. 19, 1915.

THE wall of the hollow article is formed of sections of vulcanisable plastic material (rubber) with a skin of rubber containing no, or very little, sulphur, attached to the edges which are ultimately to be united. The sections are vulcanised, the skins moistened with sulphur chloride, the sections assembled and united by pressing the moistened skins together. The sections may also be only partially vulcanised in the first instance, vulcanisation being completed after the complete article has been built up.—E. W. L.

Vulcanisable plastics: Manufacture of articles embodying fibrous filaments and—, Process of manufacturing rubber articles. R. B. Price, New York, Assignor to Rubber Regenerating Co. U.S. Pats. (A) 1,211,228, and (B) 1,211,351, Jan. 2, 1917. Dates of appl., Dec. 1 and Feb. 9, 1915. (B) Renewed June 6, 1916.

IN the manufacture of articles composed of fibrous

filaments and vulcanisable plastic (rubber), the material is partially vulcanised, in the absence of materially distorting conditions. The article (*e.g.*, a tyre) is then built up of this partially vulcanised material, and vulcanisation is completed under pressure. In (A) the process is applied to materials in which each filament of fibrous material is enclosed in vulcanisable plastic material.—E. W. L.

Gutta-percha substitute from paper impregnated with waterproof substances; Preparation of a—, G. Münzel, Leipzig, Ger. Pat. 275,121, Nov. 2, 1915.

PAPER is impregnated with potassium acetate and then waterproofed by treatment in a half-dried condition with a solution of an aluminium salt of a fatty acid, being finished with a coat of suitable lacquer. The potassium acetate has the effect of making the paper pliable.—J. F. B.

XV.—LEATHER; BONE; HORN; GLUE.

Tannins: Biological detection and valuation of—, R. Kobert, Collegium, 1916, 164—174, 213—225. *Chem.-Zeit.*, 1917, 41, Rep., 12. (See also this J., 1915, 672.)

THE author describes three methods of finding the maximum dilution at which a tannin solution exerts astringent action, as shown by the coagulation of fresh blood corpuscles. The first is the determination of the visible limit, *i.e.*, that dilution beyond which there is no coagulation visible to the naked eye. The second is the determination of the filtration limit, *i.e.*, that point when the coagulated corpuscles are retained by a filter paper, which allows unaltered corpuscles to pass through. The third method is to find the reaction limit, *i.e.*, when the liquor, after separation of the blood coagulum, no longer gives a coloration with ferric chloride. Of these, the filtration limit is the most useful, lying between the other two. Analysis of tannins by the use of hide powder gives only the tannin content, and does not distinguish between weakly and strongly astringent tannins as does the biological method.—F. C. T.

Gelatin; Osmotic pressure of—, W. Biltz, G. Bugge, and L. Mehler. *Z. physik. Chem.*, 1916, 91, 705—712. *Z. angew. Chem.*, 1916, 29, Ref., 540.

THE molecular size of gelatin was determined by measuring the height to which a gelatin solution rose in the osmometer. A dry-plate gelatin gave a value of 10,900; purified gelatin preparations values of 5500 to 15,500; and four technical gelatins, 5650 to 18,500. From these results, on the basis of the molecular weight of gelatin (900) found by Paal and by Procter, it was calculated that the molecular aggregates of good gelatin are composed of about 10 individual molecules. The absolute value of the molecular size of technical gelatins decreases with their technical value. The viscosity of gelatin increases with the increase in the size of the particles, whilst the "gold value" decreases under the same conditions. The amounts of ash in the samples examined were:—Dry-plate gelatin, 1.4; purified gelatins, 0.063 to 0.62; and technical gelatins 1.55 to 2.4%. The ash consisted mainly of calcium and phosphoric acid, with small quantities of iron, magnesium, chlorine, sulphuric acid, carbonic acid, and alkali.—C. A. M.

Study of the nitrification of different leathers and of "sulphurated" rape-cake. Guillin. See XVI.

Immunity studies on anthrax serum. Eichhorn and others. See XIXB.

PATENTS.

Mocha leather: Manufacture of ——. S. T. Thring, R. J. Luffman, and L. Forse, Yeovil, Eng. Pat. 192,986, Jan. 6, 1916. (Appl. No. 228 of 1916.)

THE grain is removed by the use of a composition such as 12½% caustic soda, 12½% caustic potash, and 75% water, applied to one side of the skin only.—F. C. T.

Chromium salts: Process for manufacture of concentrated solutions of complex organic ——. for *tanning and dyeing*. P. Kauschke, Dresden, Ger. Pat. 295,518, June 17, 1914.

CHROMIC acid in concentrated hydrochloric acid is reduced by waste materials containing proteins, such as leather cuttings, horn chips, hair, etc., and especially chrome leather waste. Several methods of starting the reaction are given, e.g., warming the mixture, adding dehydrating or easily oxidisable substances or substances capable of producing nascent hydrogen. The resulting solution of complex organic chromium salts may be used advantageously for the one-bath tanning process or as a mordant for textiles.—F. C. T.

XVI.—SOILS; FERTILISERS.

Soils: Calcium compounds in ——. E. C. Shorey, W. H. Fry, and W. Hazen. J. Agric. Res., 1917, 8, 57–77.

IN an attempt to establish the identity of calcium compounds occurring in soils by petrographic and chemical methods, 63 samples were investigated which represented 23 soil types taken from 24 localities in 19 States. Eleven different minerals were sought for in the petrographic examination, and their relative abundance is summarised in tabular form. Of these, hornblende was the most common, followed in order by plagioclases and epidote. Gypsum, dolomite, and apatite were found but once each. In the chemical investigation, determinations were made of total calcium, of the calcium extracted by 2% and by 1% hydrochloric acid, of carbonic acid, of water-soluble calcium, and of water-soluble sulphates; and from the analytical data the quantities of calcium carbonate, sulphate, silicates, and the calcium combined with humus matter were calculated, subject to certain assumptions which introduced only small errors. It was found that there were wide variations in the contents of total calcium, calcium carbonate and silicates, and no relation between the total calcium content and that of any particular calcium compound could be deduced. Further, it was possible to have two soils of the same calcium content, but containing a very different assortment of calcium compounds. In twenty-nine of the soil samples, no calcium was found in combination with "humus." Five of the soils, representing two types, were acid to litmus; these contained relatively little total calcium and calcium carbonate, and were derived from badly drained areas. A clay loam (Mecklenburg), recognised as a good alfalfa (lucerne) soil, was found to have a high calcium content but to contain practically no calcium carbonate.—E. H. T.

Phosphoric acid: Forms of occurrence of — in the soil. M. A. Jegorov, Agric. Gaz. of S. Russia, 1916, No. 13–14, 4–5, and No. 15, 1–5. Bull. Agric. Intell., 1916, 7, 1248–1249.

THE organically combined phosphorus of the soil

was separated and estimated by leaching with 3% hydrochloric acid and treating with 3% ammonia solution, the resulting solution being then filtered and precipitated with lead acetate. The washed precipitate, freed from lead with hydrogen sulphide, was re-dissolved in dilute ammonia, the liquid filtered, concentrated, and finally extracted with ether, the organic phosphorus going into solution. The soils used were, "Podzol" from Moscow, containing 0.0532% of phosphoric acid, "Tchernoziom" from Ufa (0.115%), and Tchernoziom from Kursk (0.110%). Of the total phosphoric acid in these soils, the ammonia solution removed about one-half in the first and third, and one-third in the second. The organic phosphoric acid extracted varied from 10 to 17.67% of the total phosphoric acid; its nature varied with the source, but it is apparently related to the nucleic acids. The 3% hydrochloric acid extract contained the element in both inorganic and organic forms, and during its evaporation a considerable amount of the latter was converted into the former.—E. H. T.

Soil: Method of sterilising and chloroforming — used in studying "Tchernoziom." S. Skalskij, Agric. Gaz. of S. Russia, 1916, 18, Nos. 1, 2, 5, 7, and 9. Bull. Agric. Intell., 1916, 7, 1249–1253.

THE "Tchernoziom" soils selected for the investigation were a fallow soil ploughed in April [A], a soil cleared several years previously [B], and a 3-year-old lucerne soil [C]. From each of these a surface layer (0–17.7 cm.) and a layer immediately below it (17.7–35.5 cm.) were taken, treated with various fertilisers, potted, and sown with sterilised oat seeds. The first series (a) served as controls, the second (b) was manured with potassium nitrate and magnesium sulphate, and used to determine the assimilable phosphoric acid content, the third (c) received potassium dihydrogen phosphate and magnesium sulphate, and was used to determine the assimilable nitrogen, the fourth (d) received a complete mineral dressing of potassium nitrate, potassium dihydrogen phosphate and magnesium sulphate, the fifth (e) contained soil sterilised by heating in an autoclave in steam for 1 hour under 2.5 atmos., and in the sixth (f) chloroformed soil was employed. Four plants were grown in each pot, and they were watered from below with rain water, so that the moisture content remained at the optimum throughout. The plants died in some of the sterilised samples of soil, probably owing to physico-chemical changes incurred during sterilisation. The fertility of (d) and (e) was about the same and much superior to the rest, (f) came next, followed by (c), (b), and (a). To investigate the causes of the increase in fertility, the bacterial flora in [A] was examined. The bacterial numbers in (e) and (f) were incomparably greater than in (a), greater in the shallow than in the deep soil, and greater on agar than on gelatin. In (f), the bacterial increase and the higher fertility were accompanied by an enrichment in nitrogen and phosphorus. The gain of assimilable nitrogen is ascribed to bacterial fixation of atmospheric nitrogen and to the decomposition of organic matter, that of the phosphorus to the action of soil organisms in liberating acids which attacked the phosphates, and in converting unavailable organic phosphorus into an assimilable state. The bacteria in the sterilised samples (e) were derived from the air, and the enhanced fertility was chiefly due to the increase in available phosphoric acid, which amounted to 47–76.5% in the lower layer and 88–121% in the arable strata, and which is ascribed to the decomposition of nucleins containing 5.7% of phosphorus which liberate free phosphoric acid when heated to 150° C. The nitrogen contents of the sterilised and un-

sterilised soils were the same; and as the good effects of sterilisation could not be entirely due to the increase in soluble phosphoric acid, they must also be accounted for by assuming that assimilable nitrogen is liberated from organic matter during sterilisation. The increase of available nitrogen in series (e) was clearly indicated by the rich green colour of the leaves of the young plants.—E. H. T.

Nitrification of different leathers and of "sulphurated" rape cakes; Study of the— Guillin. Compt. rend. de l'Acad. d'Agric. de France, 1916, 2, 760—769. Bull. Agric. Intell., 1917, 7, 1253—1256.

NITRIFICATION experiments were carried out with a clayey-lime soil (Gournay, Seine-et-Oise), which was treated in 1 kilo. lots with the following materials, in amounts containing 1 gm. of nitrogen: dried blood (N 14.72%), tanned leather (N 8.15%), chrome leather (8.87%), roasted leather (6.77%), leather waste treated with sulphuric acid and converted into a pasty mass (6.63%), the same treated with more acid and liquefied (7.36%), and "sulphurated" rape cake (5.62%). Nitric acid determinations were made at intervals of 1, 2, and 5 months by the Schloesing method, which was tested and found to be applicable and reliable. The following were the weights of nitric acid found after one and after three months: blood 1.080, 2.433 grms.; tanned leather, 0.166, 0.404 gm.; chrome leather, 0.003, 0.227 gm.; roasted leather, 0.220, 0.523 gm.; dissolved leather (pasty), 0.742, 1.547 grms.; dissolved leather (liquid), 0.990, 2.015 grms.; rape cake, 0.888, 2.291 grms.; untreated soil, 0.145, 0.326 gm. The effects of chrome leather and of dissolved leather upon the growth of young wheat plants was investigated in pot experiments. Ten weeks after germination, the crops were weighed, and taking the weight of the control plants as 100, that treated with chrome leather was 30, and that with dissolved leather 115. Chrome leather is therefore injurious to vegetation. Neither tanned leather nor roasted leather are suitable soil amendments. Under very favourable conditions of nitrification, the former gave 0.021 and 0.078 gm. of nitric acid after 1 and 5 months respectively, and the latter, 0.075 and 0.197 gm., per gm. of fertiliser nitrogen applied. Leather which has been thoroughly decomposed with sulphuric acid is a useful fertiliser.—E. H. T.

Manganese; Use of— as a catalyst in atmospheric nitrogen fixation by plants through bacterial agency. R. A. De Gregorio. Rev. Real. Acad. Ciencias exact., de Madrid, 1916, 14, 681—693. Bull. Agric. Intell., 1917, 7, 1256—1257.

QUANTITIES of 100 c.c. of culture bouillon of known nitrogen content, and containing mannitol and varying amounts of manganese chloride, were inoculated with pure cultures of *B. radicola*, *Clostridium pasteurianum*, and *Azotobacter chroococcum*, incubated at 22°—23° C. for 25 days, and after sterilisation analysed for total nitrogen by Kjeldahl's method. With the exception of *B. radicola*, the organisms did not function in the total absence of manganese, but in all cases its presence accelerated nitrogen fixation, the optimum quantity being 0.006 gm. of manganese ion per 100 c.c. of bouillon. With this amount three times more nitrogen was fixed than in the control vessel. Acceleration was retarded when the manganese exceeded the optimum, and with 0.02 gm. the fixation itself was retarded. Under field conditions, crops could be stimulated by fertilisers containing manganese in amount not exceeding 0.006 gm. per 100 grms. of soil. Most soils already contain more than this amount of manganese, but it is

mostly in an unavailable form. In estimating the quantity of this catalyst to be applied, the amount already present in a soluble form must be taken into consideration.—E. H. T.

PATENTS.

Manure from refuse; Manufacture of— A. D. Furse, Beckenham, Kent. Eng. Pat. 103,118, Sept. 7, 1916. (Appl. No. 12,651 of 1916.)

HOUSE or town refuse is disintegrated and a small quantity of fertile mould, butchers' offal, fish offal, beetroot waste, etc., may be added. The mass is then treated with a culture of bacteria capable of producing ammonia and fixing nitrogen, and kept at 80°—90° F. (27°—32° C.) for several days. Afterwards, the mass is dried and powdered, or it may be pressed and the liquid portion used as a manure. A modification of the process consists in sterilising the refuse by treatment with steam before the culture of bacteria is added.

—W. P. S.

Ammoniacal liquor; Process for improving the fertilising value of the— produced in the manufacture of gas or coke. A. Schubert, Parsberg. Ger. Pat. 292,145, Mar. 20, 1911.

THE ammoniacal liquor, together with the crude tar, obtained by the destructive distillation of coal is subjected to redistillation in such a manner that a final temperature of 200° C. is reached, and the distillate up to this temperature is collected and diluted with water before use as a fertiliser. The secondary changes which take place on heating the crude tar with the gas-liquor, assisted by the use of superheated steam and agitating devices, produce substances which have a stimulating influence on vegetable growth and a poisonous effect on parasites. Some of these substances have a direct fertilising value, others are made available by the action of atmospheric organisms or carbon dioxide.—J. F. B.

Fertiliser from lignite ash; Preparation of— H. Fehn. Ger. Pat. 291,858, Sep. 4, 1914.

LIGNITE ash is mixed with quicklime and the mass slightly moistened and mechanically agitated in a current of air, heat being applied if required. The process may be carried out in a drum through the horizontal axis of which air is admitted, whilst a series of paddles are attached to the inner walls of the drum. By this treatment the sulphides in the lignite ash are oxidised.—C. A. M.

Nitrolim [crude calcium cyanamide]; Apparatus for treating— G. Zarniko, Hildesheim. Ger. Pat. 291,993, Apr. 1, 1915.

NITROLIM is treated with water to decompose carbide, and mixed with moist or liquid materials to prevent dusting, in a long horizontal rotating drum, which is provided with cooling means and separate inlets for nitrolim, liquids, and inert gas, and an outlet for the finished product which can be closed by means of a cap or valve, or may be connected with a spiral conveyor which can be made to rotate in the same or an opposite direction to that of the drum so as to keep back the material. Baffle plates may be fitted inside the drum to promote the movement of the mass in either direction. The drum is surrounded by a cooling jacket. —C. A. M.

Fertiliser; Preparation of a non-dusty— of uniform composition. F. Winterfeld, Cöln-Mülheim. Ger. Pat. 295,112, Dec. 31, 1915.

NITROLIM is mixed with dolomite sand, with or without subsequent moistening of the mass with a dilute solution of syrup. —C. A. M.

Superphosphate chambers: Method and apparatus for emptying—W. Mellwig, Lehrte, Ger. Pat. 295,418, July 29, 1911.

The material is loosened by a rake-like arrangement, and a powerful current of air is directed over its surface for transporting, aerating, and drying it. The compressed air duct, which at the same time forms the shaft of the rake arrangement, terminates between the prongs of the rake in an orifice directed towards the discharge orifice of the chamber and is moved to and fro over the surface of the material by a slide and an automatic reversing gear attached to the spindle of the slide-guide, and is lowered gradually and automatically as the material is discharged, by means of a rack and pinion which operates the upright shaft.

XVIII.—FERMENTATION INDUSTRIES.

Yeast: Further methods for the preparation of permanent—T. Bokorny, Allg. Brauer u. Hopf. Zeit., 1916, 56, 1547–1550. Z. angew. Chem., 1917, 30, Ref., 49.

Yeast cells may be killed, without destroying the fermentative activity of the contained zymase, by treatment with 0.1–0.5% solutions of sulphuric acid, ammonium and sodium fluorides, formaldehyde, ferrous sulphate, ammonium oxalate, potassium chlorate, chloroform, ether, etc. Continued action of the toxic solution, however, ultimately affects the zymase also. By drying the yeast treated with these toxic solutions, after washing out the reagent used with water, permanent yeast preparations may be made similar to the so-called "acetone yeast." The process is much cheaper than the acetone and the ether-alcohol processes for making permanent yeast. Only with the fluorides were the results unsatisfactory. Rapid treatment is not necessary; for instance, in using sulphuric acid, it is advisable to leave the yeast for several hours in contact with a 0.1% solution, in order to make sure of killing all the cells.—J. F. B.

Diastase: Optical properties of—and its adsorption by kaolin and by aluminium hydroxide. M. A. Rakuzin and G. D. Flier, J. Russ. Phys.-Chem. Soc., 1916, 48, 321–324.

At 60°C., only 84–12% of Merck's diastase is soluble in water; the solution is optically inactive and gives the biuret, xanthoprotein, Molisch's, and Ostromyslenski's reactions (this J., 1916, 433), the limits of sensitiveness being 1 in 1690, 810, 6660, and 750 respectively. In two solutions of diastase, 7.19% and 7.10% of the total diastase

present was adsorbed by aluminium hydroxide, and a second treatment with the latter effected no further diminution in the specific gravity of the solution. Further, if the aluminium hydroxide is subsequently washed carefully and pressed, and then treated with hot water, the liquid shows none of the colour reactions of the original diastase solution; the adsorption is, therefore, irreversible. The adsorbed portion of the diastase fails to give Ostromyslenski's colour reaction with picramic acid. Since diastase consists of two enzymes, of which one converts starch into dextrins, the other starch to maltose it may well be that the adsorbed and non-adsorbed parts correspond with these two constituents. Diastase is not adsorbed by the electro-negative kaolin (compare W. Ostwald, Grundriss der Kolloidchemie, 1909, 421).—T. H. P.

Beers: Low alcoholic—O. Overbeck, J. Inst. Brew., 1917, 23, 3–12.

The author gives some practical details of a method of brewing beers of low alcohol-content which has furnished satisfactory results. The water employed, which is calcareous in character, is treated with 12 grains of calcium chloride per gallon. No malt substitutes are used, but admixture of a considerable proportion of foreign malt is found to have a steadying effect on the yeast, besides reducing danger of infection by wild yeasts and giving the beer a firm, permanent head. Owing to the sensitive character of the beers, as regards flavour, old hops are avoided as far as possible. One quarter of the total amount of hops used is reserved for addition to the wort about 15 mins. before turning out of the copper; this improves the real hop-flavour of the beers to a marked extent. The Yorkshire stone square system of fermentation is employed. Cleanliness is essential, since the wort remains for a long time without a protective yeast head. To avoid infection the fermenting vessels are covered with sheets of cotton twill moistened with very dilute sulphurous acid, and these sheets are sterilised after every brew. A wort of original gravity 1015°–1020°, pitched on Monday evening, is ready to rack at half-gravity on Thursday morning; racking may, however, be delayed to Saturday (but not later) if the wort is pitched with 3–4 oz. of yeast per barrel and very careful attention is given, the wort being kept within 1° of 60°F. The beer is racked into well-cleaned barrels, which, after introduction of about a wineglassful of sulphurous acid solution (sp. gr. 1.025), have stood overnight loosely shived. One-third of the usual amount of finings is added to each barrel, and after the full barrels have been shived tightly and well rolled, the beer becomes "star bright" in about 2 hours and is ready to send out. The amount of preservative used is about half that for an ordinary beer. In full barrels the beer remains in good condition for months. If brewed at an original gravity of 1016° and racked at 1008°, its alcohol-content falls within the limit for temperance beverages (1% of alcohol, or about 2% of proof spirit), but this limit is exceeded on storage. The author gives some particulars relating to Belgian and Danish beers of low alcohol-content.

—J. H. L.

Malic acid: Fermentation of—A. Lebedev, J. Russ. Phys.-Chem. Soc., 1916, 48, 725–748.

The separation and estimation of lactic acid in presence of malic acid by Kunz's method (Z. Unters. Nahr. Genussm., 1901, 4, 673) gives good results if 3 volumes of 96% alcohol instead of 2 volumes of 95% alcohol are added per 1 volume of solution; further, this addition must be made in small portions and with constant

stirring, otherwise the barium lactate is partly precipitated.

Attention is directed to the presence in commercial ether of acetaldehyde, alcohol, acetic acid, etc.; this is regarded as the source of the acetaldehyde detected by Buchner and Langheld in sugar solution fermented by means of yeast juice in presence of a phosphate.

Experiment shows that, in a concentration of 2%, malic acid is readily fermented by yeast, the decomposition it undergoes being, however, more complicated than that represented by the equation.

$\text{CO}_2\text{H}.\text{CH}_2.\text{CH}(\text{OH}).\text{CO}_2\text{H} = \text{CO}_2 + \text{OH}.\text{CH}(\text{CH}_2).\text{CO}_2\text{H}$. When its concentration is 4%, malic acid is only feebly fermented, evidently owing to the high acidity of the solution. All the results obtained show that the initial stage in the fermentation of malic acid consists in the scission of carboxyl from the group, $\text{CO}_2\text{H}.\text{CH}_2$, this change being perfectly analogous to the rupture of the aldol linking. On this account the author regards the carboxylase concerned, which is possibly not identical with the carboxylase of Neubauer and Neuberg, as belonging to the group of the aldolases. Such enzymes have not yet been isolated but undoubtedly exist, as is shown by the lactic and alcoholic fermentations of the hexoses, in which a chain of six carbon atoms is broken into two chains of three carbon atoms. It might be expected that many, if not all, dibasic acids containing the group $\text{CO}_2\text{H}.\text{CH}_2$ would be decomposed by carboxylase, and the same might be expected of polybasic acids, since citric acid is also readily fermented by yeast. In the fermentation of succinic acid, the latter appears to decompose firstly into carbon dioxide and propionic acid, but with malonic acid no decomposition is effected by yeast. The action of carboxylase is, therefore, specific. In presence of Methylene Blue, the fermentation of malic acid gives rise to acetaldehyde. It is found also that, in presence of acetaldehyde, a comparatively small proportion of lactic acid undergoes oxidation to pyrotartaric acid. The results show that, if lactic acid is fermented to alcohol and carbon dioxide, such reaction is extremely slow and must be regarded as a secondary one. From the fact that malic acid is dehydrated more slowly and feebly than lactic acid, it is supposed that in the decomposition of malic acid carbon dioxide is first split off, the lactic acid being liberated in an anhydrous condition.—T. H. P.

Tyrosol [p-hydroxyphenylethyl alcohol]; Biological synthesis of —. P. S. Pischtschimuka. J. Russ. Phys.-Chem. Soc., 1916, 48, 1—54.

THE greater part of this paper has been previously published (see Ehrlich and Pischtschimuka, this J., 1912, 506 and 1050). The formation of esters during the normal alcoholic fermentation of amino-acids appears to be a biological process of wide extent, its effect being to render harmless the excess of acids and alcohols, which would otherwise be injurious to the micro-organisms. A number of the esters of tyrosol have been prepared by ordinary chemical synthetical methods and are found to exhibit faint odours. The mixture of esters formed naturally during alcoholic fermentation has a pleasant odour, but this is probably due to the presence of admixed indole derivatives.—T. H. P.

XIXA.—FOODS.

Manufacture of Flour and Bread Order.

UNDER the "Manufacture of Flour and Bread Order (No. 2), 1917," it is compulsory on all millers to extract from the wheat not less than 81% of flour. Admixture of some other substance is compulsory to the extent of an additional 5%. Materials allowed to be mixed are rice, barley, maize, semolina, oats, rye, or beans, and the Food Controller reserves power to add any other cereal. Further admixture to the extent of an additional 10% is permitted. Mixtures must be made by the millers before selling their flour. The Order comes into effect as regards millers on March 12th and as regards vendors of bread on March 26th.

Egg albumin; Behaviour of ferric oxide and hydroxide towards —. M. A. Rakuzin. J. Russ. Phys.-Chem. Soc., 1916, 48, 95.

WHEREAS aluminium hydroxide is an excellent adsorbent and the adsorptive capacity of dry alumina is only 3—4 times less than that of the hydroxide, neither ferric hydroxide nor oxide exerts any adsorptive action when immersed for 24 hours in an aqueous solution of egg albumin. Since albumins are adsorbed more readily than other substances, it may be concluded that the latter will not be adsorbed by ferric hydroxide or oxide.—T. H. P.

Egg albumin; Adsorption of — by aluminium oxide and hydroxide. M. A. Rakuzin and E. M. Brando. J. Russ. Phys.-Chem. Soc., 1916, 48, 95—97.

ONLY when chemically pure does aluminium hydroxide exert its full adsorptive power on aqueous solutions of egg albumin. Commercial precipitated alumina is applicable as an adsorbent after having been dried to constant weight in a steam oven, such aluminium hydroxide then giving identical results in the hands of different experimenters. The adsorptive power is diminished by the presence of moisture. Aluminium oxide exerts but a feeble adsorptive action on albumin solutions. The above conclusions appear to hold also for solutions of substances other than albumin.—T. H. P.

Egg albumin; Specific gravity of aqueous solutions of —. M. A. Rakuzin and G. D. Flier. J. Russ. Phys.-Chem. Soc., 1916, 48, 458—461.

THE albumin of hens' eggs is in the state of a saturated solution containing about 15% of the albumin, together with small proportions of fats and salts. At 17° C. the saturated solution contains 15.35% and the specific gravities at this temperature of solutions of different concentrations are: 1%, 1.00283; 5%, 1.01341; 10%, 1.02666; 15%, 1.03942. The limiting solubility of albumin being 15.35%, the specific gravities for solutions of higher concentrations (up to 60%) given in Witz's table (*Chemiker-Kalendar*) are without experimental foundation. For 5% solutions, the following results were obtained: (1) untreated egg-albumin, sp. gr. at 15° C., 1.01341; $[\alpha]_D = -36.6^\circ$; (2) fat-free albumin, prepared by extraction with light petroleum, sp. gr. at 15° C., 1.01344; $[\alpha]_D = -36.6^\circ$; (3) fat- and salt-free albumin, obtained by treating a solution of the fat-free albumin with lead acetate and decomposing the lead albuminate with hydrogen sulphide, sp. gr. at 15° C., 1.01288; $[\alpha]_D = -36.6^\circ$ —T. H. P.

Protein "bodies" and "anti-bodies" as products of adsorption. M. A. Rakuzin. J. Russ. Phys.-Chem. Soc., 1916, 48, 465—468.

From analogy with the separation into toxin and anti-toxin occurring when anti-diphtheritic and other serums are treated with adsorbents, the author regards the selective adsorption of proteins, enzymes, etc., by aluminium hydroxide as separation into an adsorbed portion and a non-adsorbed "anti-body." Thus egg albumin $[\alpha]_D^{20} = -37.1$, yields 19.22% of adsorbed albumin, $[\alpha]_D^{20} = -56.0$, and 80.78% of "anti-albumin," $[\alpha]_D^{20} = -32.6$; egg albumin peptone, $[\alpha]_D^{20} = -95.24$, gives 24.49% of adsorbed peptone, $[\alpha]_D^{20} = -156.68$, and 75.51% of "anti-peptone," $[\alpha]_D^{20} = -75.0$; and diastase (optically inactive) yields 7.10% of adsorbed diastase I, and 92.90% of "anti-diastase," the latter but not the former giving Ostromyslenski's reaction with picramic acid. In the case of the solid paraffins of Grosny petroleum, adsorption effects removal of the lower homologues present, and it may be assumed that the adsorbed fractions of proteins, enzymes, and serums are also of lower molecular weight than the non-adsorbed fractions remaining in solution.—T. H. P.

Legumin as the analogue of casein. M. A. Rakuzin and G. F. Pekarskaja. J. Russ. Phys.-Chem. Soc., 1916, 48, 469—470.

LEGUMIN (Merck's) resembles casein in its physical and chemical characters. Contrary to the statement of Osborne and Harris concerning the legumin of horse-beans, it does not dissolve in 10% sodium chloride solution, but it dissolves in water containing 0.5% of hydrochloric acid (1:2) and 0.2% of pepsin, its specific rotation in this solution being $[\alpha]_D^{20} = -12.88$. It contains 0.16% of phosphorus and it gives the following colour reactions, the sensitiveness being indicated in brackets: biuret (1:3030), Millon's (1:1510), Adamkiewicz's (1:14920), Molisch's (1:14920), Pettenkofer's (1:3030), and Ostromyslenski's (1:1510).—T. H. P.

PATENTS.

Bread or the like: Manufacture and composition of —. E. S. and G. Roworth, Matlock Bath, and F. C. Lynn, Matlock. Eng. Pat. 100,295, Jan. 21, 1916. (Appl. No. 1024 of 1916.)

A PRODUCT for use in bread-making is prepared by mixing 5 lb. of cornflour, $4\frac{1}{2}$ lb. of starch, $\frac{1}{2}$ lb. of arrowroot, and $\frac{1}{2}$ lb. of sugar in 12 pints of water, pouring into 36 pints of boiling water, and boiling until gelatinised. A small quantity of alum may be used with the ingredients. In making bread, about 60 lb. of the product is divided into small pieces, added to the mixing water at 90—94° F. (32—34° C.), with yeast and salt, and worked into dough with 20 stones of flour in the ordinary way.—J. H. J.

Margarine: Manufacture of —. K. Esley, Nijmegen, Holland. Eng. Pat. 103,343, Jan. 26, 1916. (Appl. No. 1252 of 1916.)

FROM 0.5 to 1% of an alkali or alkaline-earth salt of formic, acetic, or propionic acid, or a mixture of the same, is added to the fat or ingredients in order to preserve the buttery aroma of the margarine. An alkali lactate may also be added if desired (see Eng. Pat. 2013 of 1915; this J., 1916, 324).—W. P. S.

Margarine: Preparation of an emulsion with fruity aroma from eggs to be used, especially in place of milk or cream, in the manufacture of —. L. Bernegau, Berlin-Halensee. Ger. Pat. 295,351, Mar. 21, 1914.

FRESH white-of-egg is treated at about 40° C. with freshly expressed pineapple juice (containing yeast cells), and the resulting liquid mixed with sugar, emulsified with fresh egg yolk, and sterilised by heating. The emulsion is suitable for blending with coconut oil or hydrogenated oils to produce an edible fat.—C. A. M.

Food suitable for cattle and poultry. Midland Cattle Products, Ltd., and J. Austin, Birmingham. Eng. Pat. 103,333, July 6, 1916. (Appl. No. 9519 of 1916.)

A MIXTURE of cereal meal, 2 parts, and fresh blood, 1 part by weight, is spread in layers not more than 0.5 inch thick, and dried. During the drying the temperature is raised gradually from 100° F. (38° C.) to 500° F. (260° C.). If necessary, the above mentioned quantities are varied so that the product shall contain approximately 20% of proteins and 70% of carbohydrates.—W. P. S.

XIXB.—WATER PURIFICATION; SANITATION.

Anthrax serum: Immunity studies on —. A. Eichhorn, W. N. Berg, and R. A. Kelsner. J. Agric. Res., 1917, 8, 37—56.

SIMILAR methods to those used in the preparation of diphtheria antitoxin were used in an examination of anthrax serum. When the serum was treated with 30% of saturated ammonium sulphate solution, the euglobulin was precipitated, and when the saturation of the filtrate was raised to 50%, the pseudoglobulin was precipitated and carried down the anthrax-immune bodies with it. This precipitate was pressed and dialysed in running tap-water, and the concentrate obtained in the dialyser was preserved with chloroform. When this globulin concentrate was injected into animals inoculated with anthrax, death was prevented in many cases. In analysing the serum and the globulin, the total coagulable protein was determined by adding acetic acid, filtering, and weighing the precipitate. The total globulin was determined by adding half-saturated ammonium sulphate solution and centrifuging at 3000 revolutions per min. for 40 mins. The liquid was poured off, the precipitate dissolved in distilled water, and the total coagulable protein determined. The therapeutic treatment of anthrax in animals and man with the serum and the globulin gave favourable results. Experiments were made on the standardisation of anthrax serum by means of the complement-fixation method, and the results pointed to this method proving an accurate one.—J. H. J.

PATENTS.

Water-softening. F. Blumenthal, Cologne-Braunsfeld, Germany. U.S. Pat. 1,212,007, Jan. 9, 1917. Date of appl. Apr. 26, 1915.

A SUBSTANCE for softening water is prepared by precipitating a solution of sodium silicate with a solution of ferrous chloride, and washing, pressing, and drying the precipitate, which forms into hard lumps. On being moistened, the lumps break up into particles of 1—2 mm. size, which are dried at a low temperature.—J. H. J.

Water, sewage, and liquid manufacturing-waste: Means for treating—F. Noble, Brooklyn, N.Y., U.S. Pat. 1,211,481, Jan. 9, 1917. Date of appl., Sept. 17, 1913.

THE polluted liquid is passed through a broad, shallow tank, containing submerged perforated receptacles holding calcium carbonate and hypochlorite. When these chemicals are saturated with the liquid, hypochlorous acid is evolved and is diffused through the liquid, producing oxidising effects. The suspended matter is deposited within the tank.—J. H. J.

Odours from gases, fumes, etc.: Device for eliminating—S. D. Eisendrath, Chicago, Ill., U.S. Pat. 1,211,691, Jan. 9, 1917. Date of appl., Apr. 7, 1913.

THE gas to be purified is collected in a receptacle and passes out from it at the top by a pipe with an inverted U-bend in which is a water spray. The pipe is connected with a discharge flue and has another upright U-bend in it, which has a spray directed into the bend, with a shield in front of the spray.—J. H. J.

Inse. ticides, sheep dip, and the like. G. J. Lemmens, Waterbury, and P. J. Fryer, Tonbridge, Kent, Eng. Pat. 103,458, Oct. 7, 1916. (Appl. No. 14,278 of 1916.)

THE fruit, berry, seed, or other portions of plants of the *Menispermaceæ* order (particularly *Cocculus indicus*, fish-berry) are ground and, if desired, mixed with soap, sulphur, or other ingredients.—W. P. S.

Liquid and solid materials [sewage]: Purification of—E. J. M. Janvier, Paris, U.S. Pat. 1,214,166, Jan. 30, 1917. Date of appl., Jan. 29, 1913. SEE Eng. Pat. 27,775 of 1913; this J., 1914, 1169.

Manufacture of manure from refuse. Eng. Pat. 103,148. See XVI.

XX.—ORGANIC PRODUCTS; MEDICINAL SUBSTANCES; ESSENTIAL OILS.

Thebaine: Conversion of—into hydroxycodeinone and its derivatives. M. Freund and E. Speyer, J. prakt. Chem., 1916, 94, 134—178.

THEBAINE on treatment with 30% hydrogen peroxide in acid solution, or with potassium bichromate and sulphuric acid, is converted into hydroxycodeinone, $C_{15}H_{19}NO_4$, decomposing at 275° C., and containing one methoxy group less than thebaine. It gives a well-crystallised oxime, $C_{15}H_{19}N_2O_4$, identical with the oxime prepared by boiling bromocodeinone with hydroxylamine, and gives a mono-acetyl derivative, m.pt. 185—186° C., and mono-benzoyl derivative, m.pt. 245—247° C. On treating hydroxycodeinone with methyl iodide, a compound, $C_{15}H_{19}NO_4 \cdot CH_3I$, is obtained which with sodium ethoxide solution gives N-methylhydroxycodeinone. The latter gives a well-crystallised compound with methyl iodide, which splits off trimethylamine on treatment with alkali but gives no crystalline nitrogen-free derivative. Thebaine oxidised with 30% hydrogen peroxide in absence of acid does not give hydroxycodeinone but a very small amount of a deep yellow base, dehydrothebaine, $C_{15}H_{19}NO_3$, m.pt. 178°—180° C., containing two methoxy groups, which forms deep-red salts. Hydroxycodeinone when reduced with zinc dust in glacial acetic acid solution gives hydroxycodeine, $C_{15}H_{21}NO_4$, m.pt. 293° C., insoluble in alkali and containing no keto group, but giving

a monoacetyl derivative; whilst when reduced with stannous chloride and hydrochloric acid it yields an isomeric hydroxycodeine, hydroxythebainone, containing a keto group, and soluble in alkali, and probably constituted analogously to the thebainone obtained by reducing thebaine with stannous chloride and hydrochloric acid. Hydroxycodeinone on treatment with hydrogen in presence of platinum black or palladous chloride solution gives a tertiary base, dihydrohydroxycodeinone, m.pt. 220—222° C., isomeric with hydroxycodeine and hydroxythebainone, which forms well-crystallised salts and gives an oxime and an acetyl and benzoyl derivative. Dihydrohydroxycodeinone on warming with sodium amalgam is converted into a compound, m.pt. 219—220° C., of different solubility and crystalline form but which yields the same derivatives and hence is probably a tautomeric form of dihydrohydroxycodeinone. By progressive methylation with methyl iodide, dihydrohydroxycodeinone gives a series of compounds, and eventually, on heating with alkali, a nitrogen-free substance, $C_{17}H_{16}O_4$, m.pt. 214°—215° C., is obtained containing one methoxy and one keto group. Dihydrohydroxycodeinone on reduction with sodium amalgam in alcoholic solution is converted into dihydrohydroxythebainone, $C_{15}H_{23}NO_4$, m.pt. 145° C., giving well-crystallised salts and particularly a well-crystallised perchlorate, m.pt. 270° C. The constitutional formulae of hydroxycodeinone and these derivatives and the relationships between the constitutional formulae proposed and the constitutional formulae proposed for codeine and thebaine by Knorr and Helein and also by the present authors (this J., 1907, 213; 1916, 1032) are fully discussed.—T. C.

Phenylglucosides: Synthesis of the—E. Fischer and L. von Mehel, Ber., 1916, 49, 2813—2820.

WHEN a mixture of acetobromoglucose, 50 grms., dry phenol, 160, and quinoline, 19 grms., is heated on the water-bath for 1½ hours, treated with dilute acid, and shaken out with ether, there is obtained, after distilling off the excess of phenol *in vacuo*, a crystallisable residue (yield 32 grms.) consisting of a mixture of two isomeric tetra-acetylphenylglucosides in the proportion of 6 parts of the β -isomeride to 1 of the α -compound. These are easily separated by crystallisation from carbon tetrachloride and yield on saponification with barium hydroxide the already known β -phenylglucoside, hydrolysable by emulsin, and α -phenylglucoside, which is hydrolysed by yeast enzymes. The use of quinoline in the above manner affords a general method for the preparation of glucosides of aromatic, hydro-aromatic (e.g., menthol), and aliphatic alcohols. α -Phenylglucoside crystallises with 11H₂O, melts at 173°—174° C. (corr.), and has $[\alpha]_D^{20} = +180$; the corresponding tetra-acetyl compound melts at 115° C. and has $[\alpha]_D^{20}$ in benzene solution = +165. β -Phenylglucoside crystallises with 21H₂O, melts at 175°—176° C., and has $[\alpha]_D^{20} = -71.7$; its tetra-acetyl derivative melts at 127—128° C. and has $[\alpha]_D^{20} = -28.9$.—J. F. B.

Lichens: Constituents of—II. *Synthesis of rhizonic acid* A. Sonn, Ber., 1916, 49, 4589—4593.

m-DINITRO-*p*-XYLENE, which is readily obtained from *p*-xylidine, was converted by Kostanecki's method (this J., 1886, 599) into 2-nitro-*p*-xylen-6-ol and the latter methylated by treatment with dimethyl sulphate. The ether thus obtained was reduced and the amino group replaced by hydroxyl, with the formation of β -orcinol monomethyl ether (I). An aldehyde group was then introduced in

the *para* position to the hydroxyl by the action of hydrogen cyanide and chloride in presence of aluminium chloride, and the aldehyde after acetylation was oxidised with permanganate, the resulting acid after the removal of the acetyl group being identical with rhizonic acid (II), produced by the hydrolysis of naturally occurring barbatinic acid.—G. F. M.

Storax in perfumery. Chem. and Drug., Oct. 21, 1917.

MUCH of the storax of commerce is impoverished by the removal of cinnamic acid, to the compounds of which the peculiar odour of storax is due. The cinnamic acid content of storax may fall below 3%, although 30% is about the normal figure. The British Pharmacopoeia requires only 20% of the acid in the prepared storax, which represents at least 16 or 18% in the imported article, but more is really shown by the best gum-resins. Under these circumstances, it may be that, if attention were directed to other sources of cinnamic acid, it might pay better to utilise them for perfumery purposes, and to leave the storax for medicinal use. The liquid balsam of *Liquidambar styraciflua*, known in the United States as sweet gum, and used in the preparation of chewing-gums, was shown in the Nicaragua and Guatemala departments of the 1878 International Exhibition in Paris. It was in the form of a clear brownish-yellow liquid of the consistence of virgin honey, without the admixture of water usual in Asiatic storax. According to Gildemeister and Hoffmann, this storax closely resembles in almost all its properties the storax of the Levant, the oil distilled from it differing chiefly in not containing ethyl and benzyl alcohols, and in being dextro-rotatory. Another source of cinnamic acid which has not been exploited in this country is the balsam obtained in Brazil from *Myroxylon Peruvianum*. The odour of the balsam resembles that of balsam of Peru, from which it differs in readily mixing with castor oil in all proportions, thus possessing a considerable advantage for perfumery purposes. The oily portion of this balsam, containing the cinnamic acid, can be separated from it by benzene and petroleum ether. Another source of cinnamic acid is the resins of various species of *Xanthorrhoea*, called "grass-tree gums" in Australia, the best known of which in English commerce are *acaroides* (*Xanthorrhoea arborea*) and black-boy "gum" (*X. hastilis*). Although the percentage of cinnamic acid in them is small, the quantity of resin available is enormous. The volatile oil distilled from *acaroides* contains a considerable quantity of cinnamic acid, the proportion being 20% when crystallised from water. The oil itself has a storax-like odour, and, like storax, contains styrene. The liquid balsam obtained by incision from *Liquidambar Allingiana*, Blum., to which the name of "Rasamalas" is applied by the Malays, in common with that of *L. orientalis*, is deserving of examination as a source of cinnamic acid. This balsam is obtainable in Tenasserim and Borneo. It may be noted, however, that these trees only produce the balsam when the climate is warm, i.e., in latitude 20°–30°. *L. styraciflua* stands the winter in this country, but produces no balsam; and although the tree occurs as far north as Connecticut and Illinois in North America, the product is commercially produced only in the sub-tropical countries, such as Mexico, Guatemala, and Nicaragua.

Camphor: Comparative physiological action of natural and synthetic—G. Joachimowicz. Ber. deut. Pharm. Ges., 1916, 26, 427–455.

Owing to the cessation of imports of Japanese natural camphor, the German medical authorities at the beginning of the war recommended that synthetic camphor should be substituted for natural camphor in preparations intended for external use only. An extended series of comparative physiological and germicidal experiments using natural *d*-camphor, *l*-camphor, $[\alpha]_D = -10^\circ$, m.pt. 176–177°C., and synthetic camphor, $[\alpha]_D = +3.025$ (Schering) and $[\alpha]_D = -0.225^\circ$ (Boehringer), carried out on cats, using an intra-peritoneal injection in olive oil solution, on the isolated frog's heart, and with *B. coli* and *Vibrio Metchnikoff*, gave results showing that there is no qualitative or quantitative difference in the physiological or germicidal action of the three modifications of camphor, and hence synthetic camphor can effectively replace natural camphor also for internal use.—T. C.

Santene: Complete synthesis of—G. Komppa and S. V. Hintikka. Bull. Soc. Chim., 1917, 21, 13–19.

CAMPHENONE was converted by reduction into the corresponding alcohol, campheninol, and the latter either on dehydration with sodium bisulphate or by the removal of the elements of hydrogen chloride from its chloride, camphenyl chloride, gave a hydrocarbon mixture consisting essentially of a smaller fraction, b.pt. 136–140°C., to which the name camphenylene is given, and a larger fraction, b.pt. 110–112°C., which was shown to consist mainly of a hydrocarbon identical with santene. By the action of sulphuric and acetic acids identical acetates were obtained from both the synthetic and natural hydrocarbons, and the alcohol previously termed isocampheninol, m.pt. 60–65°C., obtained by their saponification, is therefore identical with santenol. This identity was further proved by the oxidation of both isocampheninol and santenol to santenone and santenic acid.—G. F. M.

Fenchylene, a new synthetic terpene. S. S. Nametkin and A. K. Rushneeva. J. Russ. Phys.-Chem. Soc., 1916, 48, 450–452.

WHEN heated at 230°C., methyl isofenchylxanthate undergoes partial decomposition, yielding the new hydrocarbon, fenchylene.

which is a volatile liquid with a faint but characteristic odour recalling that of fenchene; it boils at 139–140°C. under 760 mm. pressure, has sp. gr. 0.8381 at 20°/4°C., $n_D = 1.4491$ at 20°C., and $[\alpha]_D = -68.76^\circ$ (in alcohol). The hydrocarbon unites energetically with bromine, yields a crystalline nitroschloride, and gives *cis*-fenchocamphoric acid when oxidised with alkaline permanganate.—T. H. P.

Catalysis: Heterogeneous—[Polymerisation of pinene: decomposition of carbon bisulphide.] L. G. Gurvitch. J. Russ. Phys.-Chem. Soc., 1916, 68, 837–856.

DETAILED investigation of the reaction of pinene with floridin (see this J., 1915, 1231) leads to the conclusion that the initial products of this reaction are polyterpenes which, under the influence of the heat developed, subsequently undergo partial decomposition into simple terpenes. The formation of the polyterpenes is caused by the adsorption of the pinene on the surface of the floridin, propinquity of the pinene molecules being thus

effected; factors which impede this adsorption also retard the transformation of the pinene. A catalytic reaction of another type has been discovered in the action on carbon bisulphide of the partly dehydrated aluminium hydroxide obtained from metallic aluminium in presence of traces of mercury: this reaction, which proceeds at the ordinary temperature, is expressed by the equation, $\text{CS}_2 + 2\text{H}_2\text{O} = 2\text{H}_2\text{S} + \text{CO}_2$. The yield of hydrogen sulphide attains a maximum for a certain percentage of water in the alumina, and it is assumed that the transformation of the carbon bisulphide is a result of its adsorption, that is, of the approach of the carbon bisulphide molecules to the water molecules within the sphere of action of the molecules of alumina. In a similar manner, alumina prepared as described above causes the conversion of ethyl chloride into ethyl alcohol in the cold. The hypothesis that adsorption always forms the basis of heterogeneous catalysis also furnishes a very simple explanation of those reactions in which the formation of intermediate chemical compounds is usually assumed, for instance, the reactions of Ipatiev, Sabatier, Bredig, etc.—T. H. P.

α -Phenyl- Δ^7 -butadiene: Polymerisation of —. S. V. Lebedev and A. A. Ivanov. J. Russ. Phys.-Chem. Soc., 1916, 48, 997—1008.

α -PHENYL- Δ^7 -BUTADIENE is able to polymerise into two different products, one of them soluble, obtained on heating, and the other, insoluble, obtained at the ordinary temperature in the light. The authors find that the dimeride is a monocyclic hydrocarbon containing two double linkings; it combines with 2 mols. of hydrogen or with 2 mols. of ozone, and on oxidation with permanganate yields benzoic acid and an acid, $\text{C}_{13}\text{H}_{14}\text{O}_6$. The character of the polymerisation and the properties of the dimeride and of the polymeride indicate that in spite of individual divergences, the type of the polymerisation is the same as with derivatives of diphenyl containing aliphatic substituents. According to the scheme previously given by Lebedev (this J., 1914, 1223, 1224), the formation of the dimeride is expressed thus:—

the resulting product being 2-phenyl-4-styryl-cyclohexene and its oxidation product, α -phenyl-butane- α,γ -tricarboxylic acid, $\text{CO}_2\text{H}\cdot\text{CH}(\text{C}_6\text{H}_5)\cdot\text{CH}_2\cdot\text{CH}(\text{CO}_2\text{H})\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$. The crude polymeride obtained by heating α -phenyl- Δ^7 -butadiene at 150°C . is a colourless, viscous liquid and the dimeride separated by distillation in an atmosphere of hydrogen consists almost entirely of the modification with the higher boiling point. The pure dimeride boils at $197^\circ\text{—}196.5^\circ\text{C}$. under 5 mm. pressure and has the sp. gr. at $20^\circ/1^\circ\text{C}$. 1.0332, and the refractive index, $n_D^{20} = 1.60570$ at 20°C . The polymeride, $(\text{C}_{10}\text{H}_{10})_x$, is formed to the extent of 5% at 150°C . and is a powdery mass coagulating at about 90°C .; its behaviour towards ozone is that of polymerides of divinyl hydrocarbons, the resultant compound, $(\text{C}_{10}\text{H}_{10}\text{O}_4)_x$, being a white solid. It is concluded that the structure of the polymeride is represented by the scheme,

—T. H. P.

Toxins and antitoxins: Adsorption of — by aluminium hydroxide: Koch's tuberculin. M. A. Rakuzin and G. D. Flier. J. Russ. Phys.-Chem. Soc., 1916, 48, 711—716.

Of the eight ordinary colour reactions of the

proteins, the only one not given by tuberculin is the violet coloration with fuming hydrochloric acid (Liebmann's reaction); since, further, tuberculin contains phosphorus, it must be regarded as an analogue of casein. In aqueous solution its specific rotation is $[\alpha]_D = -11.62$. By adsorption with aluminium hydroxide, it is separated into: (1) 4.11% of an adsorbed antitoxin which gives only Molisch's and Ostromyslenski's reactions (this J., 1916, 133), and in composition and properties resembles pepsin, the latter giving only Molisch's reaction; (2) 95.56% of a non-adsorbed toxin which, like casein, gives the biuret, Millon's, xanthoprotein, Adamkiewicz's, Molisch's, Pettenkofer's, and Ostromyslenski's reactions. The adsorption is irreversible.—T. H. P.

Nucleic acids and alkali nucleates: Rotatory powers of —. M. A. Rakuzin and E. M. Braudo. J. Russ. Phys.-Chem. Soc., 1916, 48, 97—99.

MEASUREMENT of the rotation of commercial 5% nucleic acid solution (Parke, Davis and Co.) gives the value $[\alpha]_D = +68.51$ for the nucleic acids. As with the caseinogenates, the rotatory powers of the alkali nucleates increase with the atomic weight of the metal.—T. H. P.

Cholesterol and isocholesterol: Separation of —. A. Madinaveitia and A. Gonzalez. Ann. Soc. Esp. Ph. Ch., 1916, 14, 398—401. Bull. Soc. Chim., 1917, 22, 41.

CHOLESTEROL and isocholesterol, obtained together by energetic saponification of lanolin (cp. Moreschi, this J., 1910, 1168), may be separated after conversion into benzoates. Cholesteryl benzoate crystallises in plates and the iso-compound in needles, and the former may be separated from the latter by elutriation with water (Schulze). A better method of separation is to dissolve the mixed alcohols in ether and add an ethereal solution of anhydrous oxalic acid. A crystalline precipitate containing the two oxalates is formed. Cholesteryl oxalate, m.p. 175°C . $[\alpha]_D^{20} = -29$, separates first. The residue from the evaporation of the mother liquors has $[\alpha]_D^{20} = +27$. The former is readily converted into pure cholesterol, m.p. 147°C . The mother liquors, on treatment with benzoyl chloride, yield isocholesteryl benzoate, m.p. 190°C .—J. H. L.

Nitriles: Transformation of — into amides by hydrogen peroxide. L. McMaster and F. B. Langreck. J. Amer. Chem. Soc., 1917, 39, 103—109.

By using hydrogen peroxide of higher concentration it is possible to prepare amides from nitriles which cannot be transformed by weaker solutions of the peroxide. The transformation of benzonitrile, *m*-nitrobenzonitrile, *o*-tolunitrile, *p*-tolunitrile, *n*-naphthonitrile, terephthalnitrile, trichloroacetoneitrile, and isobutyrlacetoneitrile into the corresponding amides is described. *Benzonitrile*.—5 grms. of benzonitrile was added to 50 c.c. of a 6% solution of hydrogen peroxide and the mixture made slightly alkaline with sodium hydroxide, stirred by means of a motor-driven apparatus, and the temperature kept at 65°C . for 1.5 hours, during which time the amide separated out as white flakes. The stirring was then interrupted and the mixture cooled with ice and salt, whereupon more of the amide separated. It was filtered off, washed with cold water, dried over sulphuric acid for 18 hrs., and crystallised from absolute alcohol. Yield 92%. *m*-Nitrobenzonitrile.—1 gm. of the nitrile was added to 15 c.c. of a 20% solution of hydrogen peroxide, the mixture made slightly alkaline and heated to 65°C . The mixture was shaken vigorously, and allowed to

dark, with occasional shaking, for 24 hours. The pale yellow crystals which had separated were filtered off, washed with cold water and dried on a suction filter. The crystals were dissolved in a minimum amount of hot absolute ethyl alcohol, and the amide freed from any unchanged nitrile by suddenly cooling the hot solution in a freezing mixture. The nitrile, being less soluble than the amide, crystallised out first and was filtered off. On allowing the alcohol to evaporate, the amide crystallised out. Yield 80%. *o*-Tolunitrile, — 10 c.c. of a 15% solution of hydrogen peroxide was added to 1.1 gm. of the nitrile in a large test-tube, the mixture was made slightly alkaline, heated to 65° C., and shaken vigorously. After standing 24 hours a white crystalline mass had formed at the surface of the liquid. On warming the mixture again, the unchanged nitrile separated from the enclosing crystalline mass. The contents of the tube were again heated to 65° C., shaken, and allowed to stand for another 24 hours. The crystals were filtered off on a suction filter, dried, and re-dissolved in absolute ethyl alcohol. From the third recrystallisation the amide separated as white, semi-transparent needles, readily soluble in alcohol, moderately in ether, and quite insoluble in cold water. Yield 90%. J. B. C. K.

Collargol [colloidal silver]: Preparation of —, A. F. Gerasimov, J. Russ. Phys.-Chem. Soc., 1916, 48, 251–253.

INVESTIGATIONS on the preparation of collargol by Paal's method (this J., 1902, 916, 991) show that the reduction to metallic silver takes place mainly, if not entirely, at the expense of the silver oxide, preparations with approximately the same proportion of silver being obtained with widely varying concentrations of silver nitrate. The percentage of silver in the preparations is increased but slightly by precipitation with acids. On the basis of these results the following method of obtaining collargol is recommended. The reducing mixture is prepared by shaking 100 grms. of albumin with a solution of 15 grms. of sodium hydroxide in 500 c.c. of water until it is uniformly distributed throughout the liquid, which is then heated for about an hour in a water-bath and freed from a little flocculent precipitate by filtration. To 27–30 grms. of this solution is added the silver oxide obtained by precipitating a solution of 10 grms. of silver nitrate with potassium hydroxide and washed five times by decantation. The mixture is diluted to about 200 c.c. and heated in a water-bath, with constant shaking, for 40–60 minutes. When cold, the liquid is precipitated with a few drops of concentrated acetic acid and the precipitate washed 5 or 6 times and then dissolved in water in presence of a very small quantity of sodium hydroxide. The liquid is allowed to settle and dried, either in a desiccator over sulphuric acid or in a vacuum at about 10° C., or in a current of air free from dust; over-drying should, however, be avoided. By this method, a blue powder containing about 75% of silver is obtained. — T. H. P.

Glycerin for medicinal purposes: Substitute for —, J. Leemox, Pharm. J., 1917, 98, 186.

IRISH moss ($\frac{1}{2}$ oz.) is boiled with water for 15 mins., the extract is made up to 19 fl. oz., and 1 oz. of glucose is added.

Chemical constituents of sulphur-containing bituminous tur oils, ichthol oils, Scheibler, See IX.

Influence of the climatic conditions on the composition of vegetable oils, Pigulevski, See XII.

Immunity studies on anthrax serum, Eichhorn and others, See XIXb.

PATENTS.

Glycocoll: Process for separating — from inorganic compounds, G. Weinberg, Berlin, Ger. Pat. 291,821, Sep. 22, 1915.

THE solution of glycocoll and sodium chloride obtained in the usual way from monochloroacetic acid, ammonia, and a quantity of sodium hydroxide approximately equivalent to the monochloroacetic acid, is concentrated by heat, after evaporation of the ammonia, whereby the bulk of the sodium chloride separates from the hot solution, whilst on cooling the mother liquor the glycocoll crystallises. — C. A. M.

Picolaldehyde: Process of preparing —, L. Schmidt, Munich, Ger. Pat. 295,337, Sep. 30, 1915. Addition to Ger. Pat. 278,778 (see Fr. Pat. 471,986; this J., 1915, 249).

THE piperonal diacetate, obtained from piperonal as described in the original patent (*loc. cit.*), is treated with chlorine, and the resulting dichloro-piperonal diacetate is decomposed with water. No chloroacetic acid derivatives are formed during the chlorination. — C. A. M.

Barbituric acid: Preparation of ether-like derivatives of —, Farbenfabr. vorm. F. Bayer und Co., Ger. Pat. 295,192, Jan. 31, 1915.

ALKYL- or aralkylaryloxyalkylmalonic acids or diaryloxyalkylmalonic acids or their derivatives, e.g., the corresponding esters, acid chlorides, cyanacetates, or malononitriles, are converted into barbituric acid derivatives by the usual methods. Alternatively, monosubstituted malonic acid derivatives containing one of the above specified substituent groups are converted into barbituric acids and the second substituent group is introduced by alkylation of the resulting monosubstituted barbituric acids or of the product at an intermediate stage of the conversion. Such ether-like derivatives, containing at least one aryl residue attached to an oxygen atom, possess strong hypnotic action combined with low toxic effects. Ethylphenoxyethylbarbituric acid, diphenoxyethylbarbituric acid, C.C-propyl-*p*-cresoxyethylbarbituric acid, and C.C-benzylphenoxyethylbarbituric acid are described. — J. F. B.

Hexamethylenetetraminemethylhydroxide: Preparation of salts of —, K. H. Schmitz, Breslau, Ger. Pat. 295,736, Sept. 20, 1913.

AMMONIA, formaldehyde or one of its polymerides, and an acid or acid ion are heated for several hours and the product treated with a soluble bichromate; the resulting sparingly soluble chromate, of composition corresponding to the formula $[C_6H_{12}N_4CH_3]_2Cr_2O_7$, is decomposed with barium hydroxide, and the precipitated barium chromate filtered off. Alternatively, hexamethylenetetraminemethylhydroxide chloride, bromide, iodide, or thiocyanate is digested with silver oxide, the resulting solution of the free base is concentrated *in vacuo*, neutralised by any desired inorganic or organic acid to form the corresponding salt, and the solution evaporated *in vacuo*. The salts of this base possess the property of liberating formaldehyde in alkaline solutions, which is not the case with hexamethylenetetramine salts, and have a therapeutic value. — J. F. B.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

Hydrogen peroxide reaction: Catalysts in the —, [Prevention of fogging of photographic plates, etc.] Lüpcke-Cramer, Phot. Ind., 1916, Heft 43. Z. angew. Chem., 1917, 30, Ref., 23

THE fogging action of terpenes, resins, wood,

packing-papers, etc., on photographic sensitive materials, generally recognised to be due to the formation of hydrogen peroxide, can be prevented by the interposition of paper containing finely divided manganese dioxide which catalytically destroys the peroxide. Such protective paper is most easily prepared by soaking filter paper or black packing paper in 1% solution of potassium permanganate. (See also Russell, this J., 1899, 516.)—B. V. S.

Osmotic pressure of gelatin. Biltz and others. See XV.

PATENT.

Development films free from damp spots; Preparation of—on various baryta-coated bases. Chem. Fabr. auf Actien vorm. E. Schering. Ger. Pat. 295,502, Nov. 27, 1913.

BARYTA-COATED paper, mica, or celluloid is coated with a solution of albumin before applying the sensitive emulsion.—B. V. S.

XXII.—EXPLOSIVES; MATCHES.

Relation of oxygen to heat of combustion of organic compounds. Thornton. See IIA.

PATENT.

Explosives. Stockholms Superfosfat Fabriks Aktiebolag, Stockholm. Eng. Pat. 17,583, Dec. 16, 1915. Under Int. Conv., Dec. 23, 1914.

EXPLOSIVES possessing the favourable qualities of dynamite, but cheaper and having a much lower freezing point, are made up of the following constituents:—(A) Ammonium perchlorate, 74—80; ferrosilicon or other silicide, 6—18; wood meal, 2—6; nitrated or unnitrated naphthenes (residues from distillation of mineral oils), 4—10 parts by weight. (B) Ammonium perchlorate, 74—80; ferrosilicon, 6—18; wood meal, 2—6; nitrated or unnitrated naphthenes, 4—10; and liquid nitrotoluenes gelatinised with nitrocellulose, 10—12 parts by weight. The ferrosilicon serves to raise the temperature of explosion, and the wood meal increases the speed of detonation.

XXIV.—MISCELLANEOUS ABSTRACTS.

Specific heats of aqueous-alcoholic solutions; Calculation of—. N. A. Kolosovskii. J. Russ. Phys.-Chem. Soc., 1916, 48, 84.

THE specific heats of aqueous-alcoholic solutions may be calculated by means of the empirical formula, $C = 1 + n(C_0 - 1) + 0.004x - 0.00012x^2 +$

$0.00000069x^3$, where C is the required specific heat of the aqueous-alcoholic solution of substance, A , n the number of gram.-equivalents of this substance per 200 mols. of water in the given aqueous-alcoholic solution, x the number of molecules of alcohol per 200 mols. of water and C_0 the specific heat of an aqueous solution of 1 gram.-equivalent of substance A in 200 gram.-mols. of water. The value of C_0 is obtained from tables of physical constants. In 34 cases in which direct measurements were made of the specific heats of aqueous-alcoholic solutions, the difference between the experimental and calculated values was less than 0.005 in 27 cases and between 0.006 and 0.010 in the remaining 7 instances.—T. H. P.

Trade Report.

Prohibited exports.

AN Order-of-Council, dated 23rd February, makes the following alterations in the list of exports prohibited:—

The following headings are deleted:—(1) Copper wire and cables containing copper; (3) cordite presses; (2) gauze manufactured of copper or its alloys; (3) incorporators; (3) copper ore; (2) copper, unwrought and part wrought, all kinds, including alloys of copper (such as brass, gun metal, naval brass and delta metal, phosphor copper, phosphor bronze, and solder containing copper), copper and brass circles, slabs, bars, ingots, scrap, rods and plates and also wrought copper of the following descriptions:—Copper and brass pipes, sheets, condenser plates, brass wire, bronze wire, perforated brass sheets, perforated brass linings, and copper foil; (3) all articles wholly or partly manufactured of copper or its alloys not otherwise specifically prohibited; (2) yellow metal.

The following headings are added:—(1) Cordite presses; (1) incorporators; (1) copper ore, regulus, matte, concentrate and precipitate; (1) copper, whether refined or unrefined, unwrought, wrought or partly wrought, of all kinds and descriptions including brass, bronze, yellow metal, and all other alloys of copper; (1) all articles wholly or partly manufactured of copper or its alloys, except: (a) Articles partly manufactured of copper or its alloys exported before the 9th day of March, 1917, to all destinations not in foreign countries in Europe or on the Mediterranean or Black Sea, other than France and French Possessions, Russia, Italy and Italian Possessions, Spain and Portugal, and to all ports not in any such foreign countries, except Russian Baltic ports; and (b) articles partly manufactured of copper or its alloys in which the total weight of copper and copper alloy does not exceed 5% of the total weight of the article, and does not exceed 56 lb.

Prohibited imports. Prohibition of Import (No. 14) Proclamation, 1917.

A PROCLAMATION, dated 23rd February, prohibits as from that date the importation into the United Kingdom of the following goods, exception being made in respect of such goods as are imported under licence given by or on behalf of the Board

* The prohibition of exports is as follows:—

Goods marked (1) to all destinations;

Goods marked (2) to all ports and destinations abroad other than ports and destinations in British Possessions and Protectorates;

Goods marked (3), to all destinations in foreign countries in Europe and on the Mediterranean and Black seas, other than France and French Possessions, Russia, Italy and Italian Possessions, Spain and Portugal, and to all ports in any such foreign countries, and all Russian Baltic ports.

of Trade, and subject to the provisions and conditions of such licence:—Aerated, mineral and table waters. Antimony ware. Brandy. Cocoa, preparations of. Cocoa, raw. Diatomite and infusorial earth. Fruit, raw, of all descriptions (except lemons and bitter oranges), and almonds and nuts used as fruit. Glass manufactures not already prohibited. Hides, wet and dry. Incandescent gas mantles. Leather, dressed and undressed. Painters' colours and pigments. Perfumery. Photographic apparatus. Plated and gilt wares. Quebracho, hemlock, oak and mangrove extract. Rum. Soya beans. Sugar, articles and preparations containing, used for food (except condensed milk). Wine. Wood and timber of all kinds, hewn, sawn or split, planed or dressed.

List of trades and occupations of primary importance.

THE Reserved Occupations Committee has issued a list of trades and occupations which have been declared by the Government to be of primary importance. The following occur in this list:—*Mining and quarrying.* Coal mining. Patent fuel works. Oil shale mining, including shale oil works. Iron mining and quarrying. Copper mining. Tin and wolfram mining. Lead mining. Fireclay and silica stone mining and quarrying. Gaiister mining and quarrying. Limestone quarries (mainly supplying iron, steel, or chemical works). *Metals, machines, implements and conveyances.* All classes of workers engaged in the manufacture of the following metals or their constituent parts from the treatment of the ore to the production of the metal in standard forms, such as ingot, billet, bloom, bar, rod, sheet or section:—Aluminium, copper, iron, steel, lead, nickel, tin (smelting only), spelter, zinc and other metals (e.g., tungsten, vanadium, wolfram) needed for war purposes, and their alloys (e.g., brass, phosphor bronze). Iron foundries and steel smelting works and rolling mills. Electrical accumulator manufacture and repairing. Scientific instrument making. Slag wool making. *Pottery and glass trades.* Chemical ware (stoneware and fireclay) manufacture. Furnace firebrick (including gaiister and silica brick) manufacture. Optical and chemical glass manufacture. Optical lens and prism making. Other glass manufacture (except table and decorative ware and bottles for beer, wine, spirits and aerated waters). *Chemical, oil, etc., trades.* Coal tar products, manufacture of. Dyestuffs, manufacture of. Explosives and propellants, manufacture of. Other chemical products, manufacture of. Lubricating oils and other lubricants, manufacture of. Oil-seed crushing. Soap and candles, manufacture of. Fertilisers, manufacture of. *Leather trades.* Hide and skin markets and fat and bone factories. Fellmongery. Tanning and currying of heavy leather. Leather transmission belting manufacture. *Food trades.* Flour, oatmeal and rice milling. Machine creameries and condensed milk and milk powder factories. Margarine manufacture. Edible oils and fats, preparation of. Sugar refineries working under Government. *Miscellaneous.* Coke, manufacture of. Rubber trades. Waterproofing of fabrics for war purposes, and of paper. *Public utility services.* Gas works. Water works.

Books Received.

THE FOOD SUPPLY OF THE UNITED KINGDOM. A REPORT drawn up by a Committee of the Royal Society at the request of the President of the Board of Trade. [Cd. 8121.] H.M. Stationery Office, London. Price 4d. (See page 279.)

INDUSTRIAL AND MANUFACTURING CHEMISTRY. INORGANIC. Vol. I. By GEOFFREY MARTIN and others. 496 pages. Crosby Lockwood and Son, 7, Stationers' Hall Court, London, E.C. Price 25s.

THE present volume, which is similar in style and arrangement to the work dealing with organic chemical industries by the same author, is divided into fifty-one sections, in each of which an industry is dealt with very briefly, with copious references to the literature. The wide range of subjects covered is indicated by the following list of sectional headings and authors:—I. Solid fuels, by A. B. Searle. II. Manufacture of briquettes, by J. L. Foucar. III. Liquid fuels, by A. B. Searle. IV. Furnaces, by A. B. Searle. V. Coke ovens, by G. Martin. VI. Surface combustion, by E. Jobling. VII. Pyrometry and pyroscopy, by A. B. Searle. VIII. Refrigerating and ice-making machinery, by G. Martin. IX. Liquefaction of gases, by J. M. Dickson. X. Industrial oxygen, by G. Martin. XI. Industrial nitrogen, by G. Martin. XII. Industrial hydrogen, by H. S. Redgrove. XIII. Producer-gas, by H. S. Redgrove. XIV. The carbon dioxide industry, by H. S. Redgrove. XV. Industrial ozone, by E. Jobling. XVI. The technology of water, by H. H. Hodgson. XVII. Artificial mineral waters, by C. A. Mitchell. XVIII. The sulphur industry, by G. Martin and J. L. Foucar. XIX. Sulphuric acid, by G. Martin and J. L. Foucar. XX. Manufacture of sulphur dioxide and sulphites, by G. Martin and J. L. Foucar. XXI. Manufacture of other sulphur compounds, by G. Martin. XXII. The salt industry, by G. Martin. XXIII. Manufacture of hydrochloric acid, by G. Martin. XXIV. Manufacture of sodium sulphate (salt cake), by G. Martin. XXV. to XXVII. Sodium carbonate, by G. Martin and S. Smith. XXVIII. TECHNICAL CHEMISTS' HANDBOOK. Tables and methods of analysis for manufacturers of inorganic chemical products. By G. LUNGE. Ph.D. Second Edition. Revised. Gurney and Jackson, 33, Paternoster Row, London. 1916. 264 pages, with 21 illustrations. Price 10s. 6d. net.

IN this new edition of Dr. Lunge's well-known handbook, all the analytical factors have been recalculated on the basis of the atomic weights published by the International Committee for 1916, and the tables of specific gravity and other tables have been altered in accordance with the most recent and reliable determinations.

Official Notices.

REPORTS OF THE PROGRESS OF APPLIED CHEMISTRY.

The first volume of these reports will be issued during April. The manuscript of some of the sections not having come to hand, the volume will not be as comprehensive as was at first proposed, but it was decided to present an incomplete volume rather than delay publication any further.

CROSS AND BEVAN ESSAY PRIZE OF £20 AND LATHAM RESEARCH GRANT OF £300.

The Council have pleasure in announcing that a gift of £20 has been made by Messrs. Cross and Bevan as a prize for an essay on "The Interconnection of Economic Botany and Chemical Industry."

A further sum of £300 has also been presented by their friend, Mr. T. P. Latham, of Weybridge, to be paid in three annual instalments to such one of the competing essayists as may be judged to be of conspicuous ability, as a grant towards his expenses, on the condition that he apply himself, during three years, to research of approved character on a subject cognate with that discussed in his essay.

The immediate object of the donors is to promote the study of economic botany with special reference to its bearing on chemical industry, giving the widest possible interpretation of the relationship.

They desire, under the auspices of the Society, to assist in forming public opinion in this direction and to discover and further the career of a student of promise who may wish to devote himself to work in such a field.

The Essay Prize will be open to all members of the Society who are British subjects. The Research Grant will be limited to competitors under 25 years of age at the time of sending in the essay.

Essays are to be submitted to the Council of the Society not later than the close of the year 1917. The awards will be made promptly. Neither the prize nor the first grant will be given unless the essayist or essayists shall be deemed to have real merit. The Latham Research Student will be required to submit a report at the close of each year, to satisfy the Council that he has made and is likely to make proper use of the grant.

London Section.

Meeting held at Burlington House on Monday, March 5th, 1917.

MR. A. R. LING IN THE CHAIR.

COMPOSITION OF POWER GASES.

BY W. A. TOOKEY, M.I.MECH.E.

In the history of the development of the gas engine, working mixtures of very different compositions have been used from time to time and it must be generally admitted that, notwithstanding all preconceived ideas based upon more or less intelligent anticipation, progress has been achieved quite irrespective of the composition

of the gas forming the combustible ingredient. Thus in the earliest days Street (1791) used spirits of turpentine, the liquid being introduced into the bottom of a cylinder filled with air and to which heat was applied, while, in later years, successful operation has been obtained equally well with any and all of those power gases having greatly varying compositions, which are to be found recorded in standard works upon gas engines and gas producers.

The proper method of utilising power gases, so greatly varying in density, in calorific value, in chemical composition, and in the amount of air required for theoretically complete combustion, has been a matter which only painstaking and persevering experiment by the practical system of trial and error has discovered. Scientific research, valuable though it has been, has not aided the experimental staff in gas and oil engine manufacturing establishments to any great extent.

In making this statement it must not be thought that the author has overlooked much excellent work done by scientific men whose names will always stand well in the forefront of British technical history in connection with power gases. The early experiments of Grover of Leeds and of Dr. Dugald Clerk were undoubtedly helpful, but in a negative sort of way, as were the later researches of Bairstow and Alexander and of Prof. Bertram Hopkinson. All were conducted—almost of necessity—under circumstances greatly differing from those that actually obtain in the cylinder of a gas engine working under load and at speed. Dr. Dugald Clerk and other members of the British Association Gaseous Explosions Committee have during recent years elucidated many matters in connection with the phenomena of combustion in gas engine cylinders which before were only imperfectly realised and their researches have been described and results recorded more or less fully in the reports published from time to time. Yet so far as the author is aware there has been no definite lead given by any man of science to indicate what might be deemed the goal to aim at if it were required to manufacture a gas for power purposes without reference to prevailing circumstances in the gas making industry or any commercial interest.

The object of this paper is to discuss the subject of gas composition from the gas engine side, and the following remarks are offered by the author as an engineer, not as a chemist. That he can claim to speak from the gas engine side is due to the fact that since the year 1905 he has been called upon to carry out over 1500 tests upon gas and oil engines throughout the country, served with the various grades of town and producer gas that this number implies, as well as with the varying brands of kerosene and fuel oils that have been marketed in the country during the period. A particularly valuable and interesting series of tests by indicator—involving nearly 1000 in the London district alone—was carried out at the instance and expense of the Gas Light and Coke Co. and the South Metropolitan Gas Co. in order to ensure to their power consumers that the best results were being obtained in respect of output of power and of economy, which particular—and oft-times peculiar—circumstances permitted.

It was soon evident to the author that a mere collection of test results of a great number of engines would be of no value if the ordinary accepted methods of standardising outputs in terms of Indicated Horse Power and consumptions in terms of cubic feet of gas per I.H.P. per hour had been adopted, and in a paper read before the

Institution of Mechanical Engineers in January, 1914, he explained at length a method he had evolved for comparing engines of varying sizes, different systems of construction, and in all stages of repair and disrepair, by means of which he was able properly to estimate their relative performances. The basis of comparison took into account the ratio of total cylinder volumes to the respective clearance volumes or, what amounts to the same thing, to the pressure to which the charges of gas and air were compressed within the gas engine cylinders before ignition, that is to say coincident with the inmost position of the piston.

Briefly it may be said that the power output, in addition to being specified as "Indicated Horse Power," was also stated in terms of "mean pressure" produced by the combustion of the charge and acting upon each square inch of piston area, while the consumption of gas, as well as being referred to in terms of so many cubic feet per horse power hour, was also noted as a working fluid containing so many British Thermal Units per cubic foot—at normal temperature and pressure—on the basis of total cylinder volume before compression. In this way the author was enabled to establish with approximate truth how many lb. of mean pressure was obtained from each B.Th.U. in the mixture, allowance of course being made for the more or less completely filled cylinders such as were encountered during the whole series of indicator tests referred to.

Soon after this method of classifying test results was evolved and put into daily use it became apparent that there was a definite relation between output and consumption upon the basis above mentioned. The factor—power output in lb. of piston pressure divided by consumption in B.Th.U. per cubic ft. (or mean pressure divided by mixture strength)—being wonderfully consistent for engines dissimilar as regards construction but working at similar compression pressures, as long as the working charges were ignited properly and timely so as to secure the highest combustion pressures just after the engine piston has begun to move outwards on the power stroke. The discussion following the reading of the paper before referred to elicited from Capt. H. Riall Sankey a mathematical substantiation which demonstrated that the "factor" was also a means whereby the temperature of the charge would be computed. The author has since evaluated this "Tookey factor" for various compression pressures and in a recent contribution to the "Engineer" its relation to thermal efficiency on the Indicated Horse Power basis is referred to in graph form.

The above remarks have been made in order to explain that the author's work of recent years has been in the direction of basing test results upon mixture strengths and, as he has had peculiar facilities, he has naturally been interested in noting whether equivalent results with regard to ratio of output to consumption can be obtained with say town gas as with producer gas so long as the mixture strength in terms of so many B.Th.U. per cubic ft. is the same in each case, despite the fact that town gas has from four to five times the calorific value of producer gas and varies greatly in composition and also in the percentage of combustible to incombustible gases per unit volume. Similarly he has been interested in observing whether mixtures of kerosene vapour and air, or of liquid fuel "mists" injected in Diesel and in surface-ignition engines (generally misnamed "Semi Diesels") give similar or dissimilar "Tookey factors" either as between these various kinds of liquid fuel or between "oil" and "gas" mixtures.

The result of his observations can perhaps be best presented by a reference to the graph reproduced below from the article in the "Engineer"

which has just been referred to. It will be observed that this is a variation of the Tookey factor method of comparison inasmuch as instead of the mean piston pressures being plotted in terms of Indicated H.P., equivalent piston pressures on Brake H.P. basis are used; while as regards mixture strength, instead of this being stated in terms of B.Th.U. per cu. ft. of total cylinder volume, it is given in terms of piston displacement volume (total cylinder volume minus clearance volume).

The test results of eight engines of greatly varying characteristics as regards construction, compression pressures, etc., are plotted and it

Variation of piston pressures with mixture strength in gas and oil engines.

FIG. 1.

will be seen that speaking generally the output-consumption curves there drawn show no divergencies due to the nature of the working mixture. Town gas mixtures, as in the case of the Browett-Lindley engine—curve 4—or liquid fuel mixtures as in the case of the Willans-Diesel engine—curve 8, are practically identical when thus plotted. Such divergencies as are to be discerned throughout the eight sets of curves are explicable by the variation in the clearance volume ratio and consequent variation of maximum attainable thermal efficiency.

The chart (Fig. 1) shows the "output-consumption" curves when the former is based upon B.H.P. or the actual power derivable from the engine crankshaft for purposes of transmission. This is the basis which practical considerations would prefer as presenting a true comparison from an engine user's point of view, as distinct from that of the scientist who would prefer to compare "output-consumption" curves on the basis of I.H.P. or the pressures obtained within the

cylinder to deal with not only the load but also resistances of the engine mechanism.

To meet this scientific objection for the purposes of the present paper, the curves in Fig. 1 have been redrawn in Fig. 2 keeping the B.H.P. piston pressures as before but plotting the mixture strengths on the basis of units of total cylinder volume—that is to say piston displacement plus clearance, instead of piston displacement only. It will be seen that the position of all the curves moves to the left as compared with those in Fig. 1, and this for the reason that the number of B.Th.U. present has now been taken as being contained

FIG. 2.

in a larger volume and therefore the mixture strengths are specifically weaker.

From an examination of the curves in Fig. 2 it is obvious that the varying composition of the gas used in the various engines, whether oil "vapour" or oil "mist"; town gas of 500 B.Th.U. p. c. ft.; or producer gas of 130 B.Th.U. per cb. ft., has no apparent influence on the performance of the engines. Furthermore it is evident that, whatever the composition of the gaseous mixture, of combustible and incombustible constituents, or whether diluted by excess air or residual gases from previous explosions, the output is of the same order in all types of internal combustion engines for a given strength of mixture when calculated upon the basis first adopted by the author.

A comparison of the test results recorded in standard works on the internal combustion engine (such as that most useful and valuable treatise "The Gas, Oil and Petrol Engine" by Dr. Dugald Clerk) when recalculated upon the author's mixture strength basis proves that the richness of the full load mixtures used has been strikingly uniform and of the order of 45 B.Th.U. p. cb. ft. based upon the total cylinder volume.

Further, such comparisons prove that the

increase in thermal efficiencies (I.H.P. basis) recorded during the last thirty years or so have been such as to coincide with the change in practice due entirely to increase in clearance volume ratio. That is to say as the dead spaces behind the piston and into which the charge is compressed, have been reduced in ratio, so the relative amount of gas drawn in by the piston to bring the working mixture up to unit strength has been proportionately decreased.

It is a striking fact that on this basis, the actual thermal efficiencies attained have been in strict agreement with calculations based upon uniform mixture strength, as will be seen from the curves herewith given and reproduced from the author's remarks in the discussion upon his paper "Commercial Tests of Internal Combustion Engines" (Proc. Inst. Mech. Eng., 1914).

It will be obvious that during the period in which the tests there tabulated were made the quality of the gas must have varied very considerably, as indeed was the case as recorded in the published results. It will also be noticed that the figures relating to liquid fuel engines fall upon the

FIG. 3.

- Z.—Increasing efficiency with increasing compression pressure, due, by reason of reduction in clearance volume, to lesser total quantity of heat required to maintain equivalent mixture-strength.
 - Y.—Air standard efficiencies on basis of constant specific heat. (Inst. C.E. Committee, 1905.)

same curve and thus substantiate in no unhesitating manner the curves shown in Fig. 1. From such authoritative tests it surely can be deduced that the actual composition of power gases plays very little part in the thermal efficiency of internal combustion engines, other things being equal.

The main object in view when the writer was first called upon by the Gas Light and Coke Co. in 1911 to commence the series of tests upon engines working throughout their district was, as before stated, to adjust the mechanical details and to set the gas and air regulating devices so that the maximum benefit could be obtained from the consumers' point of view as regards maximum power output from low rates of gas consumption. As long as the engine was in good trim mechanically it was found to be a relatively simple matter to obtain the desired effect once the mixture strength of gas was determined as has been already explained and if the instant of ignition was properly timed. The method of procedure in all tests was first to get a mixture as nearly as possible 45 B.Th.U. p. cu. ft. of total cylinder volume into the cylinder—either by increasing the amount of gas passing through the gas regulating cock or by diminishing the volume of air drawn in through the inlet valve. This being secured, the ignition timing was then properly set by means of an indicator. No actual calorimetric measurements were taken during these work-a-day tests on consumers' premises for obvious reasons, but the periodically published reports of tests made in the official testing places prescribed by the Metro-

sulphed for obtaining the necessary bases for output-consumption ratios.

Since the outbreak of war the writer has had an opportunity afforded him of testing one and the same engine with "stripped" and "unstripped" gas alternately. He found that under the same

FIG. 5.

load and conditions there was a falling off in power developed per impulse on the "stripped" gas and therefore an increase of gas consumption of the order of 10 to 13%. The diagrams taken by an indicator showed that while the "unstripped" gas gave a series of regular impulses as regards power, the consecutive explosions of "stripped" gas mixtures were most irregular under similar conditions, but regularity of ignition was at once restored when the mixture strength was increased by proper adjustment to that obtained with the "unstripped" gas—and this by merely turning the gas regulator open a little more. This experience again confirms the statement already made that the composition of gas matters little but the strength or richness of working mixtures matters much.

One thing in connection with gas composition that is of the utmost importance however is its constancy as regards calorific value, for if this should vary but slightly the working of the engine will be greatly affected. This is a disadvantage in connection with the use of suction producer gas, for if by inattention or lack of skill in management of the plant, the quality of the gas be inconstant then trouble is bound to arise for, at present at any rate, it is not possible so to adjust the rate of air admission as to compensate for irregularities in calorific value per unit volume of the gas entering the engine. The consequence is that charges may remain wholly or partially unignited resulting in bumping or violent ignitions (caused by combustion of a new with a previously missed charge) at irregular intervals if due to lack of richness, or to similar bumping or early firing at each cycle if due to excess of richness. The deciding factor is the limit of mixture inflammability which the amount of air entering with the gas permits. An example of what may happen in normal work as regards variation in calorific value of gas from a suction gas producer is suggested by the accompanying chart taken from a recording calorimeter in one of the tests made by the author. An engine pulling its gas from a suction producer is fed with gas of varying calorific value per unit volume as the load may range between nil and maximum. A chart is also given based upon Dowson's figures to show these variations in respect of composition.

As an internal combustion engineer, therefore, the author would say that to a certain extent it is immaterial what kind of gas is made for this purpose of serving gas engines, but whatever its composition every effort should be made to obtain uniformity, remembering particularly that the less rich the gas in calorific value the more important is it that constancy of product should be striven for. An expert with an indicator always available

FIG. 1.

politan Gas Referees showed that, without great inaccuracy, the value of a cubic foot of town gas could at that time be taken as 500 B.Th.U. for such purposes. The reading of the gas meter and determination of mean piston pressure then

could undertake to run an engine with any and every kind of gas that could be piped to him so long as he had means of properly adjusting the proportions of gas and air and of varying the instant of ignition. But the ordinary gas engine user wants his engine to run every day and all day and day after day, with the same settings and with inexpert attendance, and this he will not be able to do unless the gas is of regularly uniform quality within close limits and is supplied at a uniform pressure through the service mains.

Chart showing variation in composition and calorific value of anthracite suction producer gas under varying loads.

FIG. 6.

The higher the proportion of incombustibles in the poorer power gases the more the encroachment upon the air capacity of an engine cylinder and consequently the limit is sooner reached in respect of mixture strength. It is a well known fact that gas producer engines are rated for output from 12½ to 25% less than the town gas figures. This can be taken as meaning that while with good coal, clean furnace, high fuel-bed temperatures, and well humidified hot air blast the smaller reduction may be expected, yet to compensate for the temporary absence of any one of these essential conditions and to cover the incidences of everyday work it is frequently found that a margin of 25% on basis of town gas powers is a much more practicable figure.

It was stated in a previous paragraph that uniformity of pressure of supply was important and it may be advisable to say a few more words upon the subject. Whatever the pressure of supply may be matters very little as long as it remains uniform. Indeed this is obvious seeing that gas engines are daily started up on a rich gas under pressure and switched over to a poorer gas under suction. All the same one hears even gas managers asking whether there should be a limiting minimum supply pressure to engines and if so what. The minimum pressure on a town gas service pipe must always be sufficient to keep the gas bag diaphragm well inflated between charges taken by the engine when working under full load. Those gas companies who have now, or are about to inaugurate a gas engine maintenance scheme would be well advised to include as a part of their instructions to employees to renew indiarubber gas bag diaphragms when flabby and irresponsive and to cleanse periodically the anti-pulsating valve attached to the diaphragm to ensure its smooth and reliable operation. Quite a large proportion

of complaints of "bad gas" or "lack of pressure" would in this way be obviated.

As to uniformity of calorific value, this is probably somewhat difficult to control having regard to practical gas making and problems and variation in fuels. But that very considerable success is obtained is borne out by the figures reported of the readings taken at the testing places prescribed by the Metropolitan Gas Referees. No doubt it is the same in other larger cities, but in many provincial towns it is the author's experience that no analysis or statement as to calorific value can be obtained because the proprietors will not sanction the expense of purchasing the necessary and simple apparatus required, even if amongst the staff a man could be found able to take daily records.

It will surely be admitted henceforward that at least a calorimeter should be considered an indispensable adjunct to the works meter even in the smallest provincial town. In one district of Suffolk the author when making a test obtained some figures for cb. ft. I.H.P. hour which seemed to require explanation. Upon application to the Manager at the Gas Works he was informed that no idea of calorific value or volumetric analysis could be obtained owing to lack of appliances but there was the coal store, there the coke stack, and

Chart showing similarity of mixture strength (theoretical) over wide range of power gases say 300 to 1000 B.Th.U. per cb. ft.

FIG. 7.

there a lighted burner. Certainly the lighted burner—flat flame—told the story of a rich gas but no more definite information was forthcoming. How successful progress of gas power business could be expected in competition with electricity in that borough was not discoverable.

It has very frequently been stated that an excess of hydrogen or of methane in power gas gives trouble in the engine cylinder, and the author has been at many tests when after an outbreak of pre-ignition the cause has been attributed by those in charge to too much hydrogen. Certainly it has frequently been reported in connection with coke oven gas that pre-ignitions occur due to a similar cause. On the other hand Prof. Bursfall, in the experiments he made at the Birmingham University, in order to study the influence of high compression, reported that with proper attention and adjustment of ignition and by taking particular care to cool the ignition plug, no trouble of pre-ignition occurred with mixtures even at compression pressures in the neighbourhood of 160 lb. per square inch.

There are a number of engines working to-day throughout the country on town gas with compression pressures exceeding 140 lb. per square inch and yet pre-ignitions are unknown in such engines. The writer's opinion is that it is a matter of mixture and when the trouble of pre-ignition exists, it can be greatly minimised or entirely obviated by reducing the amount of gas to the working charge, that is to say, by weakening the mixture. If this were not so, one could not believe that natural gas with its 92% of methane could be used at all, but yet it is in service at many places in the U.S.A. and additional support is given to the opinion by the fact that coke oven gas with its 50% of hydrogen and 36% of methane or thereabouts can be used in gas engines satisfactorily, if "to avoid pre-ignitions" a certain proportion of the charge consists of exhaust gas. The function of the latter after all is to weaken the mixture and while the same effect would logically be obtained by admission of pure air in proportionate excess, yet the very fact that such additional pure air was present, would enable still richer charges to be fired and thus increase the danger, consequently exhaust gas being inert is the better medium to use on this account.

Many people seem to forget that the working mixture of an engine is not the gas alone, nor gas and air mixture alone, but a mixture of gas, air, and residuals from previous charges. That residual gases from previous charges have an important effect will be clear from what has already been said, and it is well known amongst practical men that no engine can work to best advantage with a bottled up exhaust, that is to say, an engine which has its exhaust connection partially choked and permitting the retention of such a volume of an exploded charge as will interfere with the induction of an adequate volume of air to complete the combustion of a following charge. A producer gas engine is much more sensitive in this respect than is a town gas engine, for the percentage of combustibles in the gas constituent of the former is only of the order of 40%, whereas in town gas 90% of its volume is combustible. Thus one can say that a working mixture really consists of 40 to 90% combustible and 10 to 60% incombustible gas coming through from the producer or the service mains, oxygen 21% and nitrogen 79% in the air constituent, and residuals also of varying quantity according to site and conditions.

Some 10 or 12 years ago considerable interest, was aroused particularly in U.S.A., by experiments that were reported in the technical press at the time, of gas producers of the suction type, working without water vapour but, in place thereof, with a portion of the exhaust gases permitted to pass through the fuel bed, in regulated volumes, according to the load on the engine. It was reported at the time that very considerable success had been reached and that high compression pressures could be attained without risk of pre-ignition such as gas made with ordinary

water vapour would give under much lower compression pressures. Very little has been heard of this during recent years, probably on account of the fact that attempts to regulate the exhaust in accordance with the load mean that a great deal of circumspection is demanded by the engine attendant and it is realised that anything to do with engine operation should make as few demands as possible upon the intelligence of the attendant, otherwise gas engines get the reputation of being unreliable. It is in the author's opinion exceedingly doubtful whether hydrogen is to be blamed for pre-ignition in gas engine cylinders. Personally he has never been able to satisfy himself that pre-ignitions are directly due to hydrogen. When an engine has been working for some time quite well and suddenly begins to develop pre-ignition, it is a sure sign that something has happened at the producer end and that in consequence the calorific value of the gas has increased, but if one notices analyses of rich and poor qualities of producer gas one finds that as calorific values increase hydrogen rises practically in the same proportion as does carbon monoxide, and the latter being the slower in burning, one would have thought that the fault could not be properly placed to excessive hydrogen. It seems to the author that the increase of both has resulted in (relatively) greatly increased mixture strength, and the air supply being constant it may have changed the composition of a working mixture from one that is slow to burn into one that is fierce to burn. Thus with some ignition settings, pre-ignitions could quite well be accounted for.

An experience of the writer in this connection might be detailed. Two engines in the North of England were giving trouble. Both were fed from the same suction producer, both were running coupled, through dynamos, to the same load; and the engines would work sometimes quite comfortably throughout the working day and at other times an alarming amount of pre-ignition would occur, on one or other of the engines, which naturally produced irregular running and gave the attendant considerable trouble.

It was thought that there was too much hydrogen in the producer gas and steps were taken to reduce the amount of water flowing through. This had no effect as far as could be discerned. An experiment was also tried to drench the air going into the producer with water vapour so as to reduce the temperature of the saturated air as it entered the fuel bed and in this way to reduce the temperature of the combustion zone within the generator. This again had no good effect. Experiments were then made with the exhaust pipe and the exhaust valve settings, but showed that nothing that could be done in this direction would put an end to the casual pre-ignition. Eventually it was found that the setting of the magneto was incorrect in that it could not be sufficiently advanced. This having been put right the pre-ignition ceased and no further trouble has been experienced since as far as the author is aware.

Certainly whatever else this experience proved it could be said that the experiments had proved conclusively that the trouble was not due to the quality of the gas nor the amount of hydrogen in it.

Another experience that the author has had is an interesting one and may be of service. He was consulted in connection with an engine which had been giving serious trouble through pre-ignition, which first was put down, as usual, to too much hydrogen. The engine was still in the hands of the maker, that is to say, it had not been handed over owing to the troubles that were being encountered, but the engineer who had the matter in hand, had very carefully gone into all matters connected with it and described to the author what his tests had been and the conclusions to which these had led him. It appears that with

this particular engine pre-ignitions could be and were met with even when the engine was running under the lightest of loads and not only, as is usually the case, under heavy loads. All sorts of adjustments had been tried in connection with the water supply to the producer gas plant, but whether little, normal, or much, no benefit resulted, and pre-ignition still persisted. Eventually it was found that the gas contained a very high percentage of sulphur in the form of solid particles which were carried over from the generator through the scrubber, through a centrifugal fan and through a sawdust purifier, giving heavy deposits in each of these pieces of apparatus and forming a slimy deposit on the walls of the service main to the engine. Passing through the governor valve it quickly reduced the area through which the gas passed and even found its way into the manifold pipe supplying the four cylinders of a vertical gas engine. The peculiar feature about the whole affair was that pre-ignition did not occur in all cylinders, but only in one or other of the two centre ones. It did not occur persistently but casually. Pre-ignition in the usual way is recognised as being a sign that it will steadily get worse as time goes on and will necessitate eventually stoppage of the engine, but in this case nothing seemed to happen. Pre-ignition would take place, perhaps in one charge in a series of 100, but at other times one in 50, proving that the source of ignition, whatever it was, was momentary and not permanent in either one of the two inside cylinders. It was evident, therefore, that the working of the engine, or perhaps one should preferably say the pulsation of the gas in the manifold pipe, had the effect of causing a grain or two of sulphur to become detached and enter with the gas, which falling on to the hot piston top, and becoming ignited in the presence of air and under the influence of the added heat of compression which followed the suction stroke, set the mixture alight prematurely.

The difficulty was to find a remedy, having found the cause. The fuel was changed, different classes of anthracite coal tried, new coke was put in the scrubber, new wood-wool and sawdust in the dryer, the whole plant was stopped and thoroughly cleaned out, but all to no purpose. Even now the author believes that the trouble persists and it is clearly some local circumstance that is causing this most peculiar and unusual state of things. As a final endeavour to get rid of the bugbear the author has advised that instead of the ordinary water, rain water should be used for generating water vapour and for washing the gas. What effect this has had he does not yet know.

The upshot of the whole of this paper is that while as far as the author's experience goes, he can give no preference to any of the power gases for engine work from the point of view of their relative composition, he would like to insist upon the importance of the points alluded to earlier in the paper. That is to say, whatever composition of the power gas may be, its purity, its pressure, and its uniformity—both in composition and pressure of supply—are of far more importance from an engineer's point of view than is its calorific value.

DISCUSSION.

Mr. G. N. HUNTLY said that using brake horse power as a co-ordinate and thus introducing a variable friction factor appeared at first sight to reduce the chance of discovering a regular relation, but from the diagram shown it was clear that the author was justified. As regards the statement that over a wide range the efficiency of the gas engine was independent of the calorific value of the

fuel, since gas was bought in cubic feet and not in B.Th.U. there was a possibility of misconception.

Mr. W. J. A. BUTTERFIELD was of opinion that engineers had not given sufficient attention to the minor constituents of the gas, such as for instance carbon bisulphide, the temperature of ignition of which was very low. Pre-ignition might possibly be due to its presence. Acetylene was a gas of high calorific power and low temperature of ignition, and insufficient attention, he thought, had been given to its behaviour in the gas engine in comparison with other gases and oils.

Mr. P. H. JOSELYN said that having had considerable experience in stripping gas and never having seen the calorific power reduced by more than 7%, although 5% was about the average, he could not understand why the consumption in a gas engine should increase 10 to 15%, as quoted by Mr. Tookey, when running on stripped gas.

Prof. J. S. S. BRAME agreed with the author that hydrogen probably had no determining effect on pre-ignition; figures he had published a few years back showing the hydrogen content of the actual cylinder charge bore this out, and the cause must be sought, as far as the charge was concerned, in the minor gaseous constituents, probably acetylene. Mr. Butterfield's suggestion of carbon bisulphide being a possible cause of pre-ignition was worth following up. Referring to the author's remarks on the variability in composition of suction gas, he said that the author's curve really showed that with the engine running at a steady output the calorific value of the gas was uniform; it was only when change of load occurred that great variation in the gas was noted, the composition of the gas adapting itself to the load conditions.

Mr. J. W. HINCHLEY asked whether there was any conclusion to be drawn from the fact that a Norwegian engine, No. 7, appeared to be the most efficient engine examined, that is, if he understood diagrams 1 and 2 correctly. He also suggested to Mr. Tookey that his remarks, without further interpretation, might lead one to suppose that no real improvement had been made in gas engines for thirty years; he suggested that some further explanation was desirable.

Dr. R. LESSING asked whether the remarkable uniformity of curves obtained from a variety of fuels was not due to the fact that the amount of combustible matter in the mixtures was comparatively small, and the calorific value of the mixtures per cubic foot of cylinder space was made uniform by the different air requirements of each fuel. Thereby a rich fuel such as town gas had to be diluted down to practically the same calorific strength as a mixture made with poor producer gas. As the actual amount of combustible matter in these mixtures was comparatively small, it was obvious that their chemical characteristics could not be very evident, and did not show up in the author's results. However, he could not help feeling that the composition of the fuel gases and the chemical constitution of their components must influence the working of the engine. Although the output of horse-power might be the same with different mixtures, there must be differences in other respects, such as ignition temperature or propagation of explosion, with bodies of such varying constitution as benzene, methane, carbon monoxide, and hydrogen. He would, therefore, urge strongly not to disregard the composition of the combustible matter supplied to the engine, although he recognised the importance and convenience of studying the working of the engine from the point of view of B.Th.U.'s per total cylinder charge. How necessary it was to consider the quantitatively less important constituents of complex gas mixtures was shown by Mr. Tookey's

reference to the adjustment required after changing over from unstripped coal gas to a gas from which part of the benzene had been extracted, although the difference between these two gases probably amounted to less than 1% by vol. There was a danger that the author's statement, that well-made working mixtures with any kind of fuel gave approximately equal results, might be erroneously applied to the fuel gases themselves, and it would be as well to make it clear that such a misconception was not permissible. The choice between various types of gaseous or vaporous fuels must, in the first instance, depend on the cost per thermal unit, but was also largely influenced by questions of convenience, continuity of supply, capital outlay for the plant, and geographical position.

Dr. R. SELIGMAN asked if gas of low calorific power could be used in the gas engine as well as Mond gas.

Mr. W. A. TOOKEY, in reply, dealt first with the remarks of Mr. Butterfield and others with regard to the presence of small quantities of carbon bisulphide in power gases. He stated that the point raised was new to him and would no doubt prove to be well worth following up, but, speaking without full consideration of the matter, his first impression was that the presence of such minute quantities of these sulphur compounds was immaterial and had no influence upon the phenomenon of pre-ignition. The small amount of carbon bisulphide present in power gases and the very much lesser proportion present in working mixtures of gas and air could, he thought, have little or no effect.

Mr. BUTTERFIELD explained that he realised that the amount of carbon bisulphide present in working mixtures would be very small, but his idea was that, however small, it was just possible that it would act as a detonating cap and ignite the working mixture during the compression stroke under certain conditions.

Mr. TOOKEY said that the suggestion might possibly be valuable in explaining the cause of pre-ignition in rare instances, but his experience had been so far that pre-ignitions could be entirely cured by proper regulation of gas and air mixtures and by correctly timing the ignition. So far he had never met a case of pre-ignition which did not yield to treatment of this description.

He would hardly care to say what was the lowest calorific value of gas that could be piped to power consumers. He was inclined to think that gas of about 400 B.Th.U.'s would be a desirable minimum, but much depended upon other factors. Mr. Huntly had pointed out that calorific value itself was one standard and did not take into account the purchase price or whether the consumer was getting value for his money. Mr. Tookey said that he thought this was rather beside the point under discussion, as chemists and engineers could approach the subject entirely from a physical rather than a commercial standpoint. In the matter of £ s. d. the gas undertakings and their consumers could well be left to look after their own interests.

It would be realised that very little depended upon the density of the gases in respect to output of gas engines when it was a daily occurrence for engines to be started up on comparatively rich town gas and then switched over to relatively poor producer gas, the former having a density of perhaps 0.4 and the latter one of 0.8 in relation to air. There was no practical difficulty in getting the heavier gas into the engine for it merely meant a slight lowering of the suction line as depicted in an indicator diagram taken with a weak spring.

Replying to Mr. Joselin's remarks, the author said that in the case mentioned in the paper the "stripped" gas was about 5% lower in calorific value than the "unstripped" and this accorded

with Mr. Joselin's figures. The 13% mentioned in the paper was the increased consumption of gas to generate the same power without any alterations having been made to the mixture strength, as indeed was explained, but this increase was entirely due to the irregularity of ignition, i.e., while one charge would be fired less promptly than with the "stripped" gas, succeeding charges would be fired later and still later, involving wasteful consumption of gas. It was to correct this late and irregular firing that adjustment of the gas and air mixtures was made, and as soon as the mixture strength had been brought up to the requisite value, consecutive charges were fired regularly, so bringing the 13% increased consumption down to 5%—equivalent to the difference in calorific values of the "stripped" and "unstripped" gas.

Professor Brame had pointed out that the chart exhibited by the author showed that, speaking generally, suction producer gas was of fairly regular composition. The author stated that this was so as long as the load upon the engine was unchanged; if it were changed the calorific value of the gas was at once affected, rising for higher powers and falling for lower powers, as indeed was depicted by the diagram separately shown. This involved slight adjustments being made to the air regulation in order to obtain most economical results, but the author did not wish it to be thought that suction gas producer plants were unreliable or required an undue amount of attention. The fact was that practical considerations and the cheapness of gas production made it unnecessary for the average attendant to keep the working mixture tuned up to the most economical point, and the many thousands of engines working in all parts of the world and with all kinds of fuel, such as anthracite, charcoal, coke, cotton seed, and waste combustible materials of almost any kind sufficiently demonstrated that suction gas plants were reliable to a very great extent.

Mr. Hinchley must not draw the conclusion he suggested, for the Norwegian engine shown in one of the charts as being most efficient implied no lack of skill on the part of British inventors. This was an engine made with a very greatly restricted clearance volume in order that high compression pressures should be attained and that tar oils could be burnt. The diminished clearance space, other things being equal, was quite sufficient to account for the apparently more efficient working of this particular engine. Mr. Hinchley had also suggested that from the author's remarks it might be considered that no improvement in gas engine practice had been made during the last 30 years. That was quite contrary to what the author wished to emphasise, for had it not been for the improvements in gas engine construction during that period, we should still have been working with low compression engines, which, as would be seen from the diagrams, showed the lowest efficiency. It was first of all the hot ignition tube and afterwards magneto-electric ignition which had made high compression pressures practicable, to deal only with ignition improvements. For the rest it remained only to compare the engine of to-day with that of 30 years ago to see that the modern production was superior in every way.

Dr. Lessing had correctly stated the point which the author wished to make, namely, that whatever type of gas was used, its mixture with air and residuals practically eliminated all differences of calorific value within the engine cylinder. The author had at one time been of the opinion that the actual composition of the gas and the constitution of its components must influence the working of an engine, but he was bound to say that the differences that theory would expect were not discoverable in practical working.

DR. R. M. CAVEN IN THE CHAIR.

A SIMPLE AND EFFICIENT GAS ABSORPTION APPARATUS.

BY H. DROOP RICHMOND, F.I.C., AND
E. HEMBROUGH.

An apparatus which can be made without difficulty by the average glass-blower and which has proved efficient for absorption of gases such as carbon dioxide, can be made by fitting a tube

13–15 cm. long about 4 mm. internal diameter, on which 6–8 bulbs about 12 mm. diameter have been blown, and the ends of which are expanded into small funnels of about 12 mm. diameter, inside a tube of about 17 mm. internal diameter, 20 cm. long, the bottom of which is drawn out and sealed to an inlet tube of about 3 mm. diameter bent in form of a U. In this tube is placed 10–15 c.c. of absorbing liquid; the gas enters by the inlet tube and bubbles up through the bulb tube, passing from bulb to bulb, and taking up some of the liquid which overflows from the upper funnel, while fresh liquid continually runs in to replace that carried up; under the circumstances the contact between the gas and liquid is efficient. The apparatus is simple, easily made, easily cleaned, and not at all fragile. The efficiency is shown by the following:—

Two comparative experiments were made in which carbon dioxide was generated from 15 c.c. of *N*/10 sodium carbonate; in the first two of the new apparatus and one ordinary wash bottle were arranged in series; in the second two wash bottles and one of the new apparatus were used; the carbon dioxide was absorbed in baryta solution, which was afterwards titrated with *N*/2 acid, in presence of phenolphthalein. The results obtained were:—

c.c. *N*/10 baryta used for absorption.

New	10.63	Old	8.03
New	2.89	Old	1.99
Old	1.24	New	2.76
	14.76		12.78

It is seen that in each case the new apparatus was more efficient than the wash bottle, and two of these and a guard tube would absorb the carbon dioxide from such a diluted gas as employed.

This investigation was carried out in the Analytical Laboratory of Messrs. Boots Pure Drug Co., Ltd., to whom our thanks are due.

A MERCURIAL VISCOMETER.

BY F. M. LIDSTONE.

ERRATA.

In the discussion on the above paper (this Journal, March 15th, 1917, pages 271–2) the following corrections should be made:—

Page 271, col. 2, lines 28 and 27 from bottom, for “by the addition of phenol in which the . . .” read “by means of phenol of which the viscosity at different . . .”

Page 272, col. 1, line 18 from bottom, for “jet was moved” read “pipette was movable.” Delete line 12 from bottom. Line 11 from bottom, delete word “bottom,” and for “main” read “mean.” Line 7 from bottom, after “viscosity” add “within the limited range chosen here.”

February 5th, 1917.

PROF. J. W. COBB IN THE CHAIR.

OXIDATION OF OILS IN PRESENCE OF SOLUBLE METALLIC CATALYSTS.

BY W. MCD. MACKEY, F.I.C., AND HARRY INGLE,
D.S.C., PH.D., F.I.C.

In a paper read before this Section last session (this Journal, 1916, 454) we made a statement as to the relative drying power, or oxygen-carrying power, of certain metallic soaps when dissolved in oil. It was as follows:—“*That in its oil-soluble form, a metal which exists in more than one state of oxidation acts as a ‘drier’ or oxygen carrier, provided that the (salts of the) lower oxides are more stable than the higher,*” and in the present paper we are trying to show, and we think with considerable success, the truth of this dictum.

We felt compelled to justify this general statement by the examination of the action of metallic soaps on a drying as well as on a non-drying oil (i.e., olive, on which the experiments were made as recorded in the paper referred to).

The following results show how far the general theory is justified. Of course it was well known that the rate of oxidation with drying oils in the tester (for description of the Cloth Oil Tester, etc., see this J., 1896, 90) must be greater than with non-drying oils, and this is clearly shown in the table.

The results, though the tests were made on oils, seem to be of importance as regards catalytic action generally; but our work has been confined to measuring or comparing the catalytic activity of the element experimented with as regards oxygen-carrying only.*

It was hoped to be able to draw up a table showing a definite relationship between the catalytic action of the elements and the periodic law, but so far we have not been able to prove this definitely. We have, however, considered the relationships of the valencies and the oxidation states of the elements, and as a result we may make a further generalisation, thus:—

That the more oxides a metal can form the greater the catalytic power.

* Most of the results on olive oil were published in the paper already referred to.

Iodine value of linseed oil used, 178; of the olive oil, 85. Roman numbers denote valencies. Black, linseed oil experiments. Shaded, olive oil experiments.

In the table the results are given from left to right in order of activity. The position of the head of each black or shaded column represents the number of minutes in which the oiled cotton wool—7 grms. cotton wool, 14 grms. oil containing 2% metallic soap—attained a temperature of 200° C. in the Cloth Oil Tester. (Thus cobalt, 12.5 minutes with linseed oil, 24.5 with olive.) In all experiments represented by black and shaded columns the oiled cotton wool fired on standing in the open.

Copper. In the case of the copper soap in linseed oil the maximum temperature attained was 138° C. in 53 minutes, and the temperature then fell. In the olive oil experiment the maximum was 120° C. in 55 minutes, and the temperature then fell.

Tin. With linseed oil the temperature was 98° C. in 120 minutes—the usual period given for an experiment—but in 150 minutes the temperature of 200° C. was attained and the oiled cotton wool fired on standing in the open. With olive oil the temperature was 92° C. in 120 minutes. The experiment was then stopped.

It will be seen from the table how far both the theories put forward are in agreement with results. Taking the table from left to right (in order of activity):—

Cobalt forms at least two well-defined oxides; the salts of the lower are the more stable.

Manganese. A large number of oxides are known, but in the salt forms the lower are the more stable.

Nickel, like cobalt, forms at least two classes of oxides, the salts of the lower being the more stable.

Cerium forms several oxides, but the cerous compounds are the more stable. It may be added that Ulzer and Deisenhammer (Verwendung der

seltenen Erden, R. Böhm, Veit and Co., 1913) have shown that cerium salts readily act as catalysts, in their experience being little less active than those of lead. They add that with a pure cerium salt they believe that cerium would be found to be more than the equal of lead as a siccative or "drier" (catalyst), and it will be noted that our work confirms this.

Lead readily forms two series of oxidised salts; the lower is the more stable, hence its drying power.

Chromium forms a considerable number of oxides. This metal was of much interest owing to its wide use in the dyeing industry: as previously pointed out (this J., 1916, 451) it is a constant constituent of khaki dyed goods. The salts of the lower oxide, CrO , are readily oxidised but the salts of the intermediate oxide, Cr_2O_3 , are stable, the higher oxides formed, e.g., CrO_3 , readily reverting to this.

Iron forms a number of oxides. The salts of the intermediate oxide are the most stable.

Uranium forms several oxides, of which the intermediate, like those of iron and chromium, are the most stable.

Sodium. The results obtained in the Tester with this element are rather anomalous, for they show that though forming only one well-defined oxide, it acts as a catalyst, and a more active catalyst than we should have expected.

Bismuth, silver, zinc, thorium, mercury, and aluminium, it will be noted, are all towards the right of the table, i.e., they are less active than the elements on the left of the table. They only form one class of oxide, or where they form more, as in the case of mercury, the salts of the higher oxide are the more stable, thus falling in with the general theory. But it will be observed that (leaving for the moment copper and tin out of account) in all cases the introduction of a metal in oil-soluble form accelerates the increase of temperature. The explanation of this is not at present evident. We think that it is probable that the soaps are ionised

in oil solution and that the ions exerting their partial valency accelerate the oxidation of the oil; but as a generalisation it may be taken that *the solution of a metal in an oil tends to accelerate the oxidation of the oil.*

Copper shows a very remarkable behaviour under the conditions of the experiment. At first it accelerates and then retards the oxidation of the oil—this occurs both with linseed and olive oils. We have observed that with linseed oil, at a low temperature, the copper soap dissolved, giving a green solution; but on further heating, at about 200° C., a reduction took place with the separation of a reddish deposit, presumably Cu_2O . Tested by the Weger plate method both solutions exhibited equal drying power; and the drying power was considerable—nearly equal to the drying power of a lead soap in linseed oil.

The following notes with reference to the preparation of the soaps may be of interest. A sodium soap was used as the basis, and the soaps of copper, aluminium, nickel, lead, manganese, iron, and mercury were easily prepared. The silver soap had to be dried *in vacuo* over sulphuric acid in the dark.

The following soaps presented difficulties:—

Tin soap. As a neutral solution of tin is difficult to obtain the precipitation had to be effected in a slightly acid solution, and therefore a certain amount of fatty acid was present in the soap, which had to be removed by alcohol.

Bismuth soap. This was prepared in the same way as tin soap.

Uranium soap. Probably this is the first time uranium soap has been prepared. It was made by the addition of the standard soap solution to an aqueous solution of uranium acetate. Little separation took place until the soap was salted out, when a granular yellow soap was obtained.

Cerium soap. This also presented some difficulties. It could only be obtained in slightly alkaline solution and required salting out.

Thorium soap. Thorium nitrate is fairly soluble, and with soap a well-defined granular precipitate was obtained. The soap was white in colour.

In conclusion we have to thank Mr. James Miller and Mr. F. A. Horsfall; the former in particular for his assistance in the preparation of some of the more difficult soaps. Mr. Horsfall took charge of the bulk of the experimental work and has prepared the table.

THEORY OF THE ACTION OF "DRIERS."

BY HARRY INGLE, D.SC., PH.D., F.I.C.

In previous papers (this J., 1913, 639; 1916, 454), a certain amount of work on the oxidation of unsaturated compounds (drying oils) was recorded, and the theory of the chemical reactions during this process was adumbrated.

It is well known that the solution of certain metals in oils, especially drying oils such as linseed, greatly accelerates the absorption of oxygen, and hence these metals are known as driers.

The method of solution varies. "Fire boiled oils" are usually oils treated with certain salts or oxides of the drying elements at a temperature of 400 to 500° F. "Cold boiled oils" are obtained by dissolving in the oils, soaps of the drying elements at a temperature of steam heat.

Many papers have been published on their action and many compounds have been proposed for this purpose.

I wish to set forth in this short note a more explicit view of the mechanism of the action of driers on unsaturated compounds. I use this somewhat vague term purposely because there is no doubt that driers (catalysts) act upon other

unsaturated compounds besides acting on the drying oils. The action of a catalyst, a drier, on other substances than drying oils, has a most important bearing on many industries.

Now lead, one of the oldest, may be taken as a type of a drier on a drying oil. When linseed oil or other oil is heated with lead oxide or lead salts containing a volatile acid, the oil is more or less saponified and converted into a lead soap. This reaction usually requires a fairly high temperature. The other method of utilising lead has been indicated.

The products from the action of litharge may be taken as the example of the catalytic action of the lead.

Saponification (partial) results.

Let L_2 be the acids of the oil. Then

Now lead can act as a diad or a tetrad. Glycerol is but a weak acid, but it can form salts with lead; lead glyceride itself is not readily soluble in oil.

Glyceryl plumbolinoleate represents lead attached to a weak acid substance, amphoteric glycerol, which has at the same time part of its acidity reduced by the presence of linolic acid, attached to one of its hydroxyl groups. The absorption of the valencies of lead is thus little reduced, and the lead is able to exert its tetravalency and thus absorb oxygen from the air to form a peroxidised product. The following schemes will illustrate this. First of all the lead compound absorbs oxygen to become,

This compound transfers its peroxide oxygen to the unsaturated double linkages, *e.g.*, of an oil, thus:—

Or if it is desirable to summarise the reaction the following scheme may serve:—

The lead compound is alternately peroxidised and reduced and peroxidised again, the supply of oxygen from the air being practically inexhaustible. It is therefore obvious that provided that the metal still remains in solution as a soap, a very small quantity will suffice for the oxidation of an oil.

Taking lead linoleate, the action would be as follows:—

for it is found that the lead soap of linseed oil (glycerol-free) exerts a drying action.

The above theory would apply to all metals that act as "driers."

The results in the previous papers of Mr. W. McD. Mackey and myself confirm the theory, and show by actual experiment its truth as applied to the metals examined. They are not in absolute agreement in all cases with the theory, but the reasons for this are set forth in the papers.

DISCUSSION.

The CHAIRMAN said that the subjects for discussion resolved themselves into three divisions. Firstly, a number of experimental facts with both a technical and scientific value regarding the action of the metallic soaps in the oxidation of oils. Secondly, a theory put forward connecting the action of these soaps with the position of the various metals in the periodic classification, and their existence in more than one stage of oxidation, and thirdly a more complicated theory on the changes in the oil due to the action of the "driers," or accelerated thereby. He asked if the metals used in each case were pure and how the preliminary estimate mentioned in the paper of the probable similarity of cerium and lead in drying power had been arrived at.

Mr. F. W. RICHARDSON asked what was the reason for using cotton wool; he preferred asbestos wool or slag-wool. He also asked if the action of the metallic soaps on the composition of the cotton-wool had been investigated, more especially with regard to the sodium soap. He thought there was a liability to form oxycellulose. He was rather surprised at the widely different action of the cobalt and iron soaps (these metals occurring in the same group). In Mr. Ingle's theory he noted that a small amount of lead would act as carrier for an indefinite amount of oxygen under suitable conditions.

Mr. DAVIES asked if it was possible to form two soaps from one metal, *e.g.*, cobaltous and cobaltic. He noted that the more active elements here, *viz.*, nickel and cobalt, also acted as carriers of hydrogen in the hardening of oils. He also asked if a mixture of the metallic oxides had been tried.

Prof. A. G. PERKIN said his chief interest was the effect of oils in the dyeing operation. In preparing oiled cotton for these purposes it was considered that oxidation occurred and was followed by the production of insoluble lactones. He understood that Dr. Ingle held other views, and would be glad to hear these explained.

Mr. RICHARDSON asked if asbestos fibre had been tried. He said that the results were not comparable in the case of the sodium, no number having been obtained with sodium soap and olive oil. He certainly thought that this was due to the formation of oxycellulose.

Mr. W. HARRISON asked if the cotton had been dried before use, because he thought that 5% of water would make a difference in the readings. With regard to the possible influence of the cellulose in promoting oxidation, as suggested by Mr. Richardson, Dorée (*J. Chem. Soc.*, 1912, 101, 499) had stated that cellulose formed a peroxide on treatment with ozone. It was not to be expected, however, that such a compound would be formed in this case since the oils themselves were more likely to take up oxygen. The fact that oxycellulose was formed when drying oils were allowed to oxidise on cotton had been observed by the author some years ago, but its formation indicated a retarding action of the cellulose since it used up oxygen; moreover, oxycellulose, and in fact most of the oxidation products of cellulose, were reducing agents and should therefore retard the oxidation of oils.

Mr. B. A. BURRELL agreed with Mr. Richardson notwithstanding the curious results obtained with slag-wool. He had found that with fish oils cotton-wool heated more quickly than ordinary wool and actually fired. He thought that more information with regard to the preparation of the metallic soaps was desirable; were they pure or did they contain the by-products produced in their formation?

Mr. W. HARRISON asked if Dr. Ingle was acquainted with the fact that metallic soaps when dissolved in benzene caused it to conduct electricity to some

extent? It was therefore by no means impossible that ionisation might take place in benzene and in oils. The reason he asked the question about the moisture in cotton was because he thought that the water might get emulsified in the oil and thereby increase the surface exposed. This might be the explanation of the effect of sodium soap in increasing the rate of heating.

Mr. A. WOODMANSEY thought the inorganic wool would be the better of the two. He also thought that the specific heat of the fibre might cause the variation in time required for the same oil to heat up with different wools. The amount of oil per unit area, if determined, would be useful.

Mr. J. MILLER said that cotton wool was the easiest to manipulate. Slag wool might be either basic or acid and this might be a serious factor. When glass wool was squeezed in the hand in order to make an even distribution of the oil, the fibres broke into short pieces.

Mr. W. McD. MACKEY said, in answer to Mr. Davies, that 2% of the metallic soap in the oil was used in each case. A mixture of metallic oxides had not been tried. With regard to Mr. Richardson's and Mr. Harrison's remarks, Mr. Mackey said he quite appreciated the point concerning the action of the sodium soap on the cotton wool. He (Mr. Mackey) was responsible for the use of cotton wool in the experiments, his reason for using it being that he had come to the opinion that the cotton wool had no part in the reaction, unless towards the end, when the temperature rose and firing occurred. He had tried experiments under similar conditions with both cotton wool and such substances as glass wool, and had found that in experiments in which he had compared the behaviour of slag wool and glass wool with that of cotton wool in the Cloth Oil Tester, the temperature had gone up more quickly with the two former than with cotton wool (see this *J.*, 1915, p. 595). Further, with slag and glass wool it was impossible to keep an evenly exposed surface unless comparatively little oil was used, the oil tending to run to the bottom of the wool in the cylindrical cage.

The cotton wool had not been dried and no estimation of the moisture had been made. It was of course well known that moisture accelerated the reaction; thus, if the Tester leaked slightly, a little water getting inside accelerated the rise in temperature and vitiated the experiment. But in these experiments he had assumed that the little moisture present naturally in the cotton wool was driven off by the time the temperature rose above 100°C.

With reference to Mr. Burrell's remarks, it had been found that the rise of temperature was slower with ordinary wool than with cotton wool. Cotton wool was used ordinarily in the Tester because it could always be obtained of the same composition and texture. "Absorbent" cotton wool was used, *i.e.*, cotton wool which had been thoroughly extracted to remove any trace of grease.

The criticism as a whole had been very suggestive and it had been so in the case of the paper that Dr. Ingle and he gave last session, and it was to some extent owing to such questions as those raised by Mr. Harrison in the discussion that they had been encouraged to follow the matter up to the extent they had in the present paper.

Dr. INGLE said, in reply to Mr. Richardson's question with regard to sodium soap solution in oil, unless there was water present no hydrolysis of the soap could result and therefore he did not think that any oxycellulose could be formed. He was very interested to hear of experiments on the fact that metallic soaps dissolved in benzol conducted electricity. This had a very important bearing on his theory and the idea with regard to the ionisation of sodium salts dissolved in oil had been set forth in the paper.

He also drew attention to the action of cerium and thorium as applied to the gas mantle industry. All the metallic salts were bought as "pure."

The stability of the oxides and salts of iron, nickel, and cobalt was not the same. The lower oxides of the two latter were the more stable while the intermediate oxides of iron were more stable than the lowest. This would explain the results.

Asbestos had not been tried, but the authors had it in mind. The results obtained with cotton wool were comparable.

With regard to the preparation of the soaps he had little to add. They generally separated out well, but sometimes required "salting" out. They were washed with hot water on the filter, dried, and finally melted. Soaps of ferrous and ferric salts were prepared, but by the Weger plate method no difference could be detected.

In all the experiments the soaps used were dissolved in the oil at a gentle heat.

Communications.

ORGANIC VULCANISATION ACCELERATORS.

BY S. J. PEACHEY.

In reference to the above subject a communication from Dr. Spence has recently appeared in this Journal (1917, p. 118). The statements made therein appear to me to be of such an intemperate character that I feel constrained to challenge them.

In a curious preamble the writer protests that all those who have preceded him in contributing to the literature of the subject have "assumed that that which is not proclaimed from the housetop is not known, and from these faulty premises have drawn certain equally erroneous yet sweeping conclusions which it has been" his "intention sooner or later to nullify and correct."

After reviewing the discoveries made by different investigators in the new field of research he proceeds to elaborate a claim to priority which certainly cannot be said to err on the side of modesty. In effect he says that the use of the organic vulcanisation catalysts discovered and patented by Bayer and Co. in 1912 was known to him in America six months previously, and he claims further to have prediscovered the use of the nitroso-compounds which I patented in 1914 as accelerators of vulcanisation. In his own words "the proof of this assertion and the complete vindication of my position with reference to the subject I am content to leave over to a later date. At that time I will also bring evidence to show that even the reagents claimed by Peachey (English Patent 4263 of 1911) were known to me and had been used by me both scientifically and industrially several years before his application was applied for."

In so far as the above statements concern my own discovery I must point out that Spence's claim to priority is put forward unsupported by even the slenderest thread of evidence; as a matter of fairness therefore it should have been held back until such time as he chose to disclose his promised proofs. I may add that the nitroso-compounds, the use of which was patented by me, constitute a class of accelerators quite distinct from those discovered by Bayer and Co. in that the mechanism of the acceleration differs in the two cases; it would therefore be a remarkable coincidence if both types of catalyst should have been anticipated, and one is tempted to ask why Dr. Spence refrained from either publishing or patenting his discoveries.

I suggest that having put forward his claim in a scientific journal he should without delay submit the evidence which he has promised to reveal at a future date.

THE REMOVAL OF PITCH FROM SULPHITE PULP.

BY K. H. KNUDSEN.

(Abstract.)

The precise cause of the trouble experienced from the presence of resin in sulphite pulp has not yet been determined, but the evidence points to the fact that it is not necessary to remove the whole of the resin from the pulp, provided that it can be evenly distributed. A pulp with a low resin content may cause trouble whereas one with a higher content may be satisfactory.

The deleterious effects of resin are especially noticeable in the manufacture of thin paper, and occasionally the resin gives rise to considerable trouble in the bleaching of the pulp; the bleaching process seems to favour the agglomeration of the resin particles.

The author has examined a number of bleached pulp sheets containing resin spots, and has always found sulphur and lime to be present in these spots. Further examination showed that the mineral matter in these spots consisted of calcium monosulphite and silica. This points to the fact that the calcium monosulphite must have been embedded in the resin, since it could hardly have resisted oxidation during 12 to 15 hours in the bleaching beater. It would thus appear to be established that the clotting is produced mechanically by cumulative cohesion due to the slow rotation of the warm pulp. Hence more pronounced clotting will occur in the beater with pulps containing a greater number of resin-coated particles. It is probable therefore that the trouble can best be remedied during the digestion of the chips.

At the mill in which this investigation was made, the resin content of the pulp was fairly constant between 0.8 and 0.9%, and gave little trouble. On one occasion, however, trouble was found to occur in the bleaching beaters and no remedy could be found for it until the pulp was removed from the digesters when the liquor was lighter in colour than usual; this completely overcame the difficulty.

Although the advantages of the various devices and methods for removing resin from pulp during the later stages of manufacture must not be ignored, the author believes it to be of the greatest importance to prevent as far as possible the separation of crystalline deposits in the digester, since the calcium monosulphite crystals appear to facilitate the separation of the resin particles, particularly if the wood has not been properly seasoned.

Institute of Metals.

At the Annual General Meeting of the Institute of Metals, held on March 21st and 22nd, the most noteworthy feature was a general discussion on the melting of non-ferrous metals.

This discussion was opened by the PRESIDENT, Sir G. T. Beilby, who said that the object in view was to make known the best and latest developments in the melting of non-ferrous metals. The desiderata for successful results appeared to be speed of melting, purity of molten metal, i.e., freedom from contamination by gaseous and other impurities, accurate control of temperature, and economy in regard to fuel, labour, and repairs.

Furnaces designed on the principle of the laboratory gas blowpipe could not be regarded as the best type. He had had considerable experience in the use of water-gas as fuel, and he would recommend gas and air under low pressure, both measured; plenty of room for combustion, and no tall chimneys exposed to wind and weather. There should be a positive pressure in the furnace and the furnace gases should be led through a simple regenerator, which might be constructed of steel tubes so mounted in an oven that there was no "cutting" action by the gases. He drew attention to the recent formation of the Board of Fuel Research (this J., 1917, 203) and to the fact that users of fuel might afford considerable help by placing their experience at the disposal of the Board.

Mr. W. J. HOCKING read a paper on "Metal melting as practised at the Royal Mint." He pointed out that in the production of cast bars of coinage alloys, the strict requirements as to uniformity of composition tended to restrict the size of the charges. The usual charges were 2800 oz. (87 kilos.) for standard gold (Au 91½, Cu 8½%), 6000 oz. (187 kilos.) for Imperial silver (Ag 92.5, Cu 7.5%), and 400 lb. (182 kilos.) for bronze (Cu 95, Sn 4, Zn 1%) and cupronickel (Cu 75, Ni 25%). Since 1910 low-pressure coal gas had been used as fuel in place of the coke previously employed. The present installation comprised 16 furnaces for melting silver, bronze, and cupronickel, and 10 similar but smaller furnaces for gold. The large furnaces were built of Stourbridge firebrick lined with bricks, 3 in. thick, the joints

Records of costs were given for the five years, 1905-9, using coke, and for the five years, 1911-16, using gas as fuel. These showed that with gaseous fuel as compared with coke, the rate of output was more than doubled, the greatest increase being with the high-melting metals; and the cost of fuel per ton melted was reduced by about 3½%, the cost of crucibles, etc., by 32.6%, and the cost of labour by 19%, the mean total economy under the three last-mentioned heads being about 25% (see also Rigg, this J., 1914, 1157). In the period 1911-16, 9900 tons of coinage metal was melted with a total gas consumption of 121 million cubic feet, at an average cost for gas of 20.58s. per ton melted.

In a paper entitled "Coal gas as a fuel for melting non-ferrous alloys," Mr. G. B. BROOK gave the results of a test under works conditions, extending over 10 days of 10 hours each, of the melting of cupronickel (Cu 80, Ni 20%) in a gas-fired pit furnace taking a 60-lb. crucible and using Sheffield town gas (532 B.Th.U. gross), and air at a pressure of 3-6 in. of mercury. It was found that there was no difficulty in obtaining a temperature of 1400 °C., and the results of the test indicated the following advantages in favour of gas as fuel as compared with coke, *viz.*, absence of ashes, elimination of wasteful process of "slagging," economy of fuel as a result of ease of control, higher rate of melting, and reduction of impurities introduced during melting. Based on the results of the tests, the following comparison of the costs of melting, in different districts, with coke and gas respectively as fuel, was given:—

Town.	Special high-grade coke: "metallurgical," "steel," etc.	Gas (minimum rate per 1000 cub. feet).	Cost of melting cupronickel per ton (based on ruling prices for fuel).	
			Gas.	Coke.
Sheffield	40s. 3d. per ton	1s. 4d.*	24s. 2d. (found)	36s. 4d. (found)
		1s. 9d.	31s. 9d.	
Glasgow	about 40s. per ton	1s. 5d.	25s. 8d. (calc.)	36s. (calc.)
Birmingham	45s. 6d. per ton	1s. 5d.	25s. 8d. "	41s. 3d. "
London	50s. per ton	2s. 8d.	48s. 4d. "	45s. 5d.
		(Wandsworth, 2s.)	(34s. 3d.)	

* For use in gas-engines only.

being made with a mixture of carborundum, fire-sand, and sodium silicate. The central well was 19 in. diam. and 32 in. deep, and was closed, during melting, by a circular firebrick weighing 1½ cwt., for which a wheeled carriage was provided. The burner was of the Brayshaw type, and gas was supplied at 3 in. water pressure through a 6-in. service pipe, and air at 2½ lb. pressure by means of three rotary Reichhelm blowers, each with a capacity of 36,000 cb. ft. The gas consumption by the 16 large furnaces was about 15,000 cb. ft. per hour. From the burner mixing chamber the gas and air passed through a right-angled elbow pipe and a screwed nozzle with diminishing bore into the ignition hole of the furnace formed in a block of firebrick. The nozzle fitted closely in a recess in this block and was surrounded by asbestos packing, and the passage for the gas and air opened out from a bottle-neck portion of 1½ in. diam., at an angle of 30°, into the well of the furnace, the flame passing between the crucible and the side of the furnace, without impinging on either, then round the crucible in an upward double spiral. The best results were obtained when combustion was complete in the furnace itself. Care was taken to keep the furnace lining free from excrescences, and to repair faults immediately, and the life of the lining was lengthened in this way; in general the entire lining was renewed two or three times a year.

Mr. C. M. WALTER read a paper on "Metal melting by means of high pressure gas." He pointed out that there was now, at Birmingham, as part of the gas distributing system, some 24 miles of mains carrying gas at a pressure of about 12 lb. per sq. in., and that in places where a supply of high-pressure gas was not directly available, a reciprocating type of compressor, capable of compressing 10,000 cb. ft. of gas per hour to a pressure of 12 lb. per sq. in., could be installed at a cost of about £300 (pre-war prices), whilst the total cost of working would be about 1½d. per 1000 cb. ft. of gas compressed and delivered, with power at ¾d. per horse-power hour. He gave a detailed description of a furnace of 60 lb. crucible capacity, fitted with a single high-pressure injector burner (see Eng. Pat. 1872 of 1911; this J., 1912, 221) and brief descriptions of larger furnaces. These furnaces showed many advantages; the economy effected owing to reduction in metal losses in brass melting would alone more than outweigh the extra fuel cost compared with coke. In a test under foundry conditions with twelve 50-lb. high-pressure gas-fired brass-melting furnaces, the gas consumption was 7.6 cb. ft. per lb. of metal melted, whilst for melting cupronickel (80 : 20) in a 130 lb. furnace the consumption was 9.4 cb. ft. per lb., and for melting 72 : 28 cartridge metal in a 160-lb. furnace, 6.2 cb. ft. per lb. In a battery of twelve 130 lb. furnaces for melting brass for the production

of 100-lb. billets, the gas consumption was 5.9 cb. ft. per lb. of metal melted, and the maintenance cost 0.7d. per cwt. of metal melted. The maintenance cost of a 60-lb. furnace was about 1.65d. per cwt. of metal melted. For the melting of brass for medium and light cored castings, the gas consumption was about 12 cb. ft. per lb. of castings produced, the metal loss amounting to about 4% of the metal melted. The use of high-pressure gas had proved specially advantageous for melting aluminium and its alloys, and one firm alone, in Birmingham, used 25,000 cb. ft. of high-pressure gas per hour for that purpose. For melting pure nickel and for melting swarf or scrap in large pots, excellent results had been obtained by use of a double injector burner supplied with gas at a pressure of 4 lb. per sq. in. and air at 20-in. water gauge (as could be obtained with a high-pressure fan); a mixture velocity of 10,000 ft. per min. in the burner tube was thus attainable.

A paper entitled "Metal melting," by Messrs. H. M. Thornton and H. Hartley, was read by Mr. THORNTON, who pointed out that the cost per B.Th.U. was much higher for gas than for coke, and hence an increased thermal efficiency was essential to obtain successful results with gas firing. The thermal efficiency was lower the higher the pouring temperature of the molten metal. In test experiments on brass melting the metal was poured at a temperature 100° C. above the liquidus curve of the alloy; a 20% increase in gas consumption would be required to obtain a pouring temperature 100° C. higher than this. The experiments were made with a 70-lb. crucible furnace in which the furnace gases passed first through a metal preheating chamber and then around the air supply pipes. For a pouring temperature of 1000° C. yellow brass was melted with an expenditure, per lb. of metal melted, of 1200 B.Th.U. on the basis of six successive melts, 1030 B.Th.U. for 12 melts, and 960 B.Th.U. for 20 melts. With a pouring temperature of 1000° C. the loss of zinc from yellow brass by vaporisation could be reduced to 1.5% (on original zinc), but with a pouring temperature of 1180° C. the loss was about 6%. The lowest losses of zinc appeared to be obtained when a charcoal covering and a small amount of flux were used together.

An "Electric resistance furnace for melting in crucibles," devised by Dr. H. C. Greenwood and Dr. R. S. Hutton, was described by Dr. HUTTON. The furnace was constructed of sixteen upright carbon rods, 1 in. diam. and 19 in. long, arranged in a 13 in. circle and connected in series, by graphite blocks, alternately at top and bottom, to form two opposite pairs of eight rods each. A mixture of carborundum, fire-sand, and sodium silicate was pasted round the rods. The heat insulation consisted entirely of kieselguhr, but a better system would be a ring of carborundum bricks encircling the carbon rods and outside this an inner layer of fire-sand, and an outer layer of kieselguhr. The furnace was designed primarily for melting nickel-silver, and a test run of two heats (3 hours and 1 hr. 35 min. respectively; charge 90 lb.) indicated that with five heats per day, starting cold, the energy consumption would be 42.5 kilowatt-hours per cwt., corresponding to a cost of 2s. 8d. per cwt. with power at 0.8d. per unit. The thermal efficiency of the furnace was about 22%, as compared with about 6% for a gas-fired furnace, and the new plumbago crucible showed practically no change in appearance after several heats.

A paper entitled "Ideals and limitations in the melting of non-ferrous metals," by Mr. C. HERING, was read by the Secretary, Mr. Shaw Scott. The paper summarised the principles underlying the best possible conditions for the melting of metals—chiefly from the standpoint of the thermal

engineer—and indicated the directions in which progress might be made and the limitations imposed both by theory and practice.

The Secretary also read a paper by Mr. H. S. PRIMROSE, on "Metal melting in a simple crude oil-furnace." The furnace, the whole of which was above the floor level, consisted of a rectangular box of mild steel plates bolted together, lined with firebrick set in ganister so as to form a circular well. The bottom of the furnace was in one piece, and oil and air were supplied through a special burner brick which caused the oil spray to spread out in conical form and to enter the furnace with a tangential motion. When low-pressure burners were used, small high-speed electric fans, capable of producing about 12 oz. air pressure (20—22 in. water gauge), could be used to operate four furnaces simultaneously. Under these conditions the oil consumption was slightly more than 2 galls. per 100 lb. of metal melted, and 100 lb. charges of brass could be melted and poured in 35 mins., and 200 lb. charges in 50—55 mins. The furnace could be operated by unskilled labour, was easy to repair, and the pots lasted longer than in gas furnaces.

Mr. H. L. REASON gave a brief abstract of a paper on "Coke-fired furnaces," pointing out that these were more largely employed still than any other type. Furnaces of square section gave lower fuel consumptions than those of circular section and were easier to repair. An average temperature of 1250° C. was obtained in a natural-draught coke-fired brass furnace, and a temperature of 1600° C. was attainable. The melting loss averaged 5%, chiefly zinc. The greatest drawback to coke furnaces was the trouble due to clinkering, but considerable improvement in this respect had resulted from the use of furnace bottoms of the types devised by Hall (Eng. Pat. 4991 of 1915; this J., 1916, 426) and by Wigley (Eng. Pat. Appl. No. 7431 of 1916), in which loose fire-bars were mounted in a frame so that air could enter at the sides above the bars as well as up between the bars. In the event of the bars becoming choked, sufficient air could enter from the sides to ensure proper combustion, and the loose bars could be readily removed through an opening in front of the furnace.

A brief description of a "Producer-gas-fired crucible furnace" was given by Mr. T. TEISEN. The furnace (see Eng. Pat. 15,887 of 1915; this J., 1917, 36) was similar in principle to furnaces used very successfully for glass-melting in Sweden. The producer is built in the furnace and the gas passes direct to the furnace chamber, of circular section, containing six crucibles. The furnace gases are utilised to preheat the secondary air by the continuous recuperative system, the recuperator being constructed of firebrick tubes, of rectangular section, and so shaped that when assembled, conduits for the air are formed between the tubes. In a similar furnace for melting glass, using wood as fuel, the air was preheated to 1010—1060° in this way. For metal melting it had been found that the furnaces were economical in regard to fuel consumption, and the life of the crucibles was increased, and the metal loss reduced in comparison with furnaces fired with solid fuel.

Sir T. K. ROSE said that the advantages of gas firing seemed to be generally admitted. It was unfortunate that the papers afforded no data for a direct comparison of the relative efficiencies of high- and low-pressure gas. Some of the figures given on the one hand by Mr. Hocking, and on the other by Mr. Walter, would appear to indicate that no advantage as regards gas consumption was gained by using high-pressure gas for the metals of relatively low melting point.

Dr. R. S. HUTTON said that Mr. Hocking's record of results over a long period was very valuable.

He knew of no similar record from other sources. The record showed that gas firing had passed from the experimental to the commercial stage, but he wished to warn the gas interests that if continued and general success was to be achieved, there must be a regular supply of gas of uniform quality and pressure, and furnaces must be designed to permit of easy control and operation by untrained workmen. He could confirm Messrs. Thornton and Hartley as to the considerable economy of gas consumption resulting from preheating the metal.

Mr. H. J. YATES confirmed Mr. Walter's statements as to the value of using air under pressure. With gas at ordinary pressure and air at 3 lb., he had obtained gas consumptions of 5.8–6.7 cb. ft. per lb. of metal melted for cupronickel, 2.9–3.5 cb. ft. for brass, and 1.8 cb. ft. for copper. With careful management it should be possible to obtain 80 heats per pot.

Mr. L. C. HURVEY said that a good practical test of the satisfactory working of a gas furnace was to have a damper in the flue and a small hole in the furnace cover, when so long as a small flame burned at this hole, they could be sure that the furnace atmosphere was reducing. A trustworthy comparison of gas, oil, and coke-fired furnaces could be made only if each type were used under the requisite conditions for obtaining maximum efficiency, and he considered that neglect of this consideration detracted from the value of the comparative figures given by Mr. Brook in the first part of his paper. The double-jacketed tilting furnace, with the outer jacket cooled by air, which was capable of taking 6 cwt. charges and was poured direct, had proved of great value recently, owing to the saving of labour it allowed, and it might be said to have saved the situation so far as the output of brass for munitions of war was concerned.

Dr. W. ROSENHAIN thought that the high efficiency claimed for gas-fired in comparison with coke-fired furnaces was rather surprising, having regard to the fact that the solid fuel had first to be converted into gas. Was it not probable that the results were due partly to the low efficiency of existing coke furnaces, and that the latter might be improved, so as to give much higher efficiencies? Little regard was at present paid to the thermal conductivity of furnace materials, although a considerable proportion of the total heat was consumed in heating the furnace itself. It was possible to reduce the loss of heat from the furnace, but then the temperature of the inner wall increased, and the life of the furnace lining was diminished. This pointed to the need of research in regard to refractory materials. In many cases, at present, the practice appeared to be to avoid the problem of suitable refractory materials by air cooling the outer wall of the furnace. In pit furnaces there might be considerable loss of heat by conduction through the earth, and it was probable that the efficiency would be increased by interposing an insulating layer between the furnace and the earth. He could confirm Mr. Hocking as to the value of applying a carborundum wash to furnace linings. In coke-fired pit-furnaces it was a question of heat loss by conduction versus loss by radiation. With progressively increasing thickness of the wall of the furnace, the loss of heat was first reduced, but subsequently again increased owing to increased loss by conduction. It was surprising that furnaces fired direct with gas from a producer built in the furnace had not been adopted to any considerable extent for the melting of non-ferrous metals, having regard to the high value of such furnaces in the steel and glass industries. The continuous recuperative system of utilising the heat of furnace gases possessed many advantages over the discontinuous regenerative system, the chief disadvantage being the higher

cost of repairs. Electric furnaces were likely to become of steadily increasing importance in view of the increasingly stricter requirements as to purity of metal and accurate control of temperature and furnace atmosphere. In a gas furnace the atmosphere was of necessity non-homogeneous, or it would be explosive; hence it was reducing in some places and oxidising in others. The induction type of electric furnace appeared to be the most promising, for in this type the heat was generated in the metal itself.

SIR GERARD MUNTZ stated that as compared with figures of 10, 12, and 25% which had been mentioned for metal losses in melting, he considered that an average of 14% was high enough for coke-fired furnaces. One of the greatest difficulties in melting metals was the absorption of gases, leading to unsound castings. Research was needed in regard to the absorption of gases by brass, bronze, copper, and cupronickel; it was probable that different metals absorbed different gases and at different temperatures. He agreed with Dr. Rosenhain that the electric furnace would be used to an increasing extent in the future, its great advantages being the ease of control of temperature, the freedom from deleterious gases, and freedom from dirt.

Mr. H. HARTLEY said that the great differences between the results of special tests and of ordinary working in the factory indicated that efficient control of the operation of the furnace was essential. Probably better results would be obtained with furnaces of smaller size; the number of heats would be increased and this would result in a higher over-all thermal efficiency.

Mr. C. W. SPEERS pointed out that at the present time the economical use of crucibles was of special importance, as the most important material used in their manufacture came from abroad. He would advocate the payment of a bonus to workmen for all heats above a given number obtained from one crucible. The life of a crucible could be prolonged considerably by leaving the gas on whilst pouring. He also referred to an electric furnace in which the crucible itself was used as a resistance-heater (see Eng. Pat. 21,626 of 1912; this J., 1913, 1019).

Mr. S. BRAYSHAW said that in ordinary works practice, over a period of 18 months, nickel had been melted as a cost of 1s. 9d. with gas as compared with 4s. 2d. with coke. He had obtained a temperature of 1800° C. in a gas furnace with gas and air preheated, the air being at 2 lb. pressure. He thought that in the case of gas furnaces the future would lie with those using low-pressure gas and air at a few oz. (not more than 12 in. water gauge) pressure.

Mr. BARTLEY pointed out that the efficient operation of furnaces depended largely on the workmen. There were two possible lines of advance; one by raising the workmen to a higher level by training, and the other by seeking to improve mechanical devices and so eliminate the human element as far as possible.

Prof. T. TURNER expressed the opinion that the heat losses were mostly up the chimney. The volume, temperature, and composition of the chimney gases must be known and controlled. He had found that for melting a few lb. of metal in the laboratory, good results were obtainable with a simple electric furnace consisting of two carbon bars, about 3 in. thick, between and in contact with which was fitted a dish made of a mixture of clay with one-third of its weight of ground retort carbon; the carbon bars did not get very hot and hence did not burn away.

Mr. A. G. ROXBURGH gave several instances of the successful use of gas-fired furnaces. In one case in which swarf, sweepings, etc., were melted in a 12-cwt. pot, the gas consumption was 12–14

cb. ft. per lb. of metal melted. This high result was found to be due to the combustion space being too large, and by suitably modifying the furnace the gas consumption was reduced to somewhat more than 5 cb. ft.

Other papers were read in addition to the contributions to the discussion on metal melting.

Mr. O. W. ELLIS read a paper, "The general properties of stampings and chill castings in brass of approximately 60/40 composition," and a note on the "Machining properties of brass." It was shown that in finished brass stampings (Cu 55—65%) the Brinell hardness was inversely proportional to the copper content. There was no simple relation between the time of machining and the copper content or Brinell hardness. Annealing subsequent to stamping was desirable to obtain uniformity. A temperature below 650° C. was better than one above 650° C. for annealing. In practice it had been found that cold-rolled brass rods with a Brinell hardness of 140 could be machined almost as easily as stampings with a Brinell hardness of 70, and Mr. Ellis suggested an explanation of this difference based on the microstructure.

Prof. T. TURNER pointed out that the direct linear relationship between the Brinell hardness and the copper content was true only over a very limited range and when no impurities were present.

Dr. W. ROSENTHAL said that the hardness of cold-worked metals was largely strain-hardness, which differed from structural hardness in that it was anisotropic, *i.e.*, it was different in different directions. This might account for the different machining properties of cold-rolled rods and stampings. Strain-hardness might be removed by the local softening due to heat developed by the point of the tool.

Mr. J. H. ROBINSON stated that the results of Mr. Ellis were very valuable technically, in that they showed that to obtain the best results in regard to mechanical, physical, and machining properties, it was necessary to keep as closely as possible to the 60 : 40 composition for brass.

Dr. S. W. SMITH read a paper on "Surface tension and cohesion in metals and alloys," which was discussed by Sir T. K. Rose and Dr. F. C. Thompson.

A note by Dr. R. Seligman, entitled "Aluminium production by electrolysis; a note on the mechanism of the reaction," was taken as read. In this note it was pointed out that the view generally held that carbon monoxide was the sole gaseous product of the reduction of alumina by the electrolysis of a fused mixture of cryolite and alumina with a carbon anode, was incorrect. In laboratory experiments reproducing the conditions of large-scale practice, gases containing more than 3 vols. of CO₂ to 1 vol. CO had been obtained. To obtain comparable results in laboratory tests, the furnace should be heated independently and not by the current used for electrolysis, as in large scale work, because the heat loss was relatively much greater from small than from large furnaces. The consumption of anode carbon in works practice was considerably lower than was theoretically possible if carbon monoxide was the only gaseous reaction product. It was suggested that the primary gaseous product of the electrolysis was oxygen, and that whether oxygen, carbon dioxide, or carbon monoxide resulted was dependent upon such factors as temperature, current density, physical properties of the carbon anode, and rapidly with which the gases were removed.

Dr. F. C. Thompson read a paper on the "Annealing of nickel-silver (Part II.)." (For Part I., see this J., 1916, 472.) He described tests

made with an alloy containing Cu about 60, and Ni 10%, prepared under works conditions. The mechanical properties were ascertained by means of Arnold's alternating stress tester, which had been found of great value for non-ferrous metals as well as steel. When close annealed in iron pots at 800° C., the alloy had the maximum ductility after 5 hours, and satisfactory results were obtained after annealing for a shorter period even than this. The alloy melted in clay crucibles proved superior to that melted in plumbago. Ductility and toughness were improved by deoxidising with cupromanganese. Tempering and quenching experiments carried out in connection with the transition point which had been observed at 300°—400° C. in nickel-silver, gave results from which it was concluded that nickel-silver which has been annealed at 700° C. until equilibrium has been established, will consist of: (a) a stable B form when very slowly cooled, (b) a metastable A form when very rapidly cooled by quenching, or (c) a mixture of A and B when cooled at an intermediate rate. The A and B forms are soft and ductile, whereas mixtures of A and B are relatively harder and brittle. The B form may be regarded as analogous to fully annealed pearlite in steel, the A form to austenite, and mixtures of A and B to hardenite or troostite or sorbitic forms.

Research work on the simpler nickel-silvers might throw light on the nature of the hardening of steel.

Industrial Notes.

INTERNATIONAL CATALOGUE OF SCIENTIFIC LITERATURE.

THE International Catalogue of Scientific Literature is an outgrowth of the Catalogue of Scientific Papers published by the Royal Society of London. The Royal Society has issued twelve large quarto volumes giving the titles of papers published from 1800—1883, arranged under authors' names, and is now completing the author catalogue for the nineteenth century by issuing a series of volumes containing the titles of papers published in the years 1884—1900. Three of these volumes, containing authors' names from A to H, are already published. A subject index for all papers published from 1800 to 1900, each volume dealing with a separate science, is also in preparation by the Royal Society, the volumes for Mathematics, Mechanics, and Physics having been published. An absolutely complete record of the scientific literature of the nineteenth century will thus be available.

The continuance of such work into the twentieth century was obviously beyond the resources of a single society and demanded international co-operation. After lengthy preliminary discussions a conference was held in London in 1896 at which it was resolved unanimously to compile and publish a complete catalogue of scientific literature arranged according both to subject matter and authors' names, the preparation being commenced from January 1st, 1901.

The material for the catalogue is collected in the various countries by local organisations established for the purpose and generally State-aided. The final editing of the material for printing and publication is done by a Central Bureau in London directed by an International Council.

Dr. H. Forster Morley has throughout acted as Director of the Central Bureau. Seventeen branches of science are included in the scheme,

an annual volume being published for each. The entries in the subject index are in one of the following five languages: Latin, English, French, German, and Italian. In the authors' index the title in the original language is given followed by the translation into one of the above languages. The scope of the Catalogue comprises all original contributions, whether published in scientific or trade journals or as independent pamphlets or books, but not patents.

The object of this note is to make the Chemistry volume better known to industrial chemists, to which end the scheme of arrangement will be described. A separate volume with the reference letter D is issued for Chemistry, though chemical papers having special reference to other sciences are also included in the volumes for these sciences. The authors' index requires no explanation, though the fact that key numbers are attached to each paper gives some clue to the subject matter over and above what can be deduced from the actual title.

The subject index is classified under a novel system based in reality on that adopted in most text books. Key numbers are given to each section, a schedule of classification being printed at the beginning of each volume. The primary divisions are the specific chemistry of the elements, 0100; organic chemistry, 1000; analytical, 6000; industrial, 6800; theoretical, 7000; physiological, 8000; and agricultural chemistry, 8500. The object of the system, which is in reality very simple when mastered, is that a single section will give the user references to all the literature in the field, whereas numerous references to an ordinary subject index would be required, and even then important papers might be overlooked owing to their having non-descriptive titles. A worker in any subject will remember his particular key number without difficulty and at once find the pertinent pages in the catalogue. A good example of the time saved is afforded by the carbohydrate section. The 1913 issue of the Catalogue refers to 153 papers under the key numbers 1800—1850, classified on 5 pages, to find which probably one hundred different references in the annual index of this journal would be necessary.

Each element receives a key number, but they are arranged in the usual sequences: every paper in which reference is made to this element is collected under this number. Thus a worker interested in phosphorus compounds will find all the entries relating to it under 0570 and further that the papers within the section are subdivided under general, atomic weights, compounds, phosphides, hydrides, oxides, phosphoric acid, sulphides. The organic section is divided into hydrocarbons 1100, alcohols 1200, acids 1300, aldehydes 1400, ketones 1500, amino compounds 1600, azo compounds 1700, each section being further sub-divided into 10 paraffins, 20 unsaturated open chain, 30 benzenoid, 40 reduced benzenoid and cyclic derivatives.

The analytical and industrial sections are subdivided arbitrarily on lines very similar to those adopted in our abstracts, but the recollection of the key number very much facilitates reference. The physical section is sub-divided in considerable detail, and nowhere else are the references to this subject so complete. It should be emphasised that the key numbers are attached by experts who read the original papers, so that a vast amount of information is indexed to which the original title of the paper would give no clue.

The Catalogue forms by far the quickest and at the same time completest form of reference in any branch of chemistry, and it may be commended to manufacturers as likely to save a considerable amount of time when the literature has to be consulted.

The Catalogue is published in London by Harrison and Sons, St. Martin's Lane, W.C., the cost of the Annual Volume being 37s. 6d. Vol. XIII, of section D was published in November last, and contains the material received from September, 1914, to September, 1915. E. F. A.

WAR MAKESHIFTS IN GERMANY.

No one who has had the opportunity of reading the German chemical journals which have been issued since the outbreak of the war can fail to have been struck by the way in which they have served as a focus for the German characteristics of forethought and resourcefulness. Most of the national wants have been foreseen long before they occurred, and whenever it has been possible the chemist has found a substitute, although not always an efficient one.

Many of the devices which have been suggested or adopted have been mentioned from time to time in this Journal, but in most cases incidentally, and in connection with other questions, and a short summary of the steps which Germany has taken to meet some of her most pressing needs may therefore prove of interest.

Early in 1914 Germany foresaw that the struggle upon which she had then determined would be essentially a petrol war, and that every gallon of petrol would be required by her fighting services, and so the outbreak of the war found all the motor vehicles in Berlin, down to the taxi-cabs, provided with engines adapted to consume either petrol or alcohol. As some difficulties were experienced in using alcohol by itself, systematic experiments were made with mixtures of alcohol with benzene and other hydrocarbons, and the formulae giving the best results were published in the chemical journals.

The first plant for the fixation of nitrogen from the air was established in Germany not many months before the war, and at the present time the bulk of the nitrates required for the manufacture of her explosives is derived from that source. Nor is this the only direction in which nitrogen obtained from the air has been utilised. With the increasing strictness of the British blockade it became essential to discover a substitute for nitrogenous feeding-stuffs for horses and cattle, about 500,000 tons of which had been imported prior to the war. To meet this deficiency it was suggested to the authorities that a special yeast, which had a vigorous growth, but produced no alcohol, should be cultivated and pressed on a large scale. This work has been carried out under the direction of the Institute of Brewing in Berlin. Enormous shallow tanks, like swimming baths, have been erected, and in the bottom of these are fitted pipes to maintain the optimum temperature for the growth of the yeast, which is cultivated in a medium prepared from refuse material from the sugar works mixed with suitable salts, including ammonium salts obtained synthetically from the air. The compressed yeast is stated to be suitable not only as a nitrogenous fodder, but also for human food. It is estimated that before long Germany will be in a position to obtain from this source the whole of the nitrogenous fodder she requires, and that she will never again be dependent upon the outside world for her supplies.

In connection with feeding-stuffs it is significant that attention should at once have been directed to the utilisation of kitchen refuse. Within two months after the outbreak of the war a notice was issued by Prussian municipalities that all householders were required to sort their kitchen refuse. All fatty material was to be kept separate, whilst the vegetable material was to be saved for fodder.

As subsequently organised, more especially in the larger towns, it was prescribed that the fatty material should be taken to specified soap works, where the glycerin was to be separated and the soap returned to the householder. No one is allowed to make any soap privately.

One difficulty in dealing with the vegetable matter was the necessity of drying it quickly to prevent putrefaction, and it was suggested that the waste heat of the gas works should be utilised in this way, although subsequent issues of the journal do not state whether this has been done. Still more recently attention has been directed to the annual loss of potatoes by disease, and it is suggested that frost-bitten or diseased potatoes should be dried and used as an ingredient of fodder, or that they should be used in the preparation of starch. Whilst Germany has been making use of kitchen refuse in this way for over two years it is only within the last month that any proposal to prevent this loss in this country has been put forward.

The lack of oils and fats has been Germany's greatest difficulty and she has only been able to supply her wants of nitroglycerin at the expense of the health of the community. Hence the chemical papers have constantly published the results of the analyses of little-known home-grown seeds, which have never before been regarded as possible sources of oil. It has been shown that asparagus and other vegetable seeds contain a considerable proportion of oil, though it is doubtful whether they would repay the labour of extracting it. In two cases, however, the suggestion of the chemist has borne fruit. Horse-chestnuts are now systematically collected both for the separation of the large amount of oil which they contain, and for the preparation of a saponin extract to take the place of soap; whilst in Southern Germany the National Women's Guild has made itself responsible for the collection of the enormous quantities of cherry stones, which were previously thrown away. These are crushed and the kernels separated by an ingenious method of treatment with a solution of a salt of such specific gravity that the kernels float on the surface while the shells sink. The kernels are then dried and the oil expressed in the usual way. By means such as these Germany has made great additions to her supplies of oils, but the deficiency is too great to be materially alleviated by any device short of the synthesis of fat.

Mention might also be made of the various detailed experiments which have been carried out to discover palatable substitutes for tea, coffee, and cocoa, and of those upon which the composition of the so-called war-bread has been based. In every direction the German places himself in the hands of the expert chemist, and it is only the lack of raw material in certain essential particulars, which has prevented the chemist from solving every material difficulty with which Germany is now face to face.

C. A. M.

POTASH RECOVERY AT BLAST FURNACES AND CEMENT WORKS.

During the last year or two schemes have been put in operation in America for the recovery of potash as a by-product in certain manufactures, such as iron and Portland cement.

As regards the former, an account of what has

been done by the Bethlehem Steel Company was given recently before the American Institute of Mining Engineers by Mr. R. J. Wysor, the superintendent of the blast furnaces. An analysis made five years ago of the fine yellowish fume removed from the bottom of the stove checker-work showed the presence of about 15% of potash soluble in water. Further investigation proved that considerable quantities of the material could be recovered, but the prices offered for it for fertilising purposes did not at that time justify the cost of the operation. But the situation was changed with the rise in price caused by the war, and for some time past the dust has been sold at a good profit. The average potash content in the ore mixture charged into the furnaces is found to vary between 0.27 and 0.29%, the soda ranging from 0.13 to 0.63%, and calculations indicate that for each ton of pig iron produced nearly 60 lb. of the alkali oxides are charged in. Some of this alkali passes out with the gas, some with the slag, and some in other ways. At Bethlehem all the gas for the stoves and boilers, as well as for the gas engines, is washed, except from one furnace, in a tower spray washer, and it might be supposed that practically all the alkaline material in the dust, most of it being readily soluble in water, would thus be removed. In fact, the bulk of it is washed out, but it is remarkable that much of the water-soluble alkali does remain in the gas current leaving the washers, and about 21% of the potash, but apparently only about 5% of the soda, entering the primary washers, passes through them. A possible explanation is that the particles of fume are in such a fine state of subdivision as to escape contact with the relatively large drops of water. The water-soluble content of the dry ignited dust recovered from the stoves and boilers, having previously passed through the wet washers, varies from 5 to 20%. In the period between April 1, 1915, and July 1, 1916, the alkaline dust collected amounted to 36 car-loads with a total weight of 1073 tons, and from it 106 tons of water-soluble potash was obtained. But the amount recovered is an insignificant part of the total potash charged into the furnaces, two-thirds of which, or about 15 lb. per ton of pig iron produced, is lost in the wash-water and stove and boiler-house stacks. With the object of securing higher economy experiments have been carried out with a Cottrell electric dust precipitator, connected to the raw gas main leaving one of the dust catchers. These have shown that practically all the dust and fume entering the treater can be precipitated, and as several samples analysed had a potash content of 10%, the dust leaving the dust catcher is evidently much richer in potash than the relatively heavy particles retained by it. Mr. Wysor expressed the view that in the future dry cleaning will be adopted in many blast furnace plants, with the reclamation of many thousands of tons of potash now lost.

At the Hagerstown works of the Security Cement and Lime Company a Cottrell plant was installed last year for the recovery of potash from the kiln gases by the aid of high-tension current at 76,000 volts. The power supply is three-phase current at 440 volts and 60 cycles, and the electrical equipment consists of four 15 h.p., 10 k.v.a., 220 volt single phase 60-cycle, 1800 r.p.m. motor generator sets, each directly connected to the shaft of a rotary rectifier, and four 220 to 70,000 volt 60-cycle 10 k.v.a. transformers of special construction. The volume of gas handled is approximately 180,000 cub. ft. a minute at a temperature of 900° F., and with two kilns 7 ft. by 100 ft. and three 8 ft. by 125 ft. the production of dust averages from 20 to 25 tons a day of 24 hours. The dust contains from 5 to 10% of potash in the form of potassium sulphate, and is in a very finely divided state.

Correspondence.

DETERRENT TO FLIES.

SIR,

There is a need for a substance slowly vaporisable at 40° to 50° C., in crude form, cheap, soluble in or miscible with water, which will be a deterrent to flies and fatal to maggots, which can be used for rapidly stopping fly-breeding under the circumstances now frequent on the Western front and elsewhere. This is under investigation, with other such problems, and we have ample facilities for testing the deterrent effect on flies and the fatal effect on maggots, of any substance. We have already investigated a large number of pure chemicals and are seeking the basis of correlation between chemical structure and insecticidal action. But, while the theoretical is of interest, it is the immediate practical necessity we are considering, and success will probably lie with some crude product, an intermediate in some organic process, a particular fraction in some distillation, or the like: it may depend for its action on the presence of impurities and we cannot at present indicate any one class of compound likely to contain it. We have tried a series of hydrocarbons, products of mineral oil distillations; thanks to the help of tar and coke oven distillers, we are trying this series of products: it will help greatly if, without application to individual firms, we could manage to get quite small samples of other products likely to be available, even the most wild and unlikely ones. Generally speaking we want products with boiling points between 60° C. and 300° C.; they need not be pure, but it is necessary to know what their main ingredient is; and we want things commercially available in some quantity. That the possible range is wide will be indicated by the fact that such diverse things as oleic acid, ionone, mustard oil, tetrachlorethane, wood creosote, bromoform, phenol, monomethylaniline, crude acetamide, and mesityl oxide, are interesting us. The difficulty is to get what is available and we are anxious to pay for small samples of, say, four ounces of available substances, which might possibly be useful. Will firms able to help send things? Anything sent will be tested and its insecticidal value determined: unless there is any objection, we propose to publish results and obviously we cannot test and report on proprietary insecticides. We would welcome visits from chemists or directors of chemical manufacturing companies, and would gladly show them what is being done. *I think enough has been done to justify the hope that we will find the ideal preventer of fly-breeding*, and if we can do this it will materially help the war and be valuable hereafter: it would assist very materially if we could get the help of the technical knowledge of what is avail-

able, which can only be got if technical chemists and producers will assist us.

Yours very truly, N. MAXWELL-LEFROY.

Imperial College of Science,

South Kensington, S.W.

To the Editor of the

JOURNAL OF THE SOCIETY OF CHEMICAL INDUSTRY.

FLAVINE.

SIR,

With reference to the article on "Flavine and Brilliant Green: new and powerful antiseptics" in the Journal of Feb. 15th, it is rather unfortunate that such a partiality for the name "Flavine" exists. There were already two substances to which this had been applied. Watt's Dictionary indicates that Flavine is β -diaminobenzophenone; in the colour trade, Flavine is understood to mean a certain grade of quercitron bark extract (see Schultz and Julius' Organic Colouring Matters). Now we have the name applied to a third substance.

Yours faithfully, R. A. PHILLIPS.

114, Clements Road, East Ham, E.

To the Editor of the

JOURNAL OF THE SOCIETY OF CHEMICAL INDUSTRY.

Obituary.

CYRIL DOUGLAS McCOURT.

Second Lieut. Cyril Douglas McCourt was born in 1883 and was educated at St. Charles' College, North Kensington, and at the City and Guilds of London Central Technical College, where, after gaining his Diploma in Chemistry, he served for a brief period as Private Assistant to Professor Armstrong.

In 1903 he was appointed Chief Chemist to the Morgan Crucible Company, Ltd., which post he resigned six years later in order to collaborate with Professor Bone (then of the University of Leeds) on the industrial applications of the new principle of incandescent surface combustion, which collaboration speedily resulted in the many important inventions comprised under the "Bonecourt" system of surface combustion. He was subsequently appointed consulting chemist to the Morgan Crucible Company, Ltd., which position he held up to the date of his death.

Shortly after the outbreak of the war he abandoned research work in order to join the Army. He laid down his life whilst gallantly leading, as Bombing Officer, an attack made in France on the night of 8th October, 1916.

Journal and Patent Literature.

PATENT SPECIFICATIONS may be obtained by post by remitting as follows:—

English.—6d. each, to the Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C.

United States.—1s. each, to the Secretary of the Society, who has to furnish the U.S. Patent Office with the following data:—

Patent number, date, name of patentee, and title of invention.

French.—1 fr. 05 c. each, as follows: Patents dated 1902 to 1907 inclusive, Belin et Cie., 56, Rue Ferou 8. Paris (3c.)

Patents from 1908 to date, L'Imprimerie Nationale, 87, Rue Vieille du Temple, Paris.

I.—GENERAL; PLANT; MACHINERY.

Chemical engineering equipment; Recent developments in —. H. D. Miles. Amer. Inst. Chem. Eng., Jan., 1917. J. Ind. Eng. Chem., 1917, 9, 161—166.

VACUUM drum dryers are now extensively used. An essential feature of the apparatus is that the

liquid is pumped into a small pan immediately below the drum, so that the latter does not dip into the main body of liquid; difficulties due to agitation and foaming of the liquid are thus avoided. The apparatus may be used for the recovery of dry sulphite waste from the waste liquors of paper pulp mills. An atmospheric drum dryer has been found to yield good

results in drying concentrated sodium benzenesulphonate solution. A new feature in a β -naphthol distilling apparatus is the condensing and receiving system, the vapours being drawn into an air-cooled condenser pipe, which leads into a steam-jacketed three-way valve connected with two receivers. The receivers are used alternately, and each contains a steel box in which the β -naphthol solidifies. A direct-heated shelf retort is made for use in the manufacture of sulphanilic and naphthionic acids, and for the recovery of high boiling solvents from waste; it consists of a chamber provided with heating ducts passing from one side through an opening on the opposite side. The shelves are placed between the ducts, and the retort may be worked at ordinary pressure or under reduced pressure. For the recovery of nitric acid from waste nitrating acids, an apparatus is used in which a strong current of air is passed through the waste acid contained in the retort; the hot gases from the furnace pass through double U-pipes in the retort (these pipes are always covered by the liquid). The vapours leaving the retort are conducted to condensers, and thence to a washing tower where the air is freed from nitric acid vapours. In this apparatus there is no formation of sediment during the distillation.—W. P. S.

PATENTS.

Drying and treating sewage sludge, copra, and other materials in bulk; Apparatus for —. R. H. Annison, London. Eng. Pat. 103,521, Jan. 28, 1916. (Appl. No. 1367 of 1916.)

THE material to be treated falls from a hopper in the top of a casing on to a heated table, over which it is moved by an endless conveyor having scraper plates projecting outwards. The scraper plates may be notched or recessed in irregular order to mix the material. At the further end of the table the material falls on to a second table, over which it is moved by another scraper conveyor, and then on to a third table over which it is moved by the returning portion of the conveyor, the scraper plates projecting on both sides for this purpose. After passing over another pair of tables, if necessary, the material is fed through valves to tubes, troughs, or channels containing spiral conveyors. The tubes may be of fireclay or the like. Hot air is blown in at the bottom of the casing through adjustable louvres or shutters, and passes up in a zig-zag path to heat the tables. (See also Eng. Pat. 12,670 of 1914; this J., 1915, 732.)—W. F. F.

Drying: Method and apparatus for —. J. J. Kruger, Copenhagen. Eng. Pat. 103,621, Sept. 16, 1916. (Appl. No. 13,163 of 1916.)

THE substance to be dried is surrounded by hygroscopic material and placed in a perforated casing of approximately the same shape as the substance to be dried. The perforated casing is surrounded by an outer shell, and a heating medium passed through the space between the casing and the shell causes the evaporation of the moisture absorbed by the hygroscopic material from the substance to be dried without damaging the latter.—W. H. C.

Drying apparatus. E. E. Siler, Assignor to The Universal Drying Machine Co., Chicago, Ill. U.S. Pat. 1,213,962, Jan. 30, 1917. Date of appl., Feb. 15, 1915.

THE material to be dried is moved over a slightly inclined drying bed by a conveyor carrying rotary agitators. The drying bed consists of two superposed members, the lower perforated and the upper having a series of inclined openings registering with the lower perforations and all pointing

in one direction. The material is conveyed over the bed in this direction, and air passes upward through the bed. The apparatus is contained in a casing from which the moist air is withdrawn at the top.—W. F. F.

Annealing furnaces heated by gaseous fuel. Alldays and Onions Pneumatic Engineering Co., Ltd., and P. W. Alldays, Birmingham. Eng. Pat. 103,593, May 18, 1916. (Appl. No. 7117 of 1916.)

IN an annealing furnace having a floor of great strength, the burners are arranged on either side of the furnace chamber, and the waste gases escape through flues arranged on the sides of the hearth below the floor level. The liquid or gaseous fuel and the air are pre-heated by being passed through pipes located in the waste-gas flues.—W. H. C.

Liquid-treating apparatus. A. Jensen, San Francisco, Cal. U.S. Pat. 1,213,879, Jan. 30, 1917. Date of appl., Aug. 16, 1915.

A NUMBER of helical tubes forming an agitator are mounted concentrically on a hollow, rotating, horizontal shaft to which one of the tubes is connected, the others being connected to separate conduits within the shaft. The shaft is journaled in the opposite walls of a casing, and treating liquids may be passed independently through the helical tubes in either direction. Air is exhausted from the casing.—W. F. F.

Vaporising or concentrating liquids, solutions, emulsions, suspensions, and like substances; Method of —. G. A. Krause, Munich, Germany. U.S. Pat. 1,213,887, Jan. 30, 1917. Date of appl., Nov. 29, 1916.

THE finely divided substance is injected upwards into a vertical cylindrical chamber from a nozzle. A heated gaseous drying medium is injected tangentially at the bottom of the chamber so as to pass upwards to the outlet in a spiral path of uniform diameter around the jet of substance to be desiccated.—W. F. F.

Filler mediums; Method and apparatus for cleansing —. A. L. Genter, Salt Lake City, Utah. U.S. Pat. 1,214,152, Jan. 30, 1917. Date of appl., Nov. 5, 1915.

TO facilitate the cleansing and improve the filtering capacity of a filter medium having flexible sides, a rapid succession of impulses is imparted to the opposite sides of the filter medium by directing a current of the liquid to be filtered to one side and of cleansing medium to the other.—W. H. C.

Pressure-filter. W. M. Jewell, Assignor to Jewell Engineering Co., Chicago, Ill. U.S. Pat. 1,214,167, Jan. 30, 1917. Date of appl., June 15, 1914.

PIPES embedded in the gravel below the fine material forming the filter bed, are provided with strainer heads extending downwards, through which water is discharged downwards and laterally, in jets, to wash the filter bed.—W. H. C.

Colloids; Manufacturing —. W. M. Grosvenor, Ridgewood, N.J., and L. A. Beecher, Newtonville, Mass. U.S. Pat. 1,214,299, Jan. 30, 1917. Date of appl., Oct. 7, 1913. Renewed June 30, 1915.

TO preserve the submicroscopic structure of the colloid so that the substantially dry colloid is capable of rapid hydration and dehydration and of rapidly adsorbing dyes, the colloid is first superhydrated and then dehydrated in gradual stages.—W. H. C.

Dust-separator. M. F. Williams, Assignor to Williams Patent Crusher and Pulverizer Co., St. Louis, Mo., U.S. Pat. 1,214,219, Jan. 30, 1917. Date of appl., Feb. 3, 1916.

DUST-LADEN air enters by the pipe, 1, through the enlarged portion, 3, provided with a spiral diaphragm, 7, which imparts a whirling motion to the current, into the chamber, 5. It is then deflected downwards by the baffle, 8, over the spreader-plate, 6.

—W. H. C.

Gases; Separation of — by diffusion. [Preparation of hydrogen from water-gas.] R. Wussow, Charlottenburg, Ger. Pat. 295,465, Apr. 15, 1915.

THE separation of the different components of a gas mixture is brought about by leading the gas over the surface of permeable or absorbing media. These media may be either solid or liquid, and different forms may be used simultaneously to separate the different constituents of a complex mixture: moving permeable surfaces may be used to accelerate the diffusion. The diffused gas may be removed from the farther side of the diaphragm by maintaining a low pressure or by circulating an indifferent gas, such as steam, ammonia, or carbon dioxide, which afterwards can be easily removed by solution or condensation. Diffusion may also take place through several media in succession, each of which causes a partial separation. As an example of the process, using a layer of water as permeable medium, at 0° C. this would absorb 85.2 times as much carbon dioxide as hydrogen, and at 20° C. 19 times as much. A plant has been devised on this principle for the manufacture of hydrogen from water-gas. It is claimed that with water-gas at 3.0 Pf. per cb. metre (0.01d. per cb. ft.), a product containing 99% H₂ can be prepared at a cost of 6.1 Pf. per cb. metre (0.02d. per cubic foot).—J. N. P.

Gaseous mixtures; Separation of the constituents of —. G. Claude, Assignor to Soc. l'Air Liquide (Soc. Anon. pour l'Étude et l'Exploit. des Proc. G. Claude), Paris, U.S. Pat. 1,212,455, Jan. 16, 1917. Date of appl., May 23, 1914.

SEE Fr. Pats. 175,297 and 175,316 of 1914; this J., 1916, 31.

Gases; Purification of —. G. Claude, Assignor to Soc. l'Air Liquide (Soc. Anon. pour l'Étude et l'Exploit. des Proc. G. Claude), Paris, U.S. Pat. 1,212,456, Jan. 16, 1917. Date of appl., June 20, 1914.

SEE Fr. Pat. 471,162 of 1913; this J., 1915, 163. Sodium hydroxide or other suitable substance may be used in place of lime.

Fluid-cooling apparatus. G. H. Walker, Worcester, Assignor to Heenan and Froude, Ltd., Manchester, U.S. Pat. 1,213,042, Jan. 16, 1917. Date of appl., Jan. 11, 1916.

SEE Eng. Pat. 2411 of 1915; this J., 1916, 291.

Separating solids from liquids; Apparatus for —. W. Russell, London, Assignor to The Dorr Co., Denver, Colo., U.S. Pat. 1,214,593, Feb. 6, 1917. Date of appl., Oct. 27, 1916.

SEE Eng. Pat. 11,666 of 1915; this J., 1916, 953.

Raising or forcing liquid; Method of —. H. A. Humphrey, London, Assignor to Humphrey Gas Pump Co., U.S. Pats. (A) 1,214,791 and (B) 1,214,792, Feb. 6, 1917. Date of appl., July 22, 1911. (A) Renewed June 27, 1916.

SEE Fr. Pat. 128,296 of 1911; this J., 1911, 1118.

II A.—FUEL; GAS; MINERAL OILS AND WAXES.

Coke-oven; Occurrences in the — during carbonisation. D. V. Hollingworth, Coke-Oven-Managers' Assoc., Gas J., 1917, 137, 197—198.

THE author refers to the researches of Lomax, Aitken, Bedson, and Wheeler, which indicate that coal is composed of two definite types of substances, one easily breaking up at low temperatures, yielding paraffins, the other requiring a higher temperature yielding principally hydrogen. The former, or resinous, portion produces the caking or fusing properties, and is easily oxidised by exposure to air until it no longer produces a coherent coke. Just at the time when the heat of the oven breaks down the stability of the coke, several important factors come into play and influence the character and amounts of the products formed. If the moisture content is abnormal, the yield of all products is diminished, whilst coal containing much iron will give far less ammonia than one free from iron; the presence of lime has the reverse effect. All iron pyrites should be scrupulously removed from the coal. The nature of the substances produced is largely dependent on the temperature. The valuable products obtained at different temperatures should be withdrawn from the oven as soon as possible. Moisture in the coal plays a great part in modifying the reactions and preventing the destruction of gases first formed. In the absence of the protective action of steam, it has been frequently demonstrated that with high temperatures much of the ammonia is decomposed to cyanogen, and with very high temperatures to free nitrogen. Coal should be used in as fresh a condition as possible, storage bunkers being designed with this end in view, avoiding pockets in which appreciable quantities of slack may remain undisturbed. A minimum amount of sulphur and shale should be ensured by careful attention at the picking belts and washer, the moisture in the slack being brought as near 9% as possible. Intensity of heating should be controlled, and ovens should be raised or lowered in temperature *en masse* and not individually. It is a better plan to raise or lower the gas pressure rather than adjust the gas-cocks, whilst the lowest damper consistent with a clear atmosphere in the flues should be aimed at. Ovens should be well filled with level charges and discharged in regular order. The speed of removal of products from the oven should be controlled by ensuring a regular cooling of the gases, keeping the ascension pipes and mains quite clear, using main governors, levelling the slack, and regulating the vacuum in the mains so as to leave just the slightest pressure on the oven when at the

maximum output. The use of a properly installed gas meter in conjunction with a recording calorimeter is advocated.—J. E. C.

Distillation process in the vertical [gas] retort.
J. N. E. Teune and P. J. Kummel. *Het Gas.*
Gas J., 1917, 137, 248—249, 341—342.

OBSERVATIONS are recorded on the working of intermittent vertical retorts which had been in use for two and a half years at the South Gas Works, Amsterdam. The object was to study the course of the carbonisation process over the whole twelve-hour period, during the last two of which steam is normally blown through the charge. The quantity and quality of the gas made during each hourly period was determined, and also the temperature in the charge at two points, one near the top and the other 45 in. above the bottom. The same coal (Graf Bismarck) was used in all cases. The average gross calorific value of the gas was 558 B.T.U. per cb. ft., and the yield of ammonia 0.301% of the coal or 26.2 lb. of ammonium sulphate per ton. The make of gas was 13,696 cb. ft. per ton. On modifying the process by steaming the charge at a lower pressure but for a longer time—from the end of the fifth to the end of the eleventh hour—the make of gas was slightly raised (13,880 cb. ft.), while the average gross calorific value remained practically the same (554 B.T.U. per cb. ft.). The ammonia yield rose to 0.3607% of the coal or 31.4 lb. of ammonium sulphate per ton. By inserting a pipe from below into the charge, it was possible to examine the quality and condition of the gas at various points in the core during distillation. It was concluded that carbonisation occurs from the wall of the retort inwards, and that the gas ascends in the main along the wall. Only at the beginning of a period does a portion of the gas evolved pass upwards through the core. Afterwards this is arrested by the deposition of tarry matter which chokes the passages through the coal until the later stages.—H. J. H.

Benzol recovery from coal-gas; Physico-chemical considerations on —. T. F. E. Rhead. Midland Jun. Gas Assoc., Jan. 25, 1917. Gas J., 1917, 137, 207—211.

THE author deals with the effect of viscosity, temperature, and composition on the efficiency of creosote as a washing medium for extracting benzol from coal gas. In the case of washable products of coal gas dissolved in creosote, each dissolved body exerts a fraction of its own maximum vapour pressure equivalent to the percentage in which it occurs in the creosote. From a series of vapour pressure curves given, the percentage of these constituents which the gas could carry if saturated may be ascertained. From further data the author deduces the fact that creosote can remove the toluene from 3.55 times the quantity of gas which saturates it with respect to benzene, and solvent naphtha from 10.7 times the same amount. The effect of temperature on the rate of solution, using 100 and 50 galls. of creosote per ton of coal respectively, is shown in a series of curves. A suitable wash oil for benzol extraction should not give off any large proportion of light oils when steam distilled, must take up heat quickly and cool quickly, must flow or spray readily at the washing temperature, must not emulsify with water, and must not give up naphthalene to the gas. The influence on viscosity of various factors is indicated by curves, showing effect of temperature, naphthalene content, distillation tests, etc., and the author sums up his observations in the following conclusions:—(1) Efficiency of washing is improved by using a cold oil. (2) The lighter oils in creosote help the

washing process by lessening the viscosity, but are readily distilled out by steam and contaminate the benzol. (3) Naphthalene tends to lower the viscosity but under certain conditions may pass into the gas. (4) Creosote fractions boiling above 300° C. greatly increase the viscosity. (5) A good creosote should be as fluid as possible at 10° to 15° C., give little oil distillate when steam distilled, and contain a minimum amount of naphthalene. (6) Much improved cooling is obtained by using a creosote of which the viscosity rises very little when cooled to 10° to 15° C., and the benzolised oil is more readily heated. (7) Efficiency of washing is improved by increasing the intimacy of contact between oil and gas. Washers on the spraying or atomising principle appear to offer the best field for development in this direction. (8) Specific gravity is no criterion as to whether a mixture of blast-furnace and coal-tar creosote is "spent" or not, viscosity being the best test. (9) Sufficient creosote should be in circulation to prevent the removal of light oils leaving a creosote of high viscosity.—J. E. C.

Oil-washing for [recovery of] benzene and toluene [from coal gas]. W. G. Adam. Gas J., 1917, 137, 343—344.

THE oil-washing of town gas by the Gas Light and Coke Co., London, was commenced in 1913, and its retention as a permanent feature of gas manufacture is favoured, in the interest of the maker and consumer of gas and of the conservation of national resources. While the benzol present in town gas furnishes about 50% of the illuminating power, it supplies only about 5% of the calorific power, and the former is no longer regarded as of prime importance. 1000 cb. ft. of gas sold at 2s. 6d. contains the vapours from about 2 gallons of benzol, having a sale value of about 2 shillings as a liquid fuel. The author holds that it should be sold as such, and any enrichment of the town gas stripped of benzol, when necessary, should be made by oil gas from cheap gas oil. Of the sulphur compounds left in the gas after oxide purification, oil washing removed a considerable proportion, leaving about 20 grains per 100 cb. ft. The naphthalene content could also be reduced to about 4 grains per 100 cb. ft., at which no distribution troubles were experienced. A "green oil" with sp. gr. 1.098, and yielding 80% of distillate up to 371° C., is recommended as wash oil. By using it, "strong" benzols could be produced, requiring a smaller quantity of sulphuric acid and soda than usual in the washing process. The following method of testing the benzol is recommended:—1000 c.c. of the sample is distilled up to 175° C., a fractionating column being used. The residue is creosote. After washes with alcoholic caustic soda, strong sulphuric acid, and water, the distillate is dried over calcium chloride and refractionated at the rate of 1 drop per second, an 8-bulb Young and Thomas column being used. Fractions are collected, (a) up to 85° C., (b) 85°—105°, (c) 105°—115°, (d) 115°—165° C. The specific gravities of fractions a, b, and c, when paraffins are absent, are 0.883, 0.878, and 0.868 respectively. If lower, a correction for paraffins can be applied according to the differences observed. The quantity of benzene may be taken as $a + \frac{1}{2}b$, toluene as $\frac{1}{2}b + c$, and solvent naphtha as equal to d.—H. J. H.

Calorific power of gas; Measurement of the —. Official method used by the Paris Municipality.
L. Girard and P. Lauriol. Gas J., 1917, 137, 202—205.

A FULL description of the apparatus, methods, and calculations adopted by the Services Généraux d'Éclairage of Paris for the calorimetric testing

of town gas is given. The two following formulae are used:—

$$C_1 = \frac{P(T_s - T_e)}{V} \text{ and } C = \frac{P(T_s - T_e)}{V} - 4.94p,$$

in which C_1 and C are the gross and net calorific values respectively, V is the volume of gas (in cubic metres) burnt in test, P is the weight of water (in kilos.) passing through the calorimeter during the test, T_e and T_s (in degrees C.) are the temperatures of water at the inlet and outlet of the calorimeter, and p is the quantity of water (in grms.) condensed during passage of 120 litres of gas. The figures are corrected for moisture in the gas and for error in the meter. Special precautions are taken to ensure the sample of gas being taken from a large volume of gas in the main, to keep the water used at the temperature of the town supply, and to keep the temperature of the testing room constant during the test. A typical schedule of a test with all the necessary corrections is given, and also of tests for checking the meter and thermometers.—J. E. C.

Mineral lubricating oils; Apparatus and method for testing the emulsification of—P. H. Conradson. Amer. Soc. for Testing Materials, June, 1916. J. Ind. Eng. Chem., 1917, 9, 166—167.

To determine the emulsification and demulsification values of lubricating oils (see Philip, this J., 1915, 697) 20 c.c. of water and 100 c.c. of the oil to be tested are placed in a 250 c.c. cylinder having an internal diameter of about 1½ in. Steam at ordinary pressure is passed into the mixture through a tube reaching to the bottom of the cylinder, and the churning with steam is continued for 15 mins. after the temperature of the mixture has reached 200° F. (93° C.) or when steam as such escapes from the cylinder. The cylinder is then immersed for 1 hour in water at 130° F. (54° C.) and its contents are examined for the following: (1) The volume of separated clear or turbid water; (2) the volume of separated emulsified layer (an indication of the emulsion-forming property of the oil); (3) the volume of clear separated oil (percentage of demulsification); (4) the percentage of moisture in the separated oil; this quantity should be deducted from the demulsification value.—W. P. S.

Possible partial substitution of nitre cake for sulphuric acid in the manufacture of sulphate of ammonia. Parrish. See VII.

Black damp in mines. Burrell and others. See XIXB.

PATENTS.

Coke-oven. L. Wilputte, New Rochelle, N.Y. U.S. Pat. 1,213,988, Jan. 30, 1917. Date of appl., June 19, 1916.

A COKE-OVEN structure is formed with vertical heating flues communicating with a horizontal passage at their upper ends, the openings in which are regulated by pairs of hinged dampers which may swing into position so as to meet edge to edge. The edges of the dampers are provided with registering notches to form a communicating passage when in closed position.—W. F. F.

Generators for suction gas and the like; Shells of—A. R. Bellamy and C. James, Grantham. Eng. Pat. 103,529, Feb. 2, 1916. (Appl. No. 1576 of 1916.)

The lower parts of the shells or casings of the different elements in plant for manufacture of suction gas and the like, are constructed of an outer casing and an inner metallic lining of somewhat less dimensions. The space between the two is filled with cement or the like.—J. E. C.

Gas cooler and washer. J. E. Christopher, Wigan. Eng. Pat. 103,561, Mar. 27, 1916. (Appl. No. 4487 of 1916.)

A COMBINED gas cooler and washer consists of a group of washing units, each unit consisting of a pair of concentric tubes, B and F. The inner tube,

B, is supplied with cooling liquid, which passes through apertures, E, and serves as washing medium in the concentric space. The outer surface of these units is also sprayed with the liquid to increase the area of cooling surface. The gas is subdivided into thin films in the concentric spaces, which are arranged so that their total area approximates to the area of the gas inlet, D. —J. E. C.

Aromatic bodies and gas; Process for the production of—from petroleum oils. F. W. Mann and M. L. Chappell, Berkeley, Cal., Assignors to Standard Oil Co., Richmond, Cal. U.S. Pat. 1,214,204, Jan. 30, 1917. Date of appl., Feb. 3, 1916.

PETROLEUM oils containing oils of the carbocyclic series are dehydrogenated under a pressure of 1 to 4 in. of mercury below atmospheric and at temperatures of 600°—750° C., in the presence of 500—800 cu. ft. of air for each 15—20 galls. of oil and also a contact substance such as the lower oxide of nickel.—W. F. F.

Conveying charges of material from one level to another. [Transferring coke from gas retorts to gas producers.] A. E. White, London. From Riter-Conley Manufacturing Co., Leedsdale, Pa., U.S.A. Eng. Pat. 103,697, Feb. 9, 1916. (Appl. No. 1928 of 1916.)

Pulverised fuel; System for feeding—V. Z. Caracristi, Albany, N.Y., Assignor to Locomotive Pulverized Fuel Co. U.S. Pat. 1,214,753, Feb. 6, 1917. Date of appl., Oct. 4, 1913.

III.—TAR AND TAR PRODUCTS.

Wood-tar pitches ; The free carbon of—. H. K. Benson and L. L. Davis. J. Ind. Eng. Chem., 1917, 9, 141.

ACETONE is suggested as a solvent in the determination of free carbon in wood-tar pitches ; carbon bisulphide is unsuitable for the purpose. In the following table are given the solubilities of different bitumens in acetone and carbon bisulphide respectively ; in each case, the residue insoluble in one solvent was again extracted with the other solvent :—

	Insoluble in carbon bisulphide.		Insoluble in acetone.	
		Residue insoluble in acetone.		Residue insoluble in carbon bisulphide.
	%	%	%	%
Douglas fir pitch	67.7	59.7	57.7	57.8
" " "	62.5	30.1	31.6	31.1
" " "	93.1	35.3	34.6	34.4
" " "	60.2	22.0	21.5	21.3
Hard wood pitch	18.7	3.1	2.9	2.7
" " "	59.9	18.0	17.5	17.4
Coal tar "pitch" ..	27.4	27.4	57.5	27.1
" " " "	18.4	18.0	35.3	18.5
" " " "	22.7	22.6	37.1	22.3
" " " "	17.4	17.1	33.0	16.9
Petroleum asphalt	4.1	4.0	27.1	3.9
Trinidad asphalt	42.6	42.1	69.0	41.8

Coal-tar pitches may be classed with the native and manufactured asphalts as regards the determination of free carbon.—W. P. S.

Phenols ; Identification of—. *Studies in identification.* II. E. E. Reid. J. Amer. Chem. Soc., 1917, 39, 304—309.

p-NITROBENZYL bromide reacts readily and quantitatively with alkali phenoxides, with the formation of stable nitrobenzyl ethers, which are readily purified by crystallisation from dilute alcohol and are suitable derivatives for the identification of phenols. The reaction is carried out by boiling in 95 % alcoholic solution on the water-bath for one hour

a molecular proportion of *p*-nitrobenzyl bromide with an excess of phenol and a molecule of sodium hydroxide. Water is then added to dissolve the sodium bromide, and the ether crystallises out on cooling. For the *p*-nitrobenzyl ethers of the following phenols the melting points are as given : Phenol, 91° C. ; *o*-cresol, 89.7° C. ; *m*-cresol, 51° C. ; *p*-cresol, 88° C. ; thymol, 85.5° C. ; eugenol, 53.6° C. ; and vanillin, 124.5° C.—G. F. M.

Sulphonic acid groups in aminosulphonic acids ; Displacement of—by halogen atoms. J. J. Sudborough and J. V. Lakhumalani. Chem. Soc. Trans., 1917, 111, 41—50.

SULPHONIC acid groups in the ortho- or para-positions but not in the meta-position to an amino-group are quantitatively displaced by halogen elements when these are presented to the substance in aqueous solution in the case of bromine, in glacial acetic acid with chlorine, or as iodine monochloride. Thus 2,6-dibromosulphanilic acid gave with bromine, sulphuric acid and *s*-tribromoaniline, and a similar result was obtained with 4,6-dibromoaniline-2-sulphonic acid. Iodine monochloride gave with these acids 2,6-dibromo-4-iodoaniline, and 2,4-dibromo-6-iodoaniline respectively. Chlorine gave a mixture of chlorodibromoanilines and tribromoanilines. Experiments with aniline-*o*-sulphonic acid and aniline-*p*-sulphonic acid indicated that the *o*-sulphonic group is the more readily replaced. The carboxyl group in the *o*- and *p*-positions to an amino-group was also replaceable, though with greater difficulty, by bromine, but chlorine and iodine either failed entirely to effect displacement or gave only small yields of the halogen derivative.—G. F. M.

IV.—COLOURING MATTERS AND DYES.

Indigo in Bihar ; Java—. D. J. Reid. Agric. J. India, 1917, 12, 1—26. (Compare this J., 1915, 952 ; 1917, 130.)

THE results of experience in growing indigo in Bihar from 1904—15 are tabulated. On account of the periodical flooding of the country at the time when the seed plant must be in the ground, and the doubt as to whether any remedy will be found for diseases such as "wilt" and "psylla," it is considered probable that if a regular and full supply of Java seed is to be secured, some other locality will have to be discovered for seed growing. Research should be directed towards increasing the wilt-resisting power of the plant by selection and to improving the indican content of the leaf. In the author's experience indigo is not killed outright by standing water, and wilt is not affected to any great extent by climatic influences.—F. W. A.

THE composition consists of peat, a portion of which has been treated by the viscose process to produce a binding agent which cements the unconverted portion to a coherent mass.—J. F. B.

Sulphur dioxide gas and liquid reclaimer. Process of making sulphite liquor. A. F. Richter and T. L. Dunbar, Watertown, N.Y. U.S. Pats. (A) 1,213,114 and (B) 1,213,415. Jan. 23, 1917. Dates of appl. (A) July 11 and (B) Oct. 9, 1914.

(A) AN apparatus for recovering gaseous and liquid products from a sulphite digester comprises a cooler discharging into a separator, a second cooler for the gas from the separator, and a liquor receptacle for the liquid from the separator; a gas conduit connects the second cooler with the bottom of a sulphur dioxide reclaiming tower, and a liquor-delivery conduit leads from the liquor receptacle to the top of the tower; a return pipe is provided from the bottom of the tower to the liquor receptacle, and means are provided for circulating the liquor through the system. (B) For making sulphite liquor, the products from a digester are separated into sulphur dioxide and spent liquor; the spent liquor is mixed with sulphite liquor and the mixture treated with sulphur dioxide from a burner; the excess sulphur dioxide from the burner is mixed with calcium bisulphite to form the sulphite liquor mentioned above, and the gas recovered from the digester products is mixed with the liquor derived from the combined operations.—J. F. B.

Paper machine. C. E. Pope, Holyoke, Mass. U.S. Pat. 1,211,712. Feb. 6, 1917. Date of appl. Mar. 6, 1916.

IN the drying portion of a paper machine the units of the upper tier of cylinders are placed substantially in the same vertical plane as the corresponding units of the lower tier, and the drying felts and guide rolls are so arranged that the web has a very short exposed travel in passing from a lower cylinder to the upper cylinder vertically above it, and a comparatively long exposed travel in passing from an upper cylinder to the lower cylinder of the next pair. The web of paper is held against the lower cylinder until it reaches a point where it is travelling horizontally on the upper surface of the cylinder; it is stripped from the cylinder at this point and directed into an entrance formed between the upper cylinder and the upper felt, the guide roll of the upper felt being so placed that the felt passes on to the cylinder in a line substantially radial to the companion lower cylinder.—J. F. B.

Resin size for paper manufacture; Apparatus for preparing —. B. Kniffler, Winchester, and W. A. Oppen, Stoneham, Mass. U.S. Pat. 1,215,034. Feb. 6, 1917. Date of appl. Sept. 14, 1914.

THE apparatus consists of a closed size-containing vessel with pipes both at the top and the bottom, through either of which steam under pressure may be introduced. Means are provided for forcing the heated size under pressure from the lower part of the vessel through a filtering device into a delivery pipe. The latter terminates in a pressure-preserving obstruction having a restricted dis-

charge orifice beneath the surface of water in an emulsion-container, so that the size emerging through the orifice in a fine stream is suddenly relieved of high pressure and heat, and immediate emulsification is effected.—J. F. B.

VI.—BLEACHING; DYEING; PRINTING; FINISHING.

Dyeings; Production of [brown] — by oxidation on the fibre. O. Diehl, Farber-Zeit., 1916, 27, 145.

THE development of dyeings from catechu in combination with copper and ammonium salts is accelerated by ageing in an ammoniacal atmosphere; fabric impregnated with catechu and treated as usual with chromate yields a dark coffee-brown shade. Intense brown shades are obtained in the same manner using *p*-phenylenediamine, redder than those obtained with chlorate and vanadium; the oxidation is too rapid unless large amounts of ammonium chloride or calcium chloride are introduced. The following printing paste is recommended: 850 grms. of a mixture containing 30 grms. of Paramine Extra, 137 grms. of water, and 687 grms. of thickener; 60 grms. of copper chloride solution (prepared from 25 grms. of copper sulphate crystals in 60 grms. of water and 25 grms. of barium chloride in 60 grms. of water), 29 grms. of Rongalite solution (1:9), and 100 grms. of thickener, which last-named is obtained from 750 grms. of wheat starch, 3200 grms. of water, and 200 grms. of acetic acid of 7° B. (sp. gr. 1.051).

—F. W. A.

PATENTS.

Dyeing and like apparatus; Perforated beams for —. J. T., and E. Brandwood, Bury, Lancs. Eng. Pat. 103,772, July 31, 1916. (Appl. No. 10,758 of 1916.) Addition to Eng. Pat. 17,355 of 1914 (this J., 1915, 26).

IN order to secure the periphery of the inner nickel flange still further from contact with outside bodies when the beam is rolled on a floor, and to simplify the method of making the liquid-tight joints between the inner and outer flanges, the inner nickel flange is made of lesser diameter than the outer flange, with its surface flush with the inner edge of the latter, and the joint between the two flanges is made by spinning or pressing the edges of the nickel flange or annulus into recesses in the outer flange.—F. W. A.

Dyeing vegetable fibres; Process of —. G. D. Burton, Boston, Mass. U.S. Pat. 1,214,007, Jan. 30, 1917. Date of appl. Apr. 22, 1914.

DEGUMMED fibres are dyed by treatment with a solution of the natural colouring substance originally present in the fibre and a mordant, and afterwards with a "colour-setting" agent. —B. N.

Acid colours; Fixation of — on cotton. F. W. Weeks, Edgworth. U.S. Pat. 1,213,045, Jan. 16, 1917. Date of appl. Aug. 12, 1916.

VII.—ACIDS; ALKALIS; SALTS; NON-METALLIC ELEMENTS.

Arsenic in sulphuric acid; Critical examination of Lunge's method for the rapid determination of —. J. B. Pérégryn, Ann. Chim. Analyt., 1917, 22, 24—25.

LUNGE's volumetric process, in which a measured quantity of the acid is diluted and the contained arsenic reduced by sulphur dioxide and determined in neutral (or sodium bicarbonate) solution by means of standard iodine, gives slightly lower results than the standard method involving fusion of the precipitated arsenious sulphide with oxidising mixture, precipitation as silver arsenate, and volumetric determination of silver in the latter; but the process is expeditious, and satisfactory results may be obtained by the use of an arithmetical factor.—W. E. F. P.

Zinc blende; Roasting of —. M. Hutin, Monit. Scient., 1917, 7, 25—35.

IN view of the rising price of pyrites, the use of blende and mixed zinc ores from Algeria and Tunis as a source of sulphur for sulphuric acid manufacture is becoming more general. The residue from the roasting is more valuable than in the case of pyrites, especially with ores rich in copper; the smelters pay for the roasting and sometimes for crushing. On the other hand the roasting of blende is more troublesome, necessitating more highly skilled labour, and the high temperature required causes more rapid deterioration of tools and furnaces as well as of the Glover towers. The nitrate consumption is often higher, and the presence of fluorspar in the blende causes deterioration of the lead chambers. The following quantities of blende were roasted in 1912: United Kingdom, 50,125 tons; Holland, 13,550; Germany, 191,690; Belgium, 138,390; France, 59,050; Austria-Hungary, 9780 tons.—W. R. S.

Sulphur in roasted pyrites, etc.; Critical examination of Lunge's dry method for the rapid determination of —. J. B. Pérégryn, Ann. Chim. Analyt., 1917, 22, 26—27.

LUNGE's method—in which the sulphur content of pyrites cinder, etc., is calculated from the loss of alkalinity sustained by pure sodium bicarbonate when gently heated in admixture with the material with free access of air (in an open nickel crucible)—gives results consistently lower, by $\frac{1}{4}$ to $\frac{1}{3}$ of the amount present, than those obtained by the *aqua regia* method. The process is satisfactory for control work, provided the necessary precautions as to heating, etc., are observed; and the results are not vitiated by the presence of lead or alkaline-earth sulphates in the cinder, since fritting or fusion of the charge is avoided. (Compare Lunge and Stierlin, this J., 1906, 138.) —W. E. F. P.

Orthophosphoric acid; Acidimetric determination of —, D. Balareff. *Z. anorg. Chem.*, 1916, **97**, 143–146. *J. Chem. Soc.*, 1917, **112**, ii., 101.

PHOSPHORIC acid usually contains an appreciable quantity of carbon dioxide, from which it is freed in the control experiments by heating for several hours in a gold vessel in a stream of purified air. It is then diluted with water free from carbon dioxide. Wagenaar's method (*Pharm. Weekblad*, 1911, **48**, 845) gives satisfactory results if the lead nitrate is added at the Na_2HPO_4 stage, but not otherwise. In Glaser's method, the third hydrogen ion is titrated by adding calcium, strontium, or barium chloride after the solution has become neutral to phenolphthalein, and again titrating until a permanent red coloration is obtained. This only gives accurate results in the presence of an excess of strontium chloride. The following method is recommended. The dilute solution is first titrated until the red shade of methyl orange disappears. The second ion is titrated until phenolphthalein becomes a clear red. The solution is then diluted with water free from carbon dioxide, and a neutral solution of silver nitrate is added. The titration is continued with laemoid as an indicator.

Nitre cake; Possible partial substitution of — for sulphuric acid in the manufacture of sulphate of ammonia. P. Parrish. *Gas J.*, 1917, **137**, 345–347.

THE suggested substitution of nitre cake for sulphuric acid in making sulphate of ammonia has not been enthusiastically received by manufacturers. The author, however, considers that as an emergency measure the production of a mixed salt is quite practicable. Damage to the lead work of the saturator need not be feared if the nitre cake does not contain more than 0.5% of undercomposed nitrate. The manurial qualities of the mixed sulphate produced should, according to Rothamsted experiments, be satisfactory, due to some beneficial action of the sodium sulphate. A mixed salt containing 10% of sodium sulphate is regarded as the limit to substitution in practice. If the quantity of nitre cake to attain this, is added dissolved in water, the saturator liquor will become too dilute. In the absence of a method of adding the nitre cake in the form of a solid, the author recommends introducing it dissolved in the sulphuric acid fed into the bath. The nitre cake, broken up into small pieces, is dissolved in sulphuric acid in a lead-lined tank, heated by closed steam coils, and the hot solution is then used as saturator feed. By having tanks in duplicate, one can be feeding the saturator while a fresh solution of nitre cake is made up in the other. Twelve-hour periods are worked. A fairly uniform mixed salt can be made, free from undue acidity. To make 100 tons of mixed salt containing 10% of sodium sulphate, 14.7 tons of nitre cake (32% H_2SO_4) and 87.8 tons of 70% sulphuric acid or 76.8 tons of 80% acid are required.—H. J. H.

Sodium and potassium carbonates; Double salts formed by —, J. W. Bain and C. E. Oliver. *Trans. Roy. Soc. Canada*, 1916, [iii.], **10**, 65–66. *J. Chem. Soc.*, 1917, **112**, ii., 87.

THE production of pure potassium carbonate from the ash of seaweeds, wood ashes, and the residues from sugar factories is rendered difficult by the formation of the double salt, $\text{K}_2\text{CO}_3 \cdot \text{Na}_2\text{CO}_3 \cdot 12\text{H}_2\text{O}$. According to dilatometric observations, this double salt decomposes at 35° C. in accordance with the equation $3(\text{K}_2\text{CO}_3 \cdot \text{Na}_2\text{CO}_3 \cdot 12\text{H}_2\text{O}) = 2\text{K}_2\text{CO}_3 + \text{K}_2\text{CO}_3 \cdot 3\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O} + 26\text{H}_2\text{O}$. The new double salt thus formed appears to decompose at about 130° C.

Potassium cyanide; Rate of hydrolysis of — in aqueous solution. J. Zawidzki and T. Mieczynski. *Kosmos (Lemberg)*, 1914, **38**, 1366–1375. *J. Chem. Soc.*, 1917, **112**, ii., 81–82.

STUDY of the kinetics of the auto-hydrolysis of potassium cyanide in aqueous solution at 100°, 110°, and 120° C., led to the following conclusions: (1) In dilute aqueous solution (0.25–2.0 molar), the reaction $\text{KCN} + 2\text{H}_2\text{O} = \text{H}_2\text{CO}_3\text{K} + \text{NH}_3$ is of the first order; (2) the temperature-coefficient is normal, the values being about 2.26 at 100°–110° and about 2.06 at 110°–120° C.; (3) the presence of an excess of the reaction products (NH_3 and HCO_2K), as well as of other salts and bases, has no appreciable effect on the rate of hydrolysis; (4) organic acids have a feeble accelerating action; (5) alcohols, particularly glycerol, have a much more pronounced accelerating action, which appears to depend on intermediate and side reactions.

Aluminium hydroxide; Solubility of — in solutions of ammonia and ammonium salts. E. H. Archibald and Y. Habasian. *Trans. Roy. Soc. Canada*, 1916, [iii.], **10**, 69–70. *J. Chem. Soc.*, 1917, **112**, ii., 93.

THE solubility of aluminium hydroxide in ammonia increases at first with the strength of the ammonia solution, reaches a maximum, and then decreases. These relations are considered to be connected with the formation of a more crystalline modification of aluminium hydroxide in contact with the concentrated ammonia. In presence of ammonium chloride or nitrate, the solubility of the hydroxide is considerably decreased. The addition of potassium nitrate increases the solubility to a marked extent.

Silver chloride and lead chloride; Reduction of —, A. Gawalowski. *Oesterr. Chem.-Zeit.*, **19**, 150–151. *J. Chem. Soc.*, 1917, **112**, ii., 88.

PRECIPITATED silver chloride is reduced to metallic silver by means of zinc in a few days. " AgNH_2 " gives with zinc and mercury a silvery-grey, dendritic silver tree, whilst with zinc, copper, tin, and mercury it yields at first black, dendritic deposits, which after a time become converted into silver-white dendrites. Sealy, crystalline leaflets of lead are formed by the reduction of aqueous lead chloride by zinc, whilst in the presence of ammonia the lead is precipitated in powdery, black microcrystals. If the deposit containing ammonia is acidified with dilute sulphuric acid, the odour of nitrous acid is observed, and lead is almost instantaneously precipitated in dendritic crystals.

Lead subiodide, and an improved method for preparing lead suboxide. Solubility of lead iodide. H. G. Denham. *Chem. Soc. Trans.*, 1917, **111**, 29–41.

LEAD suboxide was prepared by heating lead oxalate in a vacuum at temperatures above 270° C. but not exceeding 375° C. The pressure of the evolved gases not being allowed to rise above 5 cm. It formed a dark-coloured powder which above 335° C. became paler in colour and less reactive. When mixed with four times its weight of silica and treated with the vapour of dry methyl iodide at a maximum temperature of 202° C. in an atmosphere of nitrogen, it was converted quantitatively into lead subiodide, which formed a bright yellow powder having only about one-ninth the solubility in water of the normal iodide at 25° C. The subiodide is slowly oxidised by air, is completely decomposed by acids, and is resolved by heat into a mixture of lead and the normal iodide.—G. F. M.

Iodides; Interference of thiocyanates, ferrocyanides, and ferricyanides in the detection of— with palladium. L. J. Curtman and B. R. Harris. J. Amer. Chem. Soc., 1917, 39, 266—270.

AN excess of palladium is favourable to the detection of iodides in the presence of thiocyanates; otherwise precipitation of palladous thiocyanate or formation of soluble potassium palladodithiocyanate may prevent palladium being available for the precipitation of iodides. The interference due to ferrocyanides and ferricyanides may in most instances be overcome by boiling the reaction mixture.—T. H. B.

Alkaline-earth oxalates. W. O. de Coninck. Ann. Chim. Analyt., 1917, 22, 23—24.

THE precipitate obtained by allowing very dilute mixed solutions of barium nitrate and oxalic acid to stand for one month had the composition, $2\text{BaC}_2\text{O}_4 \cdot 3\text{H}_2\text{O}$. It was insoluble in water at 0° or 12°C .; slowly dissolved by warm, and partly decomposed by boiling water; decomposed by strong mineral acids; slowly attacked by strong formic and acetic acids; and decomposed by prolonged contact with alkalis and ammonia. Attempts to prepare a corresponding calcium compound by similar means resulted in the formation of a mixture of oxalates in which $\text{CaC}_2\text{O}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$ and $\text{CaC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ appeared to predominate. The hydrated acid oxalate of strontium, $\text{SrC}_2\text{O}_4 \cdot \frac{1}{2}\text{H}_2\text{C}_2\text{O}_4 \cdot 3\text{H}_2\text{O}$, was obtained by mixing a moderately strong solution of strontium chloride with an equal volume of fuming hydrochloric acid and then adding 3 volumes of a concentrated solution of oxalic acid. This salt was insoluble in cold water, but slightly soluble on warming and converted into $\text{SrC}_2\text{O}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$ on boiling.

—W. E. F. P.

Magnesium pyrophosphate obtained by calcining magnesium ammonium phosphate; Colour of—. D. Balareff. Z. anorg. Chem., 1916, 97, 149—160. J. Chem. Soc., 1917, 112, ii., 90—91.

THE grey or black colour often observed in ignited magnesium pyrophosphate has been attributed by Karaoglanoff to traces of organic matter. According to the author, the colour is only observed when the pyrophosphate has the dense form which results from incandescence during ignition. Reagents which remove the coloration do so by altering the texture of the precipitate, allowing oxygen to enter and oxidise the carbon. The colour depends on the water of crystallisation present. The moist, crystallised salt with $6\text{H}_2\text{O}$ yields a snow-white residue on ignition, but if kept for some weeks over phosphoric oxide, it becomes grey when ignited. There is no appreciable difference of weight between the white and coloured residues, but the grey pyrophosphate is less readily soluble in hot dilute nitric acid than the white variety. The addition of filter-paper fibres to $\text{MgNH}_4\text{P}_2\text{O}_7 \cdot 6\text{H}_2\text{O}$ causes the precipitate to darken on ignition, but if moistened two or three times with water, the residue is white. Dark residues are often obtained even when asbestos is used for filtering. Secondary changes often occur in the precipitation and ignition of the phosphate. The various methods of decolorising the residue give the same results if precautions are taken against loss. Moistening with water and adding a few crystals of ammonium nitrate removes the colour rapidly and completely.

Copper sulphide enrichment; Some reactions involved in secondary—. E. G. Zies, E. T. Allen, and H. E. Merwin. Economic Geology, 1916, 11, 407—503. J. Chem. Soc., 1917, 112, ii., 91—92.

COPPER sulphate solutions react with natural sulphides, a part of the copper being precipitated,

this being the process which is concerned in the secondary enrichment of sulphide deposits. In the experiments the minerals were used either in the form of lumps, so that the colour of the product could be determined, or more often in powder. In the latter case, the powder was sifted through silk bolting cloth, only that part being taken which passed through a cloth with 125 meshes to the linear inch and was retained by a 200 mesh. The finest flour, which adhered to the particles in sifting, was removed by washing with alcohol. The minerals after the experiment were examined microscopically and analysed. The reactions were carried out at the ordinary temperature in special glass containers in a shaking apparatus, and at higher temperatures in sealed tubes of Jena glass or silica, heated vertically in an oil-bath. When artificial sulphides were used, they were prepared by precipitation and washing, and were dried and heated in hydrogen. Pyrites is altered to covellite and chalcocite with cupric sulphate solutions. Chalcopyrite and bornite undergo the same change, whilst pyrrhotite is altered to chalcopyrite, and probably to bornite. The order of stability is: chalcopyrite, covellite, chalcocite, the last being the most stable of all, although even it is slowly altered, yielding metallic copper and sulphuric acid. The intermediate products, chalcopyrite and covellite, are most likely to be obtained when a large surface of the original sulphide is exposed to a dilute solution of cupric sulphate. Increased temperature accelerates the reactions without greatly altering their nature, but secondary reactions, such as the formation of cuprous sulphate and hydrolysis to hematite, are more marked at higher temperatures. Cuprous sulphate appears to accelerate the reactions. An increased concentration of sulphuric acid retards the above reactions. A reversal of the enrichment reactions has not been observed. Galena is more reactive than any other of the sulphides examined. The enrichment of galena, blende, pyrrhotite, and bornite is accelerated by the presence of sulphuric acid.

Sulphide sols; Reversibility of —, and the protective action of hydrogen sulphide. S. W. Young and W. R. Goddard. J. Phys. Chem., 1917, 21, 1—13.

A DIALYSING parchment cylinder was suspended in a glass vessel and provided with inlet and outlet tubes for the circulation of either water or hydrogen sulphide solution. The outer vessel was fitted with a gas-tight cover through which passed a funnel and a glass stirrer. After filling the apparatus with water, a slow stream of water saturated with hydrogen sulphide was circulated through the inner cylinder, whence some of the hydrogen sulphide diffused into the water of the outer vessel. A solution of a salt of cadmium, zinc, mercury, lead, or arsenic was then admitted a few drops at a time, at considerable intervals, to the outer vessel by means of the funnel. By reacting with hydrogen sulphide, a sulphide was formed which became dispersed throughout the solution by means of the stirrer. The free acid formed by the reaction was gradually removed by diffusion into the dialysis vessel, the solution in which was repeatedly renewed. The influence of the presence or absence of hydrogen sulphide on the colloidal state of the sulphide in the outer vessel could then be observed by circulating alternately hydrogen sulphide solution and pure water for long intervals through the inner vessel. Removal of the hydrogen sulphide from the sol in this manner ultimately caused flocculation of the sulphide in every case, and re-admission of the dissolved gas caused, in time, re-dispersion. Upon repetition it was noticed that the time required for coagulation tended to become longer

and that for re-dispersion to become shorter. It would appear that the dispersed substance in the sulphide sols is a dissociable compound of the sulphide with hydrogen sulphide, while the flocculated sulphides are either free from hydrogen sulphide or contain relatively little of it. Zinc sulphide sols were exposed to hydrogen sulphide in sealed tubes at pressures of this gas varying from 0.5 to 4 atm. Above 0.5 atm. a marked dispersive effect leading to a clearing of the sol was first obtained. This action was most marked with the gas at 1.5 to 2 atm. After standing a few months the sulphide was gradually precipitated, though the sols at about 1.5 atm., where the protective action of the hydrogen sulphide was at a maximum, were the last to flocculate. The protective effect of hydrogen sulphide against the flocculation of zinc sulphide by potassium chloride was also found to reach a maximum at about 2 atm. A thermal reversibility of zinc sulphide sols in contact with hydrogen sulphide was observed in the sealed tubes containing hydrogen sulphide under pressure. When heated, a flocculation of the sol took place, but after standing in the cold, re-dispersion occurred. The results indicate that hydrogen sulphide may exhibit on the one hand a specific dispersive action, and on the other a coagulating effect as an electrolyte.—J. N. P.

Copper sulphide: Colloidal solutions of—
S. W. Young and R. Neal. *J. Phys. Chem.*, 1917, 21, 14—31.

COPPER sulphide sols were prepared by agitating well washed copper hydroxide or carbonate or freshly precipitated copper sulphide with an aqueous hydrogen sulphide solution. The reaction was conducted in absence of air and over a period of several days. When desired, the free hydrogen sulphide was removed by dialysis. By adding electrolytes, dispersion was inhibited, the results at like concentrations being proportional to the flocculating powers of the electrolytes. Anomalous results were obtained, however, with alkali hydroxides, which caused a marked initial acceleration of the rate of dispersion, followed by the normal flocculating action. The stability of the sols was found to be greatly increased by the presence of hydrogen sulphide. Measurements made with the addition of electrolytes showed that the concentration of electrolyte necessary to cause flocculation in 24 hours is independent of the origin and method of preparation of the sol, and, within wide limits, is independent of the dilution of the sol, and of the presence or absence of free hydrogen sulphide. The relative flocculating powers of the chlorides of potassium, calcium, and aluminium, were found to be in the ratios 1:39:875. The rate of migration of the sol in an electric field was found to be largely influenced by the origin of the sol, increased by dilution of the sol, and accelerated by the addition of electrolytes, but in a way which bore no apparent relation to the flocculating value of the electrolyte used. The acceleration of the migration rate seemed to be represented by an expression of the form SKA , where K is the migration rate of the original sol, A a function of the concentration (perhaps of the conductivity) of the electrolyte added, and S a factor depending on some specific property of the particular sol used. The migration rate was greatly reduced by hydrogen sulphide and increased by its removal, the effect being readily reversible. Bubbling air or oxygen through a sol containing hydrogen sulphide affects the migration rate merely by displacing hydrogen sulphide. Re-saturation with hydrogen sulphide restored the rate to its normal value.—J. N. P.

Nitric oxide: Action of—on metallic peroxides suspended in water. B. C. Dutt and S. N. Sen. *J. Proc. Asiatic Soc. Bengal*, 1914, [N.S.], 10, 287—291. *J. Chem. Soc.*, 1917, 112, ii., 85.

WHEN nitric oxide is passed into a suspension of lead peroxide in water, a mixture of lead nitrite and nitrate is formed, the nitrate being formed by the oxidation of a portion of the nitrite by the excess of lead peroxide. With barium peroxide in water, nitric oxide yields only barium nitrite.

Monazite deposits in Ceylon. Board of Trade *J.*, Mar. 8, 1917.

THE Mineralogical Department of Ceylon announces the discovery of substantial deposits of monazite in the island. A start has been made in working the deposits in two districts of the Southern Province and in Kudaramallie, in the North-Western Province. The necessary plant for magnetic separation has been ordered.

Radium emanation: Release of—from water at different temperatures by the bubbling method. J. Moran. *Trans. Roy. Soc. Canada*, 1916, [iii.], 10, 57—66. *J. Chem. Soc.*, 1917, 112, ii., 63.

EXPERIMENTS, in which a constant current of air was bubbled through a solution of radium at temperatures ranging from 16.5° to 80° C., show that the emanation removed by the air increases with the temperature. When this method is employed in the estimation of the radium content, the solution should be kept at a constant and measured temperature.

Sublimed sulphur and its adulteration. Fonze-Diacon. *Ann. Falsif.*, 1916, 9, 333—339.

SUBLIMED sulphur as collected from the subliming chamber is graded into *grésil*, *éponges*, *grappillons*, and *candi* according to its degree of fineness. A sample taken from the floor of a chamber contained 32.7% of sulphur insoluble in carbon bisulphide, whilst another of equal fineness taken from the wall at the height of about 1 m. contained 30% of insoluble sulphur. A third sample, taken at about 2.5 m. from one of the vapour inlets, was much coarser and consisted of a mixture of the first three grades. A fourth sample, collected about 2 m. from a vapour inlet, was still coarser, and consisted of *éponges* containing only 0.3% of insoluble sulphur, whilst a sample of *candi* collected directly above an inlet consisted of large fused masses which were practically free from insoluble sulphur. The proportion of insoluble sulphur stood in direct relationship to the degree of fineness, and this also applied to commercial sublimed sulphur. The very pure sublimed product collected from the middle of the floor of the chamber passed through a 100-mesh, and (with prolonged shaking) through a 210-mesh sieve, and when fractionated by partial sifting yielded three fractions containing 30.3, 30.5, and 30.3% of insoluble sulphur respectively. In the case of the second sample the *grésil* retained by a 100-mesh sieve contained 10.1%, the coarse flowers retained by a 240-mesh sieve contained 12.5%, and the fine flowers which passed through that sieve contained 15.5% of insoluble sulphur. A very pure commercial sample as used in vineyards contained 28.2% insoluble sulphur. It passed through a 100-mesh sieve, but by treatment on a 210-mesh sieve was separated into coarse and fine flowers containing respectively 27.3 and 29.5% of insoluble sulphur. A coarser commercial product was separated into *grésil* (retained by a 100-mesh sieve), and coarse and fine flowers, containing 16.1, 19.6, and 26.3% of insoluble sulphur respectively; whilst a badly-made product of poor quality yielded *grésil* with 2.3%, coarse flowers with 4.8%, and fine flowers

with 18.7% of insoluble sulphur. In every instance of pure sublimed samples the ratio of the insoluble sulphur in the *grésil* to that in the coarse powders was less than unity. Any decrease in the proportion of insoluble sulphur on keeping is immaterial, since it affects all the fractions of the sulphur. The addition of 20 to 25% of ordinary powdered sulphur to sublimed sulphur causes this ratio to exceed unity. The insoluble sulphur is determined by treating 1 to 2 grms. of the sample with three successive portions of carbon bisulphide or 30 minutes each time, separating the extracts by centrifuging, and drying the insoluble residue in the water oven.—C. PATENTS.

Hydrocyanic acid gas; Process of generating —. C. J. Marvin, Assignor to The Braun Corporation, Los Angeles, Cal. U.S. Pat. 1,214,206, Jan. 30, 1917. Date of appl., Feb. 13, 1915.

HYDROCYANIC acid gas is generated by dropping a solution of 1 part of cyanide in 2 parts of water, in small quantities at a time, into a hot solution of sulphuric acid obtained by diluting the concentrated acid with an equal quantity of water. —B. V. S.

Perborate of sodium; [Electrolytic] manufacture of —. Deutsche Gold- u. Silber-Scheidenanstalt, vorm. Roessler, Frankfurt, Germany. Eng. Pat. 100,778, Mar. 2, 1916 (Appl. No. 3185 of 1916). Under Int. Conv., June 30, 1915. Addition to Eng. Pat. 100,153 of 1916; dated Mar. 10, 1915 (this J., 1917, 83).

IN the manufacture of sodium perborate by the electrolysis of an alkaline solution of borax, as described in the chief patent, improved yields are obtained by increasing the current density, more especially at the anode. In the examples given, the electrolytic efficiency was increased from 3.55% to 33.5% by increasing the current density at the anode from 1000 amp. per sq. m. up to 4000, with a cathode density of 820; and from 14.4% to 20.5% by increasing the cathode density from 1000 to 2000, with an anode density of 1000. —B. V. S.

Arsenates; Production of metal —. E. C. R. Marks, London, Assignee of T. A. Mitchell, Reading, Mass., U.S.A. Eng. Pat. 101,029, July 24, 1916. Under Int. Conv., July 23, 1915. (Appl. No. 10,407 of 1916.)

VIII.—GLASS; CERAMICS.

Glass; Annealing of —. F. Twyman. Soc. Glass Tech., Feb. 15, 1917.

WANT of annealing in glass leading to fracture is due to the presence of internal stress. Glass behaves at all temperatures as a viscous liquid, and exhibits a continuous and gradual variation in viscosity from almost zero at high temperatures to almost infinity at 0° C. In molten glass there is no permanent internal stress, whilst at ordinary temperatures glass is almost perfectly elastic, so that stress cannot originate at either high or low temperatures. At high temperatures internal stresses, if any, die away very quickly, but between this high temperature and the low temperature at which glass acts as an elastic solid, there is a region where internal stress may take several minutes or even hours to die away. It is this region of temperature which is important in annealing, and care must be exercised in cooling a glass object through its "annealing range" in order to free it from internal stress.

The author described the method employed to determine the annealing temperature of various glasses, and then showed that the mobility (*i.e.*, inverse viscosity) of glass doubled for each 8° C. rise in temperature. Results were given showing the rapid rise of mobility with rise of temperature. Thus, a certain glass kept at 420° C. required a period of eighty-three hours for internal stress to disappear, whilst at 580° C. the same glass was freed from stress in 0.3 second. The actual annealing temperature, *i.e.*, the temperature at which stress easily disappears and yet low enough not to cause deformation of the object, differs widely for various glasses. It is a matter of wide importance to the manufacturer to know the annealing temperature of his glass. For example, suppose the annealing temperature of a glass is 500° C., *i.e.*, stress will almost disappear from the glass at this temperature in about three minutes. Then if the glass is held at 420° C. it would require forty-five hours to anneal, whilst if kept at 580° C. it would probably go out of shape.

Annealing. S. English. Soc. Glass Tech., Feb. 15, 1917.

To obtain some knowledge of the rate of annealing at various temperatures, small glass rods were heated at the required temperature in an electric furnace, observations being carried out by means of a special apparatus built up of two Nicol prisms and a system of lenses. The well-known rings and cross as seen in an uniaxial crystal were always observed in the rod under experiment, and as the experiment proceeded the rings expanded and passed from the circle of light, the rate at which they disappeared being a measure of the rate of annealing at that temperature. The times necessary for the last four rings to disappear in the case of a chemical resistant glass were for various temperatures as follows:—500° C. 1230 mins.; 550° 50 mins.; 600° 20 mins.; 625°

12 mins. The times required for the field of view in the apparatus to become perfectly dark, i.e., until all stress had disappeared, were at 550° C., 570 mins.; 600°, 270 mins.; 625°, 18 mins.; 650°, 10 mins.

Since the annealing of glass is the relieving due to incipient softening of internal strains, the temperature at which annealing proceeds at a fairly rapid rate may be obtained by finding the temperature at which glass will yield to external forces. The apparatus for carrying out this work was described, and curves were given showing results with actual glasses.

The optical and mechanical methods of determining annealing temperatures as described by the author, yield results in close agreement, and prove that the annealing temperature of glass is considerably below the temperature of actual softening.

PATENTS.

Glass. G. A. Macbeth; G. D. Macbeth, exor., Assignor to Macbeth-Evans Glass Co., Pittsburgh, Pa. U.S. Pat. 1,211,202, Jan. 30, 1917. Date of appl., Apr. 12, 1915.

A GLASS is formed by fusing a mixture containing 1500 parts of a foundation batch for clear glass, 121 of alumina, 135 of fluorspar, and 150 parts of sodium silicofluoride. The fluorspar may be replaced by any other fluoride containing 50 per cent. of fluorine, and the silicofluoride by another fluoride. The alumina may range from 80 to 160 parts, the fluoride from 100 to 170, and the silicofluoride from 100 to 200 parts.—A. B. S.

Annealing beer. J. Plante, Verdun, Quebec. U.S. Pat. 1,211,217, Jan. 30, 1917. Date of appl., May 15, 1913.

AN annealing oven is provided with a movable pan for holding articles and with a heating device therefor. Hot air from the top of the oven is drawn through an opening into a vertical chamber in the oven wall by an adjacent injecting nozzle supplied with fluid under pressure, and the mixture passes into the oven through an opening below the pan.—W. F. F.

Brick-kiln. J. T. Underwood, Dayton, Ohio. Assignor to Underwood Engineering Co., Detroit, Mich. Re-issue 14,251, Jan. 16, 1917, of U.S. Pat. 1,105,724, Aug. 4, 1914. Date of appl., Apr. 3, 1916.

Air and gas under pressure are admitted through burners at the floor level of the kiln, near its circumference. The exit flues are arranged so that the pressure of the gases inside the kiln is greater than that of the outer atmosphere. In order to prevent leakage through the walls of the kiln, they may be coated externally.—A. B. S.

Refractory product and method of manufacturing same. Manufacture of plastic products. A. P. Taylor and J. D. Runyan, Assignors to The Charles Taylor Sons Co., Cincinnati, Ohio. U.S. Pats. (A) 1,212,846, and (B) 1,212,847, Jan. 16, 1917. Dates of appl., Dec. 8, 1915, and July 11, 1916.

(A) FLINT clay is calcined and any impurities which are thereby made visible are picked out. The calcined clay is mixed with highly refractory kaolin and plastic kaolin and the mixture is shaped and burned in the customary manner. (B) Flint clay is prepared for use in the manufacture of refractory products by calcining it and then separating the impurities thus rendered visible.—A. B. S.

IX.—BUILDING MATERIALS.

Underground building work; Destruction of — by the sulphur of peat soils. H. Kühl. Z. angew. Chem., 1916, 29, 335—336.

THE author draws attention to the fact, overlooked by Thörner (this J., 1916, 855), that underground cement work may be destroyed by soluble sulphates as well as by free sulphuric acid formed from the so-called "reactive sulphur." The destructive action of soluble sulphates has been shown by Candlot and by Michaelis to be due to the formation of a voluminous, almost insoluble double compound of calcium aluminate and calcium sulphate, $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{CaSO}_4$.

Sulphur of peat soils; Nature of the —. W. Thörner. Z. angew. Chem., 1916, 29, 363—364.

IN reply to Kühl (see preceding abstract), it is pointed out that most peat soils contain only small quantities (a few tenths per cent.) of calcium and magnesium sulphates, too small to have an appreciable injurious action on vegetation and underground building work. In the case of peat soils near the sea, the soil water may contain considerable amounts of the salts mentioned and will then undoubtedly cause injury to underground cement structures, but such action is due to the composition of the soil water and is not typical of peat soils.

PATENTS.

Wood, stone, fabrics, etc.; Process for impregnating — Elektro-Osmose Akt.-Ges. (Graf Schwerin Ges.), Frankfurt, Germany. Eng. Pat. 101,205, Apr. 5, 1916 (Appl. No. 5021 of 1916). Under Int. Conv., Aug. 18, 1915.

THE material (stone, wood, fabric, etc.) is impregnated with a 2—10% colloidal solution of chemically pure silicic acid in water (see Eng. Pat. 9237 of 1914; this J., 1914, 719). Textile materials so impregnated possess a finish which is particularly suitable for absorbing basic dyestuffs. Fibrous materials impregnated in this manner are fireproof "to a surprising degree."—A. B. S.

Plastic compositions and slabs for building and other purposes. J. C. G. Sperti and L. S. Burt, London. Eng. Pat. 103,775, Aug. 2, 1916. (Appl. No. 10,881 of 1916.)

A PLASTIC composition for roofs, partitions, floors, slabs, etc., is made of sawdust 50%, finely ground burned magnesite 25%, and pumice powder 25%, with sufficient magnesium chloride of 18—25° B. (sp. gr. 1.14—1.21) to make a semi-dry mixture and with or without the addition of colouring matter and raw linseed oil. A protected reinforcement may be embedded in this composition if desired. The addition of 1 gallon of raw linseed oil to 25 gallons of the magnesium chloride solution prevents contraction during the setting of the composition and also brightens and preserves the colour.—A. B. S.

Heat insulating chambers, walls, floors, and ceilings; Manufacture of —. J. Davies, Liverpool, and W. H. Jones, Wallasey, Cheshire. Eng. Pat. 103,839 of 1916. (Appl. Nos. 1510, Feb. 1, 1918, May 1, and 6535, May 6, 1916.)

A NON-CONDUCTING covering or heat-insulating material for walls, floors, etc., is built of independent units or slabs, each composed of a primary layer of tough organic material, such as compressed cork, which is coated on the inner face with a secondary layer of oxychloride or Portland cement in a plastic state, which is pressed into the primary layer and then dried.—A. B. S.

Roadway composition. R. F. Tompkins, New York, Assignor to The Binder Co. U.S. Pat. 1,213,555, Jan. 23, 1917. Date of appl., Aug. 15, 1913.

The composition consists of a road base, a filler, and an insoluble metallic compound of an aromatic organic acid, such as tannic acid.—A. B. S.

Binding composition for roads, etc. R. F. Tompkins, New York, Assignor to The Binder Co. U.S. Pat. 1,211,972, Feb. 6, 1917. Date of appl., Aug. 15, 1913.

A BINDING composition for roads, etc., is composed of a hygroscopic aromatic glucoside and a material insoluble in and resistant to water, such as a resinous substance or a fixed oil.—A. B. S.

Rotary cement-kiln gases; Recovery of material in the form of dust from —. L. Stevens, Assignor to Jermin and Stevens, Alpena, Mich. U.S. Pat. 1,214,725, Feb. 6, 1917. Date of appl., Aug. 19, 1915.

The flue gases from rotary cement-kilns are mixed with water, which is converted into steam by the heat in the gases, and the gases thus cooled are passed through a dust-separator which precipitates the suspended matter in a dry condition. The quantity of water mixed with the gases is increased or decreased automatically as the temperature of the gases rises or falls.—A. B. S.

Cement; Manufacture of —. J. F. Goddard, London. U.S. Pat. 1,211,910, Feb. 6, 1917. Date of appl., May 5, 1915.

SEE Eng. Pat. 13,512 of 1914; this J., 1915, 426.

X.—METALS; METALLURGY, INCLUDING ELECTRO-METALLURGY.

Rust from iron plates; Removal of —. F. W. Watson. J. Chem., Met., and Min. Soc., S. Africa, 1916, 17, 109.

A FINELY crushed mixture of 2 parts of sodium bisulphate and 1 of common salt is wetted until cohesive, applied to the iron plate, and left on till the plate is clean. The action is much more rapid if the plate is scraped every 2–3 hours and scrubbed with a wire brush and water, and the treatment repeated. When clean the plate is well washed, finally with an alkaline solution, and dried quickly.—W. R. S.

Manganese in steel; Determination of —. J. A. Cashmore. Chem. News, 1916, 114, 239.

IN the following method the delicacy of the precipitation of iron by neutralising with ammonia is avoided. One or two grms. of the sample is dissolved by means of hydrochloric acid and potassium chlorate, and after expelling free chlorine, the solution is diluted to 400 c.c., heated to boiling, and boiled for two mins. with a slight excess of zinc oxide emulsion to precipitate the iron. The precipitate is filtered off and washed with hot water; precipitation of zinc hydroxide in the filtrate is disregarded. The filtrate is heated to 60° C., treated with 1 gm. of ammonium persulphate to oxidise the manganese, and boiled with excess of ammonia. After filtering, the precipitate of hydrated manganese peroxide is washed with strong ammonia solution to remove zinc, then with hot water, dried, and ignited. Greater accuracy is obtained by dissolving the ignited residue of Mn_2O_3 in hydrochloric acid, adding a few c.c. of nitric acid, and re-precipitating the manganese with ammonium persulphate and ammonia.

Chromium; Determination of — in ferrochrome. W. Herwig. Stahl u. Eisen, 1916, 36, 646–650. J. Chem. Soc., 1917, 112, ii., 101–105.

THE volumetric estimation of chromium in ferrochrome by means of potassium permanganate gives low results if the theoretical titer number for chromium as recorded in the text-books (0.319 instead of the empirical number 0.3165) is used. On the other hand, accurate results are obtained by the sodium thiosulphate and potassium bichromate methods. The following shortened sodium thiosulphate process gives results accurate to 0.3%, and can be completed in an hour. The powdered sample is passed through a sieve of 270 meshes to the sq. cm., and 0.5 gm. is fused in an iron crucible with sodium peroxide (5–6 grms.), gentle heat being applied for about a minute until the metal has dissolved in the fused mass, after which it is heated, with gentle agitation, for two minutes with the full Bunsen flame. The somewhat cooled crucible is transferred to a beaker containing about 350 c.c. of water at 60°–80° C., the beaker immediately covered with a clock-glass, and the water cautiously boiled for five minutes to decompose the sodium peroxide completely; after being cooled, the solution is diluted to 500 c.c. and passed through a double filter. 100 c.c. of the filtrate is diluted to about 300 c.c. with water, treated with potassium iodide (1 gm.) and hydrochloric acid (sp. gr. 1.124, 40 c.c.), and, after 1 min., titrated with sodium thiosulphate. Decomposition of ferrochrome by magnesium carbonate mixture is frequently incomplete. After being sifted, the specimen should be ground for two to three hours in an agate mortar, and the mixture must be heated for at least an hour with a powerful blow-pipe flame. The residue from the first operation must be once more, at least, similarly treated.

Gold; Volatility of — at high temperatures in atmospheres of air and other gases. W. Mostowitsch and W. Plehnoff. J. Russian Metall. Soc., 1915, 419–431. Met. and Chem. Eng., 1917, 16, 153–151.

FUSED samples of purified gold, of 0.2 to 0.5 gm. weight, were placed in an unglazed porcelain or quartz boat and submitted to a stream of gas for measured intervals, extending up to $2\frac{1}{2}$ hrs., while heated in a Heraeus furnace to temperatures between 1100° and 1400° C. The metal was weighed before and after each experiment by means of a micro-balance. In atmospheres of oxygen, nitrogen, carbon monoxide or dioxide, no loss of weight could be detected at temperatures up to 1400° C. With hydrogen, however, volatilisation was observed, amounting at 1400° C., after an interval of 25 mins., to 0.98 mgrm., corresponding to a loss of 0.25%. The vaporisation was accompanied by a deep red colouring of the silica boat and the heating tube, due to the formation of a colloidal solution of gold in the quartz. This action is analogous to similar phenomena shown by copper when heated in hydrogen, and leads to the supposition that, at temperatures above 1200° C., an unstable hydride such as Au_2H_2 is successively formed and decomposed.—J. N. P.

Australian zinc industry. Ch. of Comm. J., Mar., 1917.

A NEW company, the Zinc Producers' Association Proprietary, Ltd., has recently been formed to handle all zinc concentrates produced within the Commonwealth. This is the largest and most powerful metal combination in the Southern Hemisphere and one of the most important in the world. The Commonwealth's annual output of zinc ores and concentrates amounts to 150,000 tons, and the gross value of metal is not less than

£5,000,000. All of the zinc-producing companies of Australia are members. The association is founded on a co-operative basis. One of the fundamental principles is "equality of treatment" to all members, irrespective of the tonnage of output. The Commonwealth Government is represented on the board, thus safeguarding the interests of the general community. As the result of the Commonwealth Prime Minister's efforts in England the spelter question has been settled as far as Great Britain and Australia are concerned. A contract has been entered into for a large supply of zinc concentrates per annum for Great Britain during the currency of the war, with the option of increasing the quantity.

To meet post-war conditions a comprehensive scheme covering the whole output of Australia has been adopted. The British Government has entered into a definite agreement for a term of ten years to take a minimum of 100,000 tons of Australian concentrates at satisfactory prices. As to the remainder, arrangements have been made whereby Australia will treat locally 10% of the whole of the zinc concentrates produced in the Commonwealth. Of the spelter thus produced, the British Government has further contracted to take up to 45,000 tons per annum of spelter and electrolytic zinc produced in Australia for a period of ten years. The post-war requirements of France and Belgium and other Allies are being considered.

In order to deal more effectively with the zinc concentrates reserved to Australia under the scheme, a company called the Australian Electrolytic Zinc Company has been formed. Contracts for power have been arranged with the Tasmanian Government; technical experts have been engaged and the company promises to be one of the foremost industrial concerns in the Commonwealth. Towards securing capital for Australian zinc industries the Imperial Government undertakes to advance a substantial sum at the same rate of interest as is paid by the Imperial Government, if required, to finance Australian zinc works until war restrictions are removed. The Mount Lyell company is embarking upon a new venture, and promises to be a large producer of electrolytic zinc. The enlargement of the Port Pirie zinc distillery is receiving attention. Zinc specialists have been engaged to undertake the modernization of the zinc distilling plants in Australia, and also to install and work the electrolytic zinc processes.

Aluminium scrap and swarf and cupro-nickel scrap; Government control of —.

THE Ministry of Munitions has issued orders governing the conditions under which the above metals will be controlled. The full text of the orders will be found in the issues of the *Board of Trade Journal* of March 7th and 15th respectively.

Zinc-lead smelting plant at Ekibastus, Siberia. Eng. and Min. J., 1917, 103, 266.

IN the annual report of the Irtysh Corporation, Ltd., the progress in building and putting into operation the great zinc and lead-smelting plant at Ekibastus, Siberia, which is to treat the ore of the Ridder mine, was summarised. In the zinc plant proper, the first duplex Merton calciner started in May, 1916, and one block of retorts followed in August. The zinc-distillation furnaces are of modern type, gas-fired and regenerative. Each block has an estimated output of 150 tons of spelter a month. For the first eight weeks of operation the output of spelter was about 90 tons, and the management is looking forward to a rapid increase in this up to full capacity. Additional calciners are nearing completion, and a second block of zinc retorts was to be ready by the end

of 1916. The plant has been laid out for an installation of 20 blocks of zinc furnaces, of which it is expected to have six completed by the end of 1917. Construction work on the lead-smelting plant is well advanced. The smaller of the two blast furnaces should be ready to go into commission early in 1917 and the larger one during the summer. This plant will treat the lead concentrates received from Ridder and the residues from the zinc retorts. Adjacent to the lead plant a lead refinery is being erected. It will consist of softening and drossing furnaces, desilverisation kettles, a Howard press and stirrer, and a tilting furnace for the distillation of the zinc crusts from the desilverisation kettles. The bullion refinery will produce pure gold and silver. Work on the bullion refinery is advancing, and should be completed as soon as needed.

Glucinum [beryllium]: Melting point and heat of fusion of —. G. Oesterheld. Z. anorg. Chem., 1916, 97, 1—6. J. Chem. Soc., 1917, 112, ii., 89.

GLUCINUM, prepared electrolytically from sodium glucinum fluoride, was pressed into pastilles and fused in a magnesia tube in hydrogen. The product contained 99.5% Gl, the principal impurity being the carbide. Heating and cooling curves gave the value $1278 \pm 5^\circ \text{C.}$ for the melting point. An approximate determination of the heat of fusion by comparing the duration of the arrests when equal volumes of gold and glucinum were cooled under similar conditions, gave 277 cal. per grm., whilst Crompton's rule, atomic weight \times heat of fusion \div absolute temperature of fusion = 2, gave the value 341. Glucinum has the largest heat of fusion of any metal, corresponding with its high melting point and low atomic weight.

Glucinum [beryllium]: Alloys of — with aluminium, copper, silver, and iron. G. Oesterheld. Z. anorg. Chem., 1916, 97, 6—10. J. Chem. Soc., 1917, 112, ii., 89—90.

GLUCINUM and aluminium are miscible in the liquid state and do not form a compound. The freezing-point curve has two branches, with an eutectic point at 614°C. and 4 atomic % Gl. Solid solutions are only formed at the glucinum end of the series up to 3 atomic %. The sections may be etched with dilute sodium hydroxide. It has not been found possible to alloy glucinum and magnesium, as the latter boils below the melting point of the former. The alloys with copper are complicated. The freezing point of copper is first lowered, solid solutions being formed up to 10 atomic % Gl, and beyond this the liquidus and solidus, which are separated by a very small interval, have an unusual form, passing through a minimum and a point of inflexion. The β -solution breaks up at a lower temperature; there being an eutectoid point at 575°C. and 31 atomic % Gl. There is a short ascending branch corresponding with the separation of a γ -solution, and then the freezing-point curve rises to a maximum at the composition Cu_2Gl_3 , beyond which it has not been possible to follow the alloys. The δ -solution contains from 70 atomic % Gl upwards. The transformation of β into α and γ was confirmed by quenching experiments. The eutectoid has a structure very like that of the pearlite of steel. The compound Cu_2Gl_3 is reddish-grey. The alloys may be dissolved in nitric acid for analysis, and the copper estimated by electrolysis. Silver and glucinum give a simple eutectiferous system, the eutectic point being at 878°C. and 16 atomic % Gl. Solid solutions are only formed to the extent of about 8 atomic % at the glucinum end of the series. A transformation point of 748°C. has been observed, and as pure glucinum is not allotropic, it is suggested that a compound may be formed.

The alloys increase in hardness and diminish in ductility as the glucinum increases. The alloys with iron have been examined up to 21% Gl by weight. There is an eutectic point at 1155° C. and 38.4 atomic % Gl, the region of solid solutions extending to 29%. The β - α -transformation of iron is lowered by glucinum, becoming constant at 650° C. The compound, which may have the formula FeGl_2 , is darkened by sodium hydroxide.

PATENTS.

[*Briquetting iron ores and flue dust.*] *Binding material and method of preparing same.* M. Freiburger, Charlottenburg, Germany. Eng. Pat. 7010, May 10, 1915. Addition to Eng. Pat. 15,919 of 1913 (see Fr. Pat. 460,954 of 1913; this J., 1914, 85).

THE binding material is produced by heating a mixture of highly basic aluminosilicates, or burnt lime and iron oxide or hydroxide, or an ore relatively high in lime, to a temperature below the sintering point. It is mixed with ores poor in lime, and the mixture briquetted below sintering temperature. If an ore contains an excessive proportion of lime, it is heated to below the sintering temperature, and a sufficient proportion of uncalcined ore is added to prevent expansion of the resulting briquettes. The ore or flue dust may also be elutriated, the fine portion being mixed and heated with burnt lime or basic aluminosilicate, and used to briquet the coarse portion. The binding mixture may be produced by wet grinding; the lime may be dry-slaked, or slaked with the wet fine portion from the elutriation.—W. R. S.

Steel or ingot iron; Manufacture of——. B. Talbot, Middlesbrough. Eng. Pat. 103,569, Apr. 5, 1916. (Appl. No. 4996 of 1916.)

A FURNACE is used which contains two or more separately tilting hearths, each of which is used for independent mixing or refining. (See also Eng. Pats. 22,767 of 1903 and 9110 of 1904; this J., 1904, 939; 1905, 444.)—W. R. S.

Steel ingots; Apparatus for treating——. E. J. Flynn, jun., Woodlawn, Pa. U.S. Pat. 1,212,470, Jan. 16, 1917. Date of appl., Mar. 10, 1916.

THE intermediate portion of the floor of a soaking pit is made of gradually increasing height from each end towards the centre, thus providing a pair of supports for the ingots; the pit has also an abutment on each side wall extending inwards. These supports and abutments are adapted to contact respectively with the inner corners of a

pair of opposed ingots, and with their outer sides. The ingots are thus maintained in an upright position, spaced from each other and from the sides and bottom of the pit, to obtain equal distribution of heat round them.—T. H. B.

Steel and iron; Process of making——. S. S. Knight, Berkeley, Cal. U.S. Pat. 1,213,896, Jan. 23, 1917. Date of appl., Feb. 18, 1914.

IN the manufacture of iron or steel in a basic open-hearth furnace, a layer of ferrous material low in carbon, such as steel or wrought iron scrap, amounting to 10 to 20% of the entire weight of the charge, is introduced directly on to the bottom of the furnace, and heated until reduced to a pasty condition, thus forming a protective layer. Burnt lime or limestone to the extent of 5 to 20% of the entire charge is added, then additional charges of ferrous material and carbonising material of a non-ferrous nature, chiefly free carbon, until the entire charge is completed. The temperature is then rapidly raised so as to melt the ferrous material, highly carbonised ferrous material being added, if necessary, to obtain a bath containing about 0.50 to 0.90% carbon. The heating is continued so as to reduce rapidly the quantity of materials other than iron and the metal is finished and drawn off as usual.—T. H. B.

Steel; Alloy with——. F. D. Taggart, Wyomissing, Pa. U.S. Pat. 1,213,973, Jan. 30, 1917. Date of appl., Oct. 31, 1916.

THE steel contains carbon 1.25–2.50, chromium 1.50–3.00, and vanadium 0.25%, the minor elements present not exceeding 1%.—W. R. S.

Furnaces; Electric——[for production of zinc and other metals]. F. Cochlovius, Buchschlag, Hessen, Germany. Eng. Pat. 16,602, Nov. 24, 1915. Under Int. Conv., Nov. 24, 1914.

THE reducing chamber of a rotary electric furnace, for the production of zinc and other like metals, in which the heat is produced by the resistance offered by the charge to the passage of the current, is subdivided into two or more compartments by partitions, and one or more phases of a polyphase current is supplied to each compartment. The central portions of the partitions are cut away, thus forming centrally an undivided chamber, or the partitions may be provided with perforations. A separate condensing apparatus is supplied for each compartment of the reducing chamber.—B. N.

Zinc; Recovery of——. C. H. Fulton, Cleveland, Ohio, Assignor to D. B. Jones, Chicago, Ill. U.S. Pat. 1,213,180, Jan. 23, 1917. Date of appl., July 17, 1916.

GROUND and calcined zinc ore is mixed with coke and a carbonaceous binder, such as pitch, in such proportions that when made into compact briquettes under pressure and subjected to subsequent distillation, the briquettes will maintain their form and volume. The briquettes are preheated to drive off the volatile matter of the binder and convert the latter into coke, then interposed as a continuous resistor between the electrodes of a closed electric furnace. A current is passed to heat them to a distilling temperature, and the zinc is recovered from the evolved vapour.—T. H. B.

Zinc-furnace. G. Londress and L. Rogers, Clarksburg, W. Va. U.S. Pat. 1,213,922, Jan. 30, 1917. Date of appl., June 27, 1914. Renewed Mar. 4, 1916.

IN a zinc dross furnace, a closed, inclined, cylindrical

cal chamber or dross compartment is surrounded by a spiral flue through which the gases from fireboxes beneath pass to a stack. At the lower end of the dross compartment, and adjoining the fireboxes, is a spelter box containing removable kettles adapted to receive molten zinc discharged from openings in the vertical end wall of the cylindrical chamber.—W. E. P. P.

Metals; Plating of — J. A. Law, London. From The Thermic Plating Process Co., Inc., New York. Eng. Pats. 16,867 and 16,868, Nov. 30, 1915. (See also Eng. Pat. 23,576 of 1911; this J., 1916, 123.)

THE metal to be plated (e.g. iron) is coated with a suspension of the plating metal (e.g., copper) and/or a reducible compound of the latter with carbon or other reducing agent in a spreading vehicle (e.g., crude petroleum having an asphaltic base) and heated to a temperature (2000° F., 1090° C.) sufficient to effect the necessary reduction and union.—W. E. P. P.

Aluminium; Process of plating — L. W. Bugbee, Assignor to American Optical Co., Southbridge, Mass. U.S. Pat. 1,244,271, Jan. 30, 1917. Date of appl., Dec. 4, 1916.

THE aluminium article is connected with a source of electricity and submerged in a plating bath. During the plating operation the article is subjected to an abrasive blast, the initial rate of abrasion being greater, and the final considerably less, than the rate of plating.—W. R. S.

Metal scrap; Treatment of — E. R. Sutcliffe and T. G. Hirst, Leigh, Lancs. Eng. Pat. 103,553, Mar. 8, 1916. (Appl. No. 3155 of 1916.)

SCRAP such as shavings, borings, turnings, etc., is prepared for melting by intimately mixing it with 1—3% of moistened flux (borax, soda, or potash) so that the metal particles become coated, and then briquetting the product under heavy pressure without addition of a binding agent.—W. R. S.

De-tinning and the like; Apparatus for — I. Hall, Birmingham. Eng. Pat. 103,836, July 11, 1916. (Appl. No. 452 of 1916.)

THE articles to be de-tinned gravitate from the inlet to the outlet of a slowly rotating, inclined cylinder mounted inside a concentric fixed cylinder lined with firebrick or other refractory material. Flames from gas burners are directed into the annular space between two cylinders. The articles are fed in, at the higher end, through a hopper, the outlet of which is in register, once every revolution, with an opening in the inner cylinder. The products of combustion escape from outlets in the upper part of the outer cylinder.—T. H. B.

Aluminium alloy. W. A. McAdams, Bay Shore, N.Y. U.S. Pat. 1,242,374, Jan. 16, 1917. Date of appl., Apr. 15, 1914. Renewed June 6, 1916.

THE alloy consists of about 128 parts of aluminium, 46 parts of zinc, and 29 parts of copper by weight.—T. H. B.

Ore mixtures; Separating finely divided — in vacuum vessels. F. A. M. Schiebel, Frankfurt, Germany. U.S. Pat. 1,242,566, Jan. 16, 1917. Date of appl., June 25, 1915.

THE ore pulp is subjected to successive vacuum treatments, each higher than the preceding one. The separating chambers each have the shape of

an upright cone with a discharge orifice at the top, overlying which is a vacuum bell. The bells and the chambers are connected in series by valved conduits, so that different degrees of vacuum may be produced in the various bells, at the same time maintaining a desired liquid level in one of the chambers and permitting a flow of liquid to an adjacent chamber through one of the conduits. A portion of the metallic particles present is removed from the pulp by each successive vacuum treatment.—T. H. B.

Molten metal in ingot moulds; Compound for covering the top of — J. E. Sheaffer, Burnham, Pa. U.S. Pat. 1,212,825, Jan. 16, 1917. Date of appl., Apr. 20, 1916.

THE exposed surface of molten metal is protected by a mixture of pulverised anthracite and petroleum oil in about the proportion of one quart of the latter to 100 lb. of anthracite.—T. H. B.

Concentrating ores, minerals or earths; Device for use in — or for like purposes. M. T. Taylor, Carn Brea, Cornwall. Eng. Pat. 103,858, Feb. 14, 1916. (Appl. No. 2201 of 1916.)

Lead alloys; Manufacture of — F. C. Frary, Niagara Falls, N.Y., and S. N. Temple, St. Paul, Minn., U.S.A. Eng. Pats. 101,208 and 101,209, July 19, 1916. Under Int. Conv., Aug. 13, 1915. (Appl. Nos. 10,154 and 10,155 of 1916.)

SEE U.S. Pats. 1,158,674 and 1,158,675 of 1915; this J., 1915, 1256.

Aluminium; Recovery of — from composite materials containing aluminium and silicon, such as clay, bauxite, or the like. J. E. Pollak, London. From Weaver Co., Milwaukee, Wis., U.S.A. Eng. Pat. 103,716, Mar. 1, 1916. (Appl. No. 3083 of 1916.)

SEE Fr. Pat. 481,056 of 1916; this J., 1917, 144.

Tungsten metal; Process for producing homogeneous bodies of chemically pure — of any desired shape. O. Voigtländer and H. Lohmann, Essen, Germany. U.S. Pat. 1,212,426, Jan. 16, 1917. Date of appl., Dec. 2, 1913.

SEE Eng. Pat. 27,369 of 1913; this J., 1915, 875.

Metals; Method of reducing — [electrolytically]. R. J. McNitt, Niagara Falls, N.Y., Assignor to The Roessler and Hasslacher Chemical Co., New York. U.S. Pat. 1,214,808, Feb. 6, 1917. Date of appl., May 12, 1915.

SEE Fr. Pat. 466,205 of 1913; this J., 1914, 600.

XII.—FATS; OILS; WAXES.

*Control of fats, oils, oilseeds and their products.
New branch of the Ministry of Munitions.*

THE Ministry of Munitions announce that, by arrangement with the Ministry of Food and the Board of Agriculture, they have assumed control of all fats, oils, oilseeds and their products, including oilcake, soap, and margarine. A new Branch of the Explosives Department of the Ministry is being organised under Mr. Alfred Bigland, M.P., as Controller, assisted by a Consultative Committee representing other Government Departments. Mr. Bigland has for over a year had charge of the interests of the Ministry of Munitions in respect of oils, fats, and oilseeds, required for the extraction of glycerin for use in the manufacture of propellant explosives. The Secretary of the new Branch is Mr. C. W. Bird, to whom communications should be addressed at the Oils and Fats Branch, Department of Explosives Supply, Ministry of Munitions, Storey's Gate, London, S.W. 1.

It is particularly desired that representations to the Controller of Oils and Fats, etc., should be put forward through trade associations and kindred bodies, and not by individuals and firms, in order to avoid unnecessary multiplication of correspondence.

Mineral oils will not be dealt with by the new Branch but by the existing Munitions Petroleum Supplies Branch. Essential oils, butter, and lard are also outside the scope of the new Branch's activities.

Oil testing. A. H. Gill. J. Ind. Eng. Chem., 1917, 9, 136.

1. *A test for oils by salting-out their soaps.* The test depends on the varying quantities of sodium chloride required to salt-out the soaps prepared from different oils. Two grms. of the oil is saponified with 5 c.c. of 10% sodium hydroxide solution (adding alcohol, if necessary), the mixture is evaporated to dryness, the residue dissolved in warm water, the solution cooled, neutralised with hydrochloric acid, using phenolphthalein as indicator, and then diluted to 50 c.c. Ten c.c. of this solution is placed in a bottle and titrated with sodium chloride solution (320 grms. per litre) until the lather just fails to persist for 5 mins. From the quantity of hydrochloric acid used, and this titration with sodium chloride, is calculated the amount of sodium chloride (in grms.) required to precipitate the soap from 1 gm. of oil. The following results were obtained with various oils:—Olive oil, 2.4—2.2; cottonseed oil, 10.6—11.6; linseed oil, 8.0—8.6; oleomargarine, 2.8; butter, 1.2—1.4 grms. of sodium chloride per gm. of oil. In the case of coconut oil soap, an end-point in the titration was not obtainable. II. *Test for gelatinous matter in linseed oils.* When linseed oil is saponified and the resulting soap solution shaken with petroleum spirit, the amount of suspended matter which separates at the junction of the two liquids appears to vary with the drying properties of the oil, the largest quantity being found in oils which are slowest in drying. Ten grms. of the oil is saponified with 20 c.c. of 10% sodium hydroxide solution, and the soap solution is diluted with warm water to 225 c.c.; 25 c.c. of this solution is placed in a test-tube (6 × 1 in.), 8 c.c. of 86° gasoline (sp. gr. 0.618) is added, the mixture shaken, and then centrifuged for 3 mins. at 1800 revs. per min. Ordinary linseed oil gave a layer of sludge, nearly 10 mm. in thickness, between the two layers of liquid, whilst an artists' oil yielded a sludge layer less than 5 mm. in thickness.—W. P. S.

Brazilian oil-seeds. E. R. Bolton and D. G. Hewer. Analyst, 1917, 42, 35—45.

(1) *Elæis guineensis*. The pulp oil and kernel oil are suitable for the same purposes as the palm oil and palm-kernel oil of commerce, but the characters of the fats differ considerably from those of the African products. The Brazilian kernel oil would be regarded as more valuable than the African kernel oil, whilst the pulp oil is less useful than the African product. (2) *Astrocaryum vulgare*, Mart., is another palm which grows in Maranhão, Pará, and the Amazon valley. The pulp oil is of a pale straw colour and has the consistency of vaseline. It prepared from fresh fruits, so as not to contain more than 10% of free fatty acids, it would be suitable for the manufacture of margarine. The kernel oil is a firm solid fat resembling ordinary palm-kernel oil. (3) *Astrocaryum species*. This palm, known locally as *Murumuré*, yields a kernel oil which could be used as a substitute for cacao butter and coconut "stearine." (4) *Acrocomia sclerocarpa*, Mart., is a palm which forms large forests in Paraguay. It yields a pulp oil closely resembling palm oil, but of somewhat less value. The kernel oil melts at a lower temperature than ordinary palm kernel oil. The crude fat is suitable for soap-making and when refined would be particularly suitable for the manufacture of margarine. (5) *Mucimilitiana regia*, Mart. (Anajá or kokerite palm) yields a firm, white, somewhat brittle kernel oil, which is odourless, and suitable for use as an edible fat. (6) *Cocos syagrus*. Two distinct types of this palm occur, the kernels of which give different yields of fats which are practically identical in character and suitable for food. (7) *Attalea funifera*, Mart. The pulp contains only about 1% of oil. The kernels, the shells of which are extremely difficult to crack, yield a fat resembling coconut oil, but somewhat softer. It is suitable for margarine. About 6000 tons of the kernels have been exported in two years. (8) *Eucarpus batara*. The oil prepared by the natives from the pulp of the fruit of this palm closely resembles olive oil in its physical and chemical characters, and is particularly suitable for use as a salad oil. (9) *Virola bichenhyba*, Humb., known as *Ucuhuba*, belongs to the Nat. Order, *Myristicaceæ*. It produces seeds which contain an essential oil of characteristic odour, and a fat, which, when refined, is odourless and neutral. Acid and decomposed fats yield a good candle material when distilled. (10) *Myristica platysperma*, Spruce. The kernels contain a cream-white, hard, brittle fat consisting chiefly of myristin. (11) *Pentaclethra filamentosa* is a leguminous plant, the seed-kernels of which yield a golden oil which deposits "stearine" at 20° to 21° C. The oil is readily saponified but yields a soft soap of poor colour. If refined it would probably be edible. The kernels are also rich in proteins. (12) *Pentaclethra macrophylla* is closely allied to *P. filamentosa*. The seeds are most generally known as *Maboula panza* beans. They yield an oil (sp. gr. 0.917 at 15° C.) with properties practically identical with those of 11. (13) *Caryocar species*. The kernels produce a firm, brittle, white fat, which would be suitable, in admixture with oils, as a margarine fat or lard substitute. (14) *Marins* from Maranhão and Pará are seeds of unknown botanical origin, the kernels of which yield a viscous, deep yellow oil, which could possibly be used, in admixture with mineral oils, as a lubricant. (15) *Pachira species*. The kernels, which have an odour of liquorice and fennugreek, yield a semi-solid fat with an odour of liquorice, which, however, does not prevent its being used for soap-making. (16) *Mahuba-rana*. These seeds of unknown botanical origin yielded a dark-coloured fat, which might be suitable as a candle material. (17) *Carapa guianensis*, Aubl., is

known as *Andiroba*. The oil, which is prepared by the natives, has anthelmintic properties, and is unfit for food, though it could be used for soap-making. (18) *Omphalea megacarpa*, Hemel, which belongs to the *Euphorbiaceae*, produces seeds known as *cayeté nuts*. The kernels yield an oil (sp. gr. 0.9218 at 15° C.), with the physiological properties of castor oil, but differing therefrom in its analytical characters, in not being optically active, or very viscous, and in being only slightly soluble in alcohol. The following table gives the yields and characters of the fats obtained from these seeds.

	Native names	Yield.	Melting point.		Solidif. point.	Saponif. value.	Refractive index (Zeiss) at 40° C.	Iodine value.	Free fatty acids as lauric acid in kernel oil and oleic in pulp oil.	Un-saponif. matter.

— C. A. M.

Palm oil; Colour tests for —. A. H. Gill. J. Ind. Eng. Chem., 1917, 9, 136—139.

The colour reaction for palm oil (green coloration with acetic anhydride containing a trace of sulphuric acid) described by Crampton and Simons (this J., 1905, 351) is quite untrustworthy. The test is really one for carotin rather than for palm oil, and the reaction is given by any oil which contains carotin, e.g., palm oil, butter, sesame oil, etc. —W. P. S.

Wool fat; Constituents of —. F. Röhlmann. Biochem. Zeits., 1916, 77, 298—328. J. Chem. Soc., 1917, 112, i, 78.

As a result of attempts to separate the constituents of wool fat, the author draws the conclusion that it consists of a mixture of the esters of cholesterol and of alcohols of the fatty series, including ceryl alcohol and alcohols with a smaller number of carbon atoms. He was unable to confirm the presence of carnaubyl alcohol or of ischolesterol. The fatty acids are apparently

cerotic, palmitic, and stearic acids in the more solid constituents of the fat. The more liquid constituents of the fat contain, in addition to free cholesterol, a mixture of alcohols of an oily nature, and the fatty acids are probably stearic and palmitic acids, and an optically active acid (hydroxystearic acid?), together with resin acids. From the more solid constituents of the fat there was found, in addition, mixed with the fatty acids, a substance, m.pt. 103° C., which may be the anhydride of lanoceric acid. Carnaubic acid, which has been described as a constituent of wool fat, is regarded as a mixture of cerotic acid with

acids containing a smaller number of carbon atoms.

PATENTS.

Soap-like detergents and manufacture thereof. W. Feldenheimer. London. Eng. Pat. 103,535, Feb. 3 and Mar. 13, 1916. (Appl. Nos. 1668 and 3748 of 1916.)

A MIXTURE of spent soap lyes, 25, china-clay or "killas" (see Eng. Pat. 7920 of 1914; this J., 1915, 500), 25, and soft soap, 7.5 parts by weight, with or without the addition of 1 to 2% of "nitre." The china-clay is mixed with the lye heated previously to 80° C., and the soap, in solution and also heated to 80° C., is added.—W. P. S.

Apparatus for drying and treating sewage sludge, copra, and other materials in bulk. Eng. Pat. 103,521. See 1.

Method of making food compositions [from peanuts]. U.S. Pat. 1,213,854. See XIXA.

XIII.—PAINTS; PIGMENTS; VARNISHES; RESINS.**PATENTS.**

Carbon-black; Process and apparatus for making — W. O. Snelling, Pittsburgh, Pa. U.S. Pat. 1,213,915, Jan. 30, 1917. Date of appl., Oct. 11, 1915.

A CARBONACEOUS flame is allowed to impinge upon a surface which is maintained at a temperature above 100° C., but below the temperature of the flame. This is achieved by the use of a plate of sufficient thickness to ensure that there is a substantial difference between the temperatures of its lower, carbon-collecting surface and its upper surface, which is in contact with a cooling liquid.—E. W. L.

Colours and the like; Process for thickening and filtration of — J. Jung, C. In-Ehrenfeld, Ger. Pat. 295,577, Jan. 12, 1915.

THE liquid carrying the colour in suspension is passed under pressure through a series of independent filter-cells, and the resulting paste is conveyed to a receptacle in which a vacuum filtering drum is mounted eccentrically. Compressed air is supplied to the space between the drum and the receptacle, the inlet opening for the paste being sealed by the paste itself. The cake which forms on the outer surface of the drum is compressed by an adjustable, curved, spring-like member, and is subsequently removed by a scraper. The surface of the drum is kept clean by a rotating brush near the inlet opening for the paste.

Condensation product from phenols and formaldehyde. L. Berend, Amöneburg, Germany. U.S. Pat. 1,211,414, Jan. 30, 1917. Date of appl., Mar. 19, 1914.

ARTIFICIAL soluble and fusible resins are obtained by condensing crude cresol containing *m*-cresol, or a mixture of *p*-cresol and *m*-cresol, with "a formaldehyde body" in about such quantity as the quantity of *m*-cresol in the mixture will call for, expelling and recovering the unused cresol from the product. —E. W. L.

Varnishes, paints, and other protective or coating preparations; Manufacture of — H. Terrisse, Geneva, Switzerland. Assignor to The Indestructible Paint Co., Ltd., London. U.S. Pat. 1,211,611, Feb. 6, 1917. Date of appl., Apr. 22, 1915.

SEE Eng. Pat. 23,054 of 1914; this J., 1916, 57.

XIV.—INDIA-RUBBER; GUTTA-PERCHA.

Rubber; Wet combustion in the nitrosite combustion method for the direct determination of — L. G. Wesson and E. S. Knorr. J. Ind. Eng. Chem., 1917, 9, 139—140. (See this J., 1914, 703.)

THE nitrosite is prepared in a chloroform solution and the latter is filtered into a round-bottomed flask, and evaporated. Meanwhile the portion insoluble in chloroform is also dried and extracted repeatedly with ethyl acetate dried previously over calcium chloride, the extracts being filtered into the same flask. The ethyl acetate is then evaporated and the residue in the flask treated with 15 c.c. of water containing 1 drop of hydrochloric acid, which is evaporated rapidly by the use of a current of dry air. The dry residue is heated for a further 30 mins., and then oxidised by the gradual addition of a mixture of 10 grms. of potassium bichromate and 75 c.c. of sulphuric

acid. The gases evolved are passed through a series of U-tubes containing, in order, sulphuric acid and bichromate, water containing a drop of the preceding mixture, granular zinc, calcium chloride, soda-lime (weighed), and soda-lime and calcium chloride (weighed). Heat is applied to the combustion flask to complete the oxidation, and the last traces of carbon dioxide are swept over into the absorption tubes by means of a current of air free from carbon dioxide. When 0.5 gm. of rubber is taken for the determination, the weight of carbon dioxide found multiplied by 61.8181 gives the percentage of $C_{10}H_{16}$ in the sample.—W. P. S.

Rubber; Aniline method for the determination of mineral fillers in — O. H. Klein, J. H. Link, and F. Gottsch. J. Ind. Eng. Chem., 1917, 9, 140—141.

ONE gm. of the finely-divided rubber is extracted with acetone for 4 hours, then dried at a low temperature, and transferred to a weighed centrifuge tube; 50 c.c. of pure aniline and 5 c.c. of nitrobenzene are added, the tube is covered, and the mixture is heated at 160° C. until solution of the rubber is complete. This requires from 3 to 18 hours, or more. After cooling, ether is added to fill the tube, and the contents of the tube are mixed and centrifuged for 15 mins. at 1500 revs. per min. The supernatant liquid is then decanted, and the residue centrifuged four times with ether, using 25 c.c. each time. The contents of the tube are then dried at 100° C., and weighed. The ethereal solutions decanted from the tube are united, and evaporated, and the residue is ignited in a silica basin; the weight thus found is added to that of the residue in the tube. The addition of nitrobenzene causes more rapid solution of the rubber.—W. P. S.

Rubber products; Determination of mineral matter in — J. P. Périgrin. Ann. Chim. Analyt., 1917, 22, 27—29.

THE results obtained by the direct incineration of rubber being inaccurate, owing to the losses of zinc, antimony, lead, etc. incurred, the use of anisole as a solvent for the organic constituents is recommended. 1—2 grms. of the rubber (raspings) is digested with 50—100 grms. of anisole at 100° C. for 6 hrs. or until the rubber ceases to swell; a large excess of pure benzene is then added, and the mixture allowed to stand for several days, after which the mineral matter is readily separated by centrifugal means.

—W. E. F. P.

Diphenylbutadiene. Johlin. See XX.

PATENTS.

Vulcanising plastics [rubber]; Process of — C. J. Rendall, Naugatuck, Conn. Assignor to Boston Rubber Shoe Co. U.S. Pat. 1,213,905, Jan. 30, 1917. Date of appl., May 13, 1915.

RUBBER, or similar material, is partially vulcanised in contact with air heated to vulcanising temperature, and at a pressure sufficient to prevent blowing. It is then allowed to cool, also under air pressure, and vulcanisation is afterwards completed in contact with wet steam at vulcanising temperature and pressure.—E. W. L.

XV.—LEATHER; BONE; HORN; GLUE.

Tanning materials from British Malaya. Ch. of Comm. J., Mar., 1917.

THE total value of gambier imports (in bales) into the Straits Settlements from the Malay States,

British North Borneo, and Netherlands India was £208,060 in 1913, £170,231 in 1911, £293,317 in 1915, £251,874 in 1916 (nine months). The values of the exports were £211,535 in 1913, £198,101 in 1911, £300,261 in 1915, and £267,187 in 1916 (nine months); the greater part of the exports went to the United Kingdom, United States, and France. Exports of cube gambier were valued at £165,031 in 1913, £150,723 in 1911, £153,131 in 1915, and £158,368 in 1916 (nine months); the largest consumer is British India, where it is used, as in Malaya, for chewing. In Europe, America, Australia, and South Africa, it is largely used for tanning. Cutch is imported into the Straits Settlements from Brunei and Sarawak, and is then re-exported, the value of the exports having been £10,638 in 1913, £37,918 in 1914, £16,935 in 1915, and £21,370 in 1916 (nine months); before the war Germany was the largest consumer, but recently increasing quantities have been sent to Great Britain.

PATENTS.

Gelatinising substances: Methods for finely dividing —, Akt.-Ges. für Chem. Prod. vorm. H. Scheidemandel, Assignees of E. Sahn, Berlin, Eng. Pat. 100,073, Feb. 10, 1916. (Under Int. Conv., Feb. 10, 1915. (Appl. No. 2016 of 1916.) Addition to Eng. Pat. 15,365 of 1915.

SEE U.S. Pat. 1,195,099 of 1916; this J., 1916, 1029. The liquid into which the gelatinising substance is introduced, consists of machine oil having a viscosity of 6 (Engler) at 50° C.

Manufacturing colloids. U.S. Pat. 1,211,299. See I.

XVI.—SOILS; FERTILISERS.

Acid soils: Investigations on the acidity of —, S. Osugi and T. Uetsuki, Ber. Ohara Inst. Landw. Forschungen, 1916, 1, 27—52.

Two 100-gram. portions of a soil were treated respectively with 400 c.c. of $N/10$ potassium chloride solution and the same amount of $N/10$ solution of potassium acetate. After standing for two days, with frequent agitation, the clear liquids were boiled, and the acidity determined by titrating with $N/10$ sodium hydroxide; the silicic acid and alumina-contents were also determined. It was found that the alumina in the filtrate from the potassium chloride extract was 10—20 times greater than that in the filtrate from the acetate extraction, but the acidity of the former was only $\frac{1}{2}$ — $\frac{1}{3}$ that of the latter. Various acid soils were then treated similarly and the filtrates analysed, with the result that the soils were shown to exert a selective capacity for adsorbing bases, and that the amount of bases adsorbed was equivalent to the sum of the exchanged bases and the acid liberated. Investigations of a soil in various stages of disintegration, taken from an orchard of the Ohara Institute, and including the mother rock—a quartzitic diorite, and its end-product—a red clay, showed that the percentage of bases diminished with increased weathering, and that the acidity, the loss on ignition, and the adsorptive capacity increased correspondingly. Similar experiments on artificially prepared hydrated aluminium silicates showed that their degree of acidity was closely related to the amount of base they contained.

When a soil undergoes active weathering, basic constituents are strongly adsorbed by the colloidal substances set free, and when such soils are treated with a salt solution, free acid is produced. Since the aluminium compounds present in a soil are attacked and dissolved much more readily by dilute hydrochloric than by dilute acetic acid, it is obvious that the potassium chloride extract of a soil will contain more dissolved alumina than an extract made with potassium acetate. An acid soil is to be regarded as a soil deficient in basic constituents.—E. H. T.

Plants: The injurious and stimulating actions of acids upon —, I. Onodera, Ber. Ohara Inst. Landw. Forschungen, 1916, 4, 53—110.

THE existence of free inorganic acids in soils is probably due to over-application of inorganic fertilisers, and the presence of organic acids to excessive dressings of organic manures. In investigating the influence of acids upon the germination of barley, rice, and red clover, the seeds were sorted with sodium chloride solution (sp. gr. 1.1), thoroughly washed, air-dried, and then planted in purified moist sea-sand contained in Petri dishes, to which the solution of acid was also added. The dishes were kept nearly covered and the moisture content was maintained constant. The experiments were performed in duplicate, the number of germinated seeds was counted daily for 11 days, and in some cases the lengths of the sprouts were measured. The acids used were formic, acetic, lactic, sulphuric, hydrochloric, and nitric, in concentrations varying from $N/33$ to $N/500$. Formic acid stimulated the germination of barley but not that of rice or red clover; in each case a concentration above $N/100$ proved injurious. Acetic acid much accelerated the growth of barley but hindered germination at above $N/50$. Rice responded less, and all concentrations lower than $N/71$ had the same effect; above that strength this acid retarded germination. Lactic acid did not stimulate red clover seeds, and solutions stronger than $N/83$ proved harmful to the sprouts. In solutions stronger than $N/100$, the mineral acids adversely affected the plants. Sulphuric acid in all concentrations used retarded the germination of barley and red clover, but accelerated that of rice up to the sixth day. Nitric acid weaker than $N/100$ markedly stimulated both germination and growth. By weighing the clover plants at the end of the experiments, it was found that the average effect of the three mineral acids was about the same as that of the three organic acids. The effect of acids upon the growth of young barley, rice, soya bean, rye, bean (*Phaseolus vulg.*, L.), and radish plants was investigated in water cultures containing 0.125% of Sach's solution, of acidity $N/2880$, the growth being under observation for 12 days. The concentrations above which harmful effects ensued varied considerably. Thus for lactic acid and rice it was $N/125$, and for the same acid on rye, beans, and radishes $N/1500$. For the mineral acids the maximum concentrations were $N/250$ for rice and $N/500$ for barley. In general, plant growth was considerably stimulated by moderately concentrated acids, and in particular by nitric acid (used in the form of urea nitrate) containing 0.05 gram. per litre. The latter fact, taken in conjunction with the favourable stimulating action on germination, should prove of great importance in manuring. The order of toxicity of the acids investigated was: hydrochloric (greatest), sulphuric, formic, butyric, acetic, nitric, and lactic. Plants grown in an acid culture develop abnormally in height, their root development is quickly arrested, but the growth of the foliage is continuous.—E. H. T.

Acid phosphate and raw rock phosphate: Relative availability of— in Indiana field tests. S. D. Conner. J. Ind. Eng. Chem., 1917, 9, 154—155.

FIELD tests with various crops (maize, wheat, hay, potatoes) showed that the use of acid phosphate as a fertiliser yielded far better results than were obtained by the use of raw rock phosphate: soils treated with the latter, however, yielded better crops than did the untreated soil.—W. P. S.

Polash; Banana stalks as a source of—. H. E. Billings and A. W. Christie. J. Ind. Eng. Chem., 1917, 9, 153—154.

DRIED banana stalks contain 16.46% of potash (K₂O) and, as a fertiliser, compare favourably with dried kelp. When charred and leached, 1 ton of the dried stalks yields 27 lb. of 90% potassium carbonate. (See also Ellis, this J., 1916, 456.)
—W. P. S.

Oranges: Effect of fertilisers on the composition and quality of—. H. D. Young. J. Agric. Res., 1917, 8, 127—138.

NEITHER potash nor phosphate exerted any effect on oranges grown at the Californian University Citrus Experimental Station. The application of nitrogenous manures gave coarser fruit with a little less juice and a slightly lower sugar content, and this result was the same whether the nitrogenous fertiliser was applied alone or in conjunction with potash or phosphate, or with both. In every case where nitrogen was applied, the fruit contained an increased percentage of that element.
—E. H. T.

Field trials; Experimental error in—. C. Miyake. Ber. Ohara Inst. Landw. Forschungen, 1916, 1, 111—121.

THE magnitude of the experimental error involved in estimating a crop of barley, and a rice crop, at Morioka (Japan) was determined by subdividing each field into one hundred small unit plots ($\frac{1}{100}$ th acre), and harvesting the grain on combinations of 3, 5, and 10 units selected in different ways. The standard deviation decreased as the number of combined units was increased, and it was always smaller when the units were chosen at random than when adjacent units were selected. The probable error for the barley was $\pm 3.3\%$, and for the rice $\pm 1.8\%$. For English crops and unit plots of $\frac{1}{100}$ th acre, Hall and Russell recorded $\pm 5\%$. In estimating the total yield of a field crop by this method of partial harvesting, it is advisable to use various methods of sampling. Of the six methods employed, the "scattering" and the "diagonal" gave the best results. In the former, ten plants were taken from each of ten small unit plots situated in different parts of the field; in the latter, two ropes were stretched diagonally across the field and the plants growing nearest to them were selected.—E. H. T.

Possible partial substitution of nitre cake for sulphuric acid in the manufacture of sulphate of ammonia. Parrish. See VII.

PATENTS.

Fish meal and the like; Manufacture of—. W. West, Grimsby, Lincoln. Eng. Pat. 103,493. Jan. 17, 1916. (Appl. No. 746 of 1916.)

FISH offal, for the production of fish meal, is treated in the inner receptacle of a double-walled vessel, steam being passed into the annular space through inlets in the outer wall, and thence to the material through perforations in the inner vessel.

Steam may also be supplied from a perforated pipe, extending substantially the whole length of the double-walled vessel.—B. N.

Potassium [salts]; Process of extracting— from minerals. H. Blumenberg, Los Angeles, Cal., Assignor to E. B. Mapel, New York. U.S. Pat. 1,214,003, Jan. 30, 1917. Date of appl., Apr. 3, 1916.

A REFRACTORY mineral containing potassium, such as feldspar, is powdered, mixed with an equal quantity of powdered sodium nitrate or an alkaline-earth nitrate, and heated to 1200°—1500° F. (650°—815° C.) in a closed chamber till the liberation of oxides of nitrogen ceases. The fused mass is ground, treated with sulphuric acid, the solution filtered off, and the potassium sulphate separated from other salts by crystallisation. The potassium in the mineral is thus rendered available as a commercial fertiliser.—W. F. F.

Manure or fertiliser; Manufacture of an artificial—. A. Messerschmitt, Stolberg, Germany. U.S. Pat. 1,214,346, Jan. 30, 1917. Date of appl., Oct. 25, 1916.

POTASSIUM minerals, e.g., silicates, mixed with phosphates and a basic substance, are calcined, and then treated with a hot concentrated solution of calcium nitrate.—B. N.

XVII.—SUGARS; STARCHES; GUMS.

Levulose; Determination of— in presence of dextrose. L. Loewe. Proc. Soc. Exper. Biol. and Med., New York, 1916, 13, 71—72. J. Chem. Soc., 1917, 112, ii. 49.

THE method depends on the yellow coloration developed after boiling and addition of a 0.2% solution of orcein and an 85% solution of phosphoric acid; the yellow colour becomes orange on addition of alkali. The test is made quantitative by colorimetric comparison with a standard levulose solution treated with the reagents. Levulose was detected in 1 c.c. of a 0.05% solution. Sucrose interferes, owing to hydrolysis by the acid.

d-Glucose [dextrose]; Studies on the forms of— and their mutarotation. C. S. Hudson and J. K. Dale. J. Amer. Chem. Soc., 1917, 39, 320—328.

FOR the purpose of studying the mutarotation coefficient of glucose, pure α - and β -glucose were prepared in quantity by the following method. "Corn sugar," prepared by the acid hydrolysis of corn (maize) starch, was dissolved in five times its weight of water, decolorised with decolorising carbon, and evaporated *in vacuo* to a syrup, containing 70—75% of solids, and to this an equal weight of glacial acetic acid was added. Crystallisation soon commenced and was complete in a few hours, giving a yield of 60—70% of pure glucose after drying in a vacuum at 50° C. From this purified glucose β -glucose was obtained by dissolving 500 grms. in 50 c.c. of water and adding 600 c.c. of hot glacial acetic acid, with stirring. Crystallisation commenced in the hot liquid and the crystals, filtered off with the aid of suction, consisted of 93% β -glucose. By recrystallising twice from concentrated (1 in 1) ice-cold aqueous solution, with the addition of alcohol, a pure product was obtained having an initial rotation of +19.0°. α -Glucose is the predominating form when crystallisation occurs slowly at ordinary temperature from somewhat dilute acetic acid. Thus the addition of 1000 c.c. of glacial acetic acid to a solution of 500 grms. of glucose in 250 c.c. of water gave, after washing with alcohol, a pure α -glucose which had an initial rotation of -110° .

Syrups for canning and preserving. J. B. McNair. J. Ind. Eng. Chem., 1917, 9, 151—153.

TABLES are given showing galls, of water or oz. of sugar per gall, of syrup required to change a syrup from a given degree Brix to another given degree Brix at 17° C., and for similar changes in the sp.gr. of the syrup. The tables are calculated from the empirical formula: $y = 1.4x + 0.002512x^3$, where x = degrees Brix of syrup and y = the oz. of sugar added per gall. of water at 17° C. (See also this J., 1916, 701.)—W. P. S.

Double salts formed by sodium and potassium carbonates. Bain and Oliver. See VII.

PATENT

Maltose and process of making the same. F. J. Hemig, Assignor to Crown Maltose Co., Chicago, Ill. U.S. Pat. 1,214,160, Jan. 30, 1917. Date of appl., Feb. 12, 1915.

STARCH in solution is subjected to the action of diastatic enzymes, the solution is then sprayed into a drying atmosphere, and the resulting dry substance, consisting of spheroidal particles containing more than 90% of reducing sugars, calculated as maltose, is collected.—W. P. S.

XVIII.—FERMENTATION INDUSTRIES.

Wine: Microanalysis of— M. Ripper and F. Wohack. Z. landw. Versuchs-Wesen, Oesterr., 1916, 19, 372—381. J. Chem. Soc., 1917, 112, ii., 106.

WOHACK'S method of estimating glycerol in wine (this J., 1915, 974) has been modified to render it suitable for micro-analysis. 0.5 c.c. of wine which has been evaporated to half its original volume and treated with barium acetate and tannin (100 c.c. of wine, 10 c.c. of 10% barium acetate solution, and as much tannin as can be placed on the point of a knife) is brought into a decomposition flask and treated with 1.5 c.c. of hydriodic acid (sp. gr. 1.96). The decomposition vessel is a quartz or glass tube filled with platinised quartz or platinised asbestos, and is shielded from direct contact with the flame by asbestos paper and iron gauze. The rest of the process is the same as that previously described. The complete process, including evaporation of the wine, occupies 1½ hrs., and gives very accurate results with a minimum expenditure of time, labour, and cost.

Cider vinegar: Volatile reducing substance in— R. W. Balcorn. J. Amer. Chem. Soc., 1917, 39, 309—315.

THE volatile reducing substance present in the distillate from cider vinegar consists largely, if not wholly, of acetyl-methyl-carbinol, $\text{CH}_3\text{CH}(\text{OH})\text{CO}\cdot\text{CH}_3$, which is shown to be a normal constituent of cider vinegar. From the distillate diacetylphenylsazone was prepared and identified, but that it originated from the carbinol and not from diacetyl was proved by the fact that dilute solutions of the latter were yellow in colour, had no reducing properties, and gave a quantitative yield of the dioxime, whereas the vinegar distillate was colourless and gave no dioxime.—G. F. M.

Cream of tartar: Manufacture of— in South Australia. W. A. Hargreaves. S. Aust. Dept. of Chem., Bull. No. 3, 1916, 1—12.

THE imports into the Commonwealth of Australia for the year 1913 amounted to 2101 tons of cream of tartar and 180 tons of tartaric acid, of which

S. Australia took 190 tons and 65 tons respectively. The average value of cream of tartar works out at £87 and of tartaric acid at £120 per ton. The average annual production of wine in S. Australia is close on 3 million gallons, of which just about one-half is distilled for spirits, at a stage too early for the deposition of any quantity of argol. It is estimated that during storage in casks for two years, 1—6 lb. of argol separates per 1000 galls. of wine, so that from the wine which is not distilled 2½—2¼ tons of cream of tartar should be available per annum, on the basis of a 70% yield from the argol. A very much larger quantity is obtainable from the lees, in which cream of tartar amounts to about 30% of the dry substance. The quantity of wet lees per 1000 gallons of wine varies within wide limits according to circumstances; a conservative estimate gives 6000 galls. of thick lees from 250,000 of wine; the thick lees contains 2.35 lb. of dry solids per gall. One and a half million gallons of wine should therefore yield 11¼ tons of cream of tartar, and it should be possible to obtain a further similar amount from the wine used for distillation, by separating the lees for treatment. The recovery of cream of tartar from the grape marc has not received detailed attention, but if the mares contain about 3% of the salt, there should be a still larger supply, possibly up to 100 tons, available from this source. Cream of tartar may be prepared from argol by treating the material with sodium carbonate, extracting the readily soluble sodium potassium tartrate, and decolorising the solution with animal charcoal, then liberating the acid potassium tartrate by sulphuric acid. For the treatment of the lees, Rasch's neutral process is quite satisfactory. The material is roasted at about 150° C. to decompose the proteins and colouring matters, so that a clear filtrate may be obtained on extraction. The residue is extracted with hot water or mother liquor so as to yield a 6% solution, from which the tartar is crystallised on cooling and then decolorised and purified by recrystallisation. For the treatment of mares, the alcohol may first be recovered in specially adapted stills and the tartar crystallised gradually in shallow wooden vessels from the distillation residue.—J. F. B.

Utilisation of ammonium chloride by yeast. Hoffman. See XIXA.

XIXA.—FOODS.

Yeast [bakers']; Utilisation of ammonium chloride [as food] by— C. H. Hoffman. J. Ind. Eng. Chem., 1917, 9, 148—151.

FURTHER experiments on the use of ammonium chloride as a yeast food (see this J., 1916, 1030) show that, during the progress of fermentation of dough, the ammonium chloride is utilised by the yeast and is converted into yeast-protein. This is confirmed by the fact that the ammonium salt disappears most rapidly between the third and fifth hours of the fermentation, and also by the fact that ammonia cannot be recovered from the fully fermented bread. That there is no increased gas production when yeast is grown in a sucrose solution containing ammonium chloride, whilst a large increase occurs when the salt is added to dough (which contains the necessary substances for yeast production), indicates that the ammonium chloride is a yeast food and not a mere enzyme stimulant. The disappearance of the ammonium chloride cannot be attributed to enzymes of the flour or to bacterial action, for in a dough made of flour, water, salt, sugar, and

ammonium chloride, to which no yeast was added, the amounts of ammonia recoverable at the time of mixing and after 5 hours were identical.—W.P.S.

Proteins ; Adsorption of tin by — and its relation to the solution of tin by canned foods. B. C. Goss. J. Ind. Eng. Chem., 1917, 9, 144—148.

THE solution of tin by canned foods is not dependent on, or proportional to, the acidity alone, and, in the case of foods of relatively slight acidity which dissolve large amounts of tin, the greater part of the tin is in the form of an insoluble and stable complex. The tin after being dissolved from the lining is removed from solution by the proteins, carbohydrates, etc., present. Whether this is due to adsorption of tin ions or to hydrolysis of the tin salts with subsequent adsorption of the stannous hydroxide, in either case the acid is regenerated and able to dissolve more tin. The former explanation seems to be the more probable, since tin is taken up equally well by proteins even from concentrated acid solutions. The reaction differs, however, from a true adsorption in that it is not reversible. It appears, from the results of artificial digestion experiments, that the greater part of the tin is so firmly adsorbed in the food that it will be eliminated directly in the digestive processes and will not exert the characteristic physiological action of soluble tin salts.

Alimentary pastes ; Drying machine for —. A. Tegoli, Assignor to Tegoli Drying Apparatus Manufacturing Co., Ltd., Santa Rosa, Cal. U.S. Pat. 1,214,239, Jan. 30, 1917. Date of appl., May 24, 1916.

A DRYING chamber is provided with air-circulating

chambers at either end. A fan circulates the air through the drying chamber and circulating chambers, and an air passage connecting the two circulating chambers extends over the top of the drying chamber, means being provided for regulating the flow of air from this passage into the drying chamber. Fresh air is admitted to one of the circulating chambers, whilst the other is fitted with an outlet.—W. P. S.

XIXB.—WATER PURIFICATION ; SANITATION.

Mines ; Black damp in —. G. A. Burrell, I. W. Robertson, and G. G. Oberfell, Bureau of Mines. Bull. 105, 1916. 88 pages.

"BLACK DAMP" is best defined as an accumulation of carbon dioxide and nitrogen in excess of the percentage found in pure atmospheric air. Changes in mine air are dependent on the velocity of the air in the mine passages, the amount of coal with which it comes in contact, the amount of methane given off by the seam, the extent to which the coal reacts with oxygen, and the temperature and moisture content of the mine air. Men are able to work for a long time in an atmosphere containing 3—4 % of carbon dioxide, but with less efficiency, and fatigue occurs sooner. Even 1—2 % of the gas diminishes efficiency. Rapid breathing is produced more quickly by an excess of carbon dioxide than by a corresponding deficiency in oxygen, and when due to the latter cause points to serious danger. The susceptibility of mice and canaries to an atmosphere poor in oxygen is about the same as that of men ; they cannot therefore be used to give warning of such atmospheres to exploring parties. The chief cause of the depletion of oxygen and increase of carbon dioxide in mine air is the reaction between the oxygen and the coal, as a result of which some of the oxygen is occluded in the coal, some is converted to water and carbon dioxide (the amount of this last is never equivalent to the oxygen absorbed), while the larger part is retained in combination, possibly with unsaturated constituents of the coal. Explosive mixtures of methane and air become non-explosive when the oxygen in the atmosphere falls below about 11 %. Carbon dioxide has only a slightly greater effect than nitrogen in reducing the explosibility of methane-air mixtures. In 111 samples of mine air collected from 29 mines, the percentage of black damp varied from 0.14 to 82.92 %, and the average percentage of carbon dioxide in the black damp was 11.5 and of nitrogen 89.5 %. A large number of analyses are given in order to show how the composition of mine air changes in traversing the workings. Black damp containing methane may be lighter than air. Details are given regarding the percentage of oxygen necessary to support the combustion of various flames in presence of varying amounts of nitrogen or carbon dioxide. The paper includes a bibliography and numerous references in the text and also deals with the atmospheric conditions in certain metal mines and their relation to the presence of decaying timber, etc.—F. C.

XX.—ORGANIC PRODUCTS; MEDICINAL SUBSTANCES; ESSENTIAL OILS.

Eucalyptus Australiana; *Essential oil of* ——. R. T. Baker and H. G. Smith. Proc. Roy. Soc., N.S. Wales, 1916, 49, 511. Perf. Essent. Oil Rec., 1917, 8, 50. (See also this J., 1916, 978.)

THE average working yield of oil is from 2.5% in June to 5.4% in October, from the green leaves and terminal shoots. The crude oil from an experimental complete distillation showed:—sp. gr. 0.9157 at 15° C.; n_D^{20} 1.4614; solubility 1:1.2 in 70% alcohol. It contained 70% of cineol and a little piperitone, to which the peppermint odour of the leaves is due. Samples of oil distilled in the first hour contained from 69.5 to 81% of cineol; a sample of the "second hour" oil contained only 20%. The oil distilled in the third hour was very small in quantity and also contained 20% of cineol. J. F. B.

α -Pinene; *Isomerisation, polymerisation, and formation of additive products of* ——. H. J. Prins. Chem. Weekblad, 1916, 13, 1264—1276. J. Chem. Soc., 1917, 112, i, 90.

ON warming a solution of levorotatory α -pinene in glacial acetic acid at 60°–70° C. with 5% of phosphoric acid (sp. gr. 1.7), *l*-limonene is formed, with development of heat. Strong mineral acids, and aluminium, ferric, and zinc chlorides convert α -pinene into a product resembling colophony. α -Pinene combines with water, alcohol, and organic acids, forming alcoholic derivatives of the borneol or terpineol type.

Sabinols; *Isomeric* ——. V. Paolini and G. Rehora. Atti R. Acad. Lincei, 1916, [v], 25, ii, 377–381. J. Chem. Soc., 1917, 112, i, 90.

DISCORDANT values have been given by different investigators for the physical constants of sabinol, but no attempt seems to have been made to separate stereoisomeric modifications. The authors have prepared from savin oil a sabinol hydrogen phthalate, $\text{CO}_2\text{H}\cdot\text{C}_6\text{H}_4\cdot\text{CO}_2\cdot\text{C}_{10}\text{H}_{15}$, which recrystallises in tufts of white, silky needles, m. pt. 95° C., $[\alpha]_D^{20} = -14.63'$ (in methyl alcohol). Hydrolysis of this ester yields sabinol, b. pt. 208° C., sp. gr. at 15° C., 0.9518, $n_D^{20} = 1.4895$, $[\alpha]_D^{20} = +7.56'$, and treatment of the sabinol with phthalic anhydride yields solely the hydrogen phthalate just described. These two compounds appear to be definite chemical individuals. That savin oil contains no other isomeric sabinol has been shown in the following manner. The uncrystallisable syrup obtained after removal of the solvent from the mother liquors of the hydrogen phthalate was converted into the strychnine salt, which, when crystallised several times and hydrolysed with cold, dilute hydrochloric acid, gave only the acid phthalate described above. Strychnine sabinol phthalate, $\text{C}_{30}\text{H}_{46}\text{O}_6\text{N}_2$, crystallises in shining, white needles, m. pt. 200°–201° C.

Diphenylbutadiene. J. M. Joldin. J. Amer. Chem. Soc., 1917, 39, 291–293.

THE hydrocarbon, $\text{C}_{16}\text{H}_{14}$, m. pt. 49° C., obtained by the dehydration of acetophenone-pinacene with acetic anhydride, is regarded with certainty as diphenylbutadiene although no characteristic derivatives could be obtained with bromine. The substance readily polymerises with the formation

of viscous resins. Acetophenone-pinacene was conveniently prepared by the action of magnesium methyl iodide on benzil in ethereal solution.

—G. F. M.

Benzaldehyde; *Determination of chlorine in synthetic* ——. M. S. Salamon. Perf. and Essent. Oil Rec., 1917, 8, 41–42.

THE following simple technical method gives satisfactory results, only very slightly lower than the values obtained by the Carius method:—About 1 gm. of the benzaldehyde is heated in a retort with 10 c.c. of concentrated sulphuric acid and 5 c.c. of strong nitric acid. The heating must be very gradual, and the mixture should not be allowed to froth until the end of the operation. The fumes are collected in a solution of silver nitrate and heating is continued until no farther precipitate is produced, which will require somewhat less than three hours. The silver solution is then acidified with nitric acid, boiled to decompose any sulphite, and the chloride is determined in the usual way.—J. F. B.

Vanillin; *Qualitative test and colorimetric method for the determination of* ——. C. Estes. J. Ind. Eng. Chem., 1917, 9, 142–144.

WHEN vanillin is heated with acid mercuric nitrate solution, a violet coloration is produced which is characteristic of vanillin, and the intensity of the coloration is directly proportional to the quantity of this substance present. In the case of alcoholic vanilla extracts, 5 c.c. of the sample is placed in a 50 c.c. flask, 6 c.c. of water and 1.5 c.c. of the reagent (see below) are added, the flask is placed in boiling water for 20 mins., then cooled rapidly, its contents diluted to 50 c.c., and the coloration obtained compared with that given by a known quantity of vanillin under the same conditions. The procedure is the same for non-alcoholic extracts except that only 1 c.c. of the reagent is required. The acid mercuric nitrate solution is prepared by dissolving mercury in twice its weight of nitric acid (sp. gr. 1.42) and diluting the solution with 25 times its weight of water. The results obtained agree with those found by the gravimetric method.—W. P. S.

Adrenalin solutions; *Physiological and chemical evaluation of the activity of* ——. J. S. White. Pharm. J., 1917, 98, 159–160.

ADRENALIN solutions gradually deteriorate owing to oxidation, advancing decomposition being indicated by the solution becoming first pink, then red, and finally brown. In the pink solutions the loss of activity is too small to be determined by physiological tests, but red solutions show a measurable loss of activity, and brown solutions are unfit for use. The addition of sulphurous acid to adrenalin solutions masks these colour changes but in no way retards oxidation. Adrenalin preparations are best standardised by determining the transitory rise in blood pressure after intravenous injections of known amounts. The pink coloration obtained by heating a dilute solution of adrenalin with potassium iodate and hydrochloric acid is extremely sensitive and permanent and is proportional to the amount of adrenalin present. 5 c.c. of a 1:50,000 solution of pure adrenalin with 5 c.c. of dilute hydrochloric acid (2.5 c.c. of $N/10$ HCl in 100 c.c.) and 5 c.c. of 0.2% solution of potassium iodate, on heating almost to boiling point and allowing to stand 15 minutes, gives a coloration which can be exactly matched by mixing 1 part of a 2% solution of potassium-platinic chloride in dilute hydrochloric acid with 3 parts of a 1.2% solution of cobalt chloride in dilute hydrochloric acid, and then suitably diluting,

and this standard can then be employed to standardise solutions of adrenalin colorimetrically. Results obtained by the colorimetric method are only comparative and may differ widely from results of physiological tests.—T. C.

Antipyrine: Determination of — M. François. J. Pharm. Chim., 1917, 15, 97—105.

THE gravimetric method for the determination of antipyrine as iodoantipyrine gives less accurate results than the volumetric method, which consists in titrating an alcoholic solution of antipyrine containing mercuric chloride with an alcoholic solution of iodine until a permanent yellow colour is obtained, one molecule of antipyrine under these conditions absorbing two atoms of iodine. The alcoholic solution of iodine, which rapidly loses strength on keeping, is best standardised against an alcoholic solution of pure antipyrine.—T. C.

β -Hydroxybutyric acid: Gravimetric determination of — D. D. Van Slyke. Proc. Soc. Exp. Med., New York, 1916, 13, 131. J. Chem. Soc., 1917, 112, ii., 107.

IF 175 c.c. of a β -hydroxybutyric acid solution containing 9% of sulphuric acid, 2% of mercuric sulphate, and 0.25 grm. of potassium bichromate is boiled under a reflux condenser for one hour, 7.7 mgrms. of the acetone compound of mercuric sulphate is precipitated for each mgrm. of β -hydroxybutyric acid present. The acid may vary from 1 to 9 mgrms. without affecting the ratio if the concentrations of the other reagents are kept constant.

Identification of phenols. Reid. See III.

PATENTS.

α -Dimethyl- γ -piperidines, substituted in the α -position, including their N-methyl derivatives: Manufacture of — H. M. Judd and G. A. R. Kon, London. Eng. Pat. 103,541, Feb. 5, 1916. (Appl. No. 1768 of 1916.)

BY using sodium in amyl alcohol instead of sodium or aluminium amalgam for reducing the corresponding γ -piperidones, the resulting piperidine derivative is almost entirely the physiologically active isomer instead of a mixture of two isomers. A better yield is obtained and the trouble of isomerising the mixture is saved. Details are given of the reduction of vinylacetoneamine (aaa-trimethylpiperidone).—B. V. S.

Formaldehyde: Manufacture of — G. Calvert. London. U.S. Pat. 1,213,740, Jan. 23, 1917. Date of appl., Dec. 24, 1915.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

Half-tone process: Experiments on the — A. J. Bull, W. J. Smith, and E. L. Turner. Phot. J., 1917, 57, 8—11.

THE effects of variations in different parts of the

process of production of a half-tone print were examined. In one set of experiments a step-print on glossy bromide paper was used as subject and the reproductions were compared with it, measurements being made in a specially designed photometer and results plotted in percentages of reflected light. The number of variables is so great and some of them so difficult of exact control that in most cases a number of negatives were prepared and an average one selected for the preparation of the half-tone block. The effect of variations in the shape of the stop, of relative aperture of lens, of lead ferricyanide and copper-silver methods of intensification, "flashing" (exposure to white paper), and variations in the screen distance, were all tested, but in no case were more marked differences obtained than might be due to variations in wet collodion plates. In the second set of experiments, a carbon step print was used as subject, the photometer was altered to suit its surface, and dry plates were used instead of wet ones. The general conclusions are that round and square stops give practically the same effect, that wet collodion plates and gelatin dry plates yield different gradations, that differences produced by variations of the stops are small, and that the type of dot formation and rendering of gradation are independent of magnification if the aperture ratio is kept constant.—B. V. S.

[Photographic] plate speeds. O. Bloch. Phot. J., 1917, 57, 51—61.

IN working out a standard method to examine the variation, if any, of plate speeds with different developers, several complications were met with which show that the H. and D. speed of a plate is not constant but varies with the conditions of exposure and development, the variations not being similar in all plates. Both intensity scale (wedge screen) and time scale (sector wheel) exposures were used; in the former case it was shown that there was no appreciable selective colour absorption of the wedge, and in the latter case the intermittency failure was avoided by using only single revolutions of the wheel, slow and uniform motion being given by a gramophone motor. It was found that for all plates, within certain exposure limits, and using developers to which bromide had been added, definite H. and D. speeds were obtained (depending partly on the developer) but only above certain limiting values of gamma, which are often quite high. With slightly restrained or unrestrained developers some plates (generally of the fast developing type) have definite speeds for all normal ranges of gamma, but the exposure conditions are still limited. With other plates, generally of the slow-developing, fast portrait type, the H. and D. speed is higher for short development for which there is no distinction between under and correct-exposure, the whole plate curve being practically a straight line; each gamma has its own inertia value which increases with gamma until the curve becomes normal; in some cases, however, this occurs only with higher gammas than would be obtained in normal use. The failure of the reciprocity law, for one emulsion examined, is not completely expressed by Schwarzschild's rule (for equal effects $I_1 t_1 = I_2 t_2$) a lower gamma being obtained for the same development where I is high and t short. The actual value of $\log i$ obtained in a measurement is therefore dependent on the composition of the developer, the γ obtained in development, the value of q , the nature of the exposure (time or intensity scale), and the actual values of time and intensity, as well as on the plate; there is also the possibility of the change of the plate with age. Results are given of comparisons on various plates of developers all to the same formula apart from the reducer.

made with metol-quinol, metol, quinol, pyro-soda, ortol, and glycin, the times of development being varied to suit the developer. With the same six reducers, on one plate, developing in each case to a γ of about 1, quinol and, in a more marked degree, glycin gave low H. and D. numbers, while the other four gave very nearly the same results. A method is given of determining the velocity constant of development (K) depending on a simple evaluation of D_x and the formula $K = \frac{1}{t} \log_e D_x = d$. It is suggested that a simpler method of marking plate speeds should be adopted, or that the manufacturers should agree to a standard method. B. V. S.

Latent image: The influence of time upon the

H. J. Channon. *Phot. J.*, 1917, 57, 72—81.

DETAILS are given of some of a large number of experiments started in 1891 with the object of ascertaining the effect of time on the latent image. In one set of experiments all the exposures were made together and subsequently developed at intervals of several years, and in another set the exposures were made at intervals of several years and then developed together. The chief effects are loss of density, particularly in the high densities, and general veil which appears to have the effect in some cases of a supplementary exposure in improving shadow detail. Both effects vary considerably with different makes of plate. Photoregression was noticed in two cases where the plates were already old at the time of exposure. Experiments were also made to determine the effect of air and moisture on photoregression and veil. B. V. S.

Dyes as sensitisers of carbon tissue and gum paper

H. Waago. *Amator-Fotografen*, Jan., 1917, 6. *J. Phot.*, Feb. 23, 1917, 96.

AN account is given of the work of A. A. Meisling (*Dansk Fotografisk Tidsskrift*, Nos. 9 and 10, 1916) on the hardening effect of various substances on gelatin, gum, etc., under the influence of light. In addition to chromium compounds, which are the chief agents used in the carbon and gum processes, the hardening effect is produced by other substances including Erythrosin, Auramine, and other aniline dyes. The hardening is attributed to the formation of formaldehyde. Erythrosin-sensitised papers may be prepared by soaking the carbon or pigment tissue for a few minutes in a solution of 1 part of the dye in 10,000 of water. Neither paper is sensitive when quite dry, but the gum paper needs only a little moisture and can be used in contact with the negative: the carbon paper requires to be quite damp and must be protected on both sides with celluloid during printing. Both papers are equal to the bi-chromate-sensitised tissues in speed to daylight, and faster to artificial light, and they also keep better.

B. V. S.

"Hypo" [sodium thiosulphate]; Removal of — from photographic plates by washing with water.

A. V. Elsdon. *Phot. J.*, 1917, 57, 90—94.

THE rate of removal of "hypo" from fixed plates was determined by fixing the plate in a known quantity of "hypo" solution, removing and draining, transferring to a definite quantity of water for a definite time, repeating this washing three times, and finally determining the amount of "hypo" removed from the plate each time and left in it after the last washing. It was found that there is no adsorption of the "hypo" the removal being in agreement with Ostwald's

equation $x_n = \left(\frac{a}{m+a} \right)^n x_0$ where x_0 and x_n represent the original and final amounts of "hypo" for

n washings, a the volume of solution left in the plate, and m the volume of each washing water, if the time in the washing water is long enough to ensure equilibrium between it and the solution in the film. At 60° F. (15.5 C.) equilibrium is nearly reached in 2 minutes and quite reached in 5 mins. With washing periods of 1 min. and draining periods of $\frac{1}{2}$ min. after each washing, the "hypo" was removed practically completely by 3 washings of 1 oz. each for a plate $3\frac{1}{2}$ in. \times 2 $\frac{1}{2}$ in. XXIII.—ANALYSIS.

Potassium: Determination of — as per chlorate. G. P. Baxter and M. Kobayashi. *J. Amer. Chem. Soc.*, 1917, 39, 249—252.

ALCOHOL containing 0.1% of perchloric acid is found to dissolve as little potassium perchlorate as any practicable mixture, though the salt is appreciably soluble even in that liquid. Absolute alcohol must be used, as the solubility of the perchlorate is fairly sensitive to the presence of small proportions of water in the alcohol. The recommendation of Davis (this J., 1912, 1045) to wash with a liquid already saturated with the salt is endorsed. With a solution saturated at 0° C. there is no danger of deposition of salt owing to change of temperature, and such a solution gives no precipitate when treated at 0° C. with a large amount of sodium perchlorate. In presence of sodium chloride some of the sodium salt is retained by the potassium perchlorate; the precipitate should, therefore, be re-dissolved and the solution again evaporated with perchloric acid. The precipitated potassium perchlorate is transferred, after washing by decantation, to a platinum-sponge crucible, dried at 200° C., and weighed. The washing liquid saturated with potassium perchlorate is prepared by dissolving a suitable proportion of the salt in the alcohol at a high temperature, before adding the perchloric acid.—T. H. B.

Sulphates of some divalent metals; Titration of — by the electric conductivity method. H. S. Harned. J. Amer. Chem. Soc., 1917, 39, 252—266.

In a titration of a solution of magnesium sulphate with standardised sodium hydroxide solution, the electric conductivity changes little, if at all, during the course of the reaction, but after an amount of sodium hydroxide equivalent to the magnesium sulphate has been added, the conductivity increases suddenly owing to the high mobility of the hydroxyl ion. A sharper end point is obtained if, instead of sodium hydroxide, a reagent is added which will precipitate both ions of magnesium sulphate from the solution; the conductivity then falls rapidly during the course of the reaction, and rises rapidly after the reaction is complete. Such a reagent is barium hydroxide, when the solution contains a sulphate of a metal which possesses a difficultly soluble hydroxide. In using barium hydroxide it is necessary to remove all carbon dioxide from the solution and to keep it free from carbon dioxide during the titration. This necessitates a special form of apparatus, in which the solution can be boiled under reduced pressure. The electrodes should remain stationary with regard to each other and in respect to their position in the solution. The titrating solution must be run into the cell without coming into contact with carbon dioxide. Diagrams are given of typical curves obtained from titration of various sulphates by plotting bridge wire readings against c.c. of barium hydroxide solution. The method can be used for the determination of magnesium in magnesium sulphate, in a solution containing magnesium sulphate, calcium sulphate, and sulphuric acid, and in dolomite. The sulphates of copper, nickel, and cobalt can also be titrated by this method, but the titration of cadmium sulphate did not give accurate results because of its strong tendency to form an oxysulphate which is difficultly soluble.—T. H. B.

Molybdenum; Determination of — by potassium iodate. G. S. Jamieson. J. Amer. Chem. Soc., 1917, 39, 246—249.

The molybdenum solution is reduced by passing through a tube containing 30-mesh amalgamated zinc, and received directly into a hydrochloric acid solution of iodine monochloride, and the molybdenum is estimated by titration with potassium iodate. The latter readily oxidises the molybdenum to Mo_2O_5 and a sharp end point is obtained when conversion into the pentoxide is complete. The iodine monochloride solution is prepared by dissolving 10 grms. of potassium iodide and 6.44 grms. of potassium iodate in 75 c.c. of water in a glass stoppered bottle, adding 75 c.c. of concentrated hydrochloric acid, then 5 c.c. of chloroform, and adjusting to a faint iodine colour by violent shaking, adding dilute solutions of iodide or iodate as required. Exposure of the zinc during the reduction causes no error in the titration, as would be the case if permanganate were used, because any hydrogen peroxide formed does not react with iodine monochloride or potassium iodate. After reduction the titration is effected rapidly at first, then slowly, with thorough shaking, until the chloroform indicator is decolorised. It is important to maintain not less than 10% of actual hydrochloric acid in the solution to prevent hydrolysis of the iodine monochloride during the titration, and to keep the solution thoroughly cooled and in a shaded place during the titration, especially if much molybdenum is present, to obtain a sharp end point. The equation involved is $\text{KIO}_3 + \text{Mo}_2\text{O}_3 + 2\text{HCl} = \text{Mo}_2\text{O}_5 + \text{I}_2 + \text{KCl} + \text{H}_2\text{O}$. Further oxidation to MoO_3 is very slow (2 to 3 days).—T. H. B.

Tin; Electroanalysis of — without platinum electrodes. T. Batuecas. Anal. Fis. Quim., 1916, 14, 495—511. J. Chem. Soc., 1917, 112, ii., 106.

GUZMAN'S method (this J., 1915, 1227) has been applied to the estimation of stannous and stannic tin in salts and of the metal in alloys, using a copper cathode and a graphite anode. Hydrochloric acid is employed as electrolyte in the analysis of tin salts, a mixture of hydrochloric and tartaric acids in the separation of tin from zinc and from cadmium, and an ammoniacal tartrate solution in the separation of tin from silver.

Ammonium phospho-molybdate precipitate; Occlusion of iron by the —. E. H. Archibald and H. B. Keegan. Trans. Roy. Soc. Canada, 1916, [iii.], 10, 67—68. J. Chem. Soc., 1917, 112, ii., 95.

THE factors which influence the occlusion of iron by ammonium phospho-molybdate have been examined. In the case of dilute solutions, the amount of occluded iron is independent of the quantity of iron in the solution, but in more concentrated solutions it increases with the quantity of dissolved iron. For solutions of the same iron concentration, the quantity of occluded iron increases somewhat more rapidly than the concentration of the phosphoric acid. The dilution of the solution has no appreciable influence on the amount of occluded iron when the quantities of iron and phosphoric acid remain the same. The iron is occluded at the time of precipitation, and is not removed by washing. It is suggested that a definite chemical compound is formed.

Trade Report.

Prohibited exports.

By an Order in Council, dated March 12th, exportation of the following is prohibited to all destinations:—Calcium carbide, potassium and sodium prussiates and mixtures containing them, sodium cyanide and mixtures containing it, raw cotton, uranium and its alloys and ores, oleaginous kernels, nuts, seeds, and products of all kinds, baking powder, malt extract.

Restricted occupations order.

THE Minister of Munitions has issued an Order, dated 28th February, ordering that the occupier of a factory, workshop, or other premises shall not, except as herein provided, take or transfer into employment in any industry or occupation mentioned in the Schedule, whether to fill a vacancy or otherwise, any man who has attained the age of 18 and has not attained the age of 61, whether the man has previously been so employed or not.

The occupier of any factory, workshop, or premises may, however, take or transfer men into his employment with the consent of the Director-General of National Service given on the ground that the employment is expedient for the purpose of executing a Government contract, or on the ground that the work on which the men are to be employed is of national importance, but subject in all cases to any conditions which the Director-General may impose: and an employer may take

back into his employment any man who has joined His Majesty's naval or military forces, on his retirement from those forces under proper authority, if the man is taken back in accordance with an undertaking given by the employer before the man joined.

Work which is directly or indirectly required for the purpose of any Government contract must be given priority over any other work in that industry or occupation.

The following are among the trades mentioned in the Schedule: Manufacture of bottles for beer, wines, spirits, and aerated waters; manufacture of bricks (other than firebricks) and tiles; manufacture of china and earthenware; glass beveling, engraving, silvering, and staining; papermaking; manufacture of wall paper; manufacture of linoleum, oil-cloth, and table baize; manufacture of aerated waters; brewing and malting; manufacture of sugar and chocolate confectionery; electro-plating; manufacture of photographic apparatus and materials.

Priority of work in certain industries.

ACCORDING to an Order of the Minister of Munitions, dated March 8th, the work in certain industries is to be divided into three classes, A, B, and C; work of class A must in all cases take priority over work in Class B or C, and work in Class B over work in Class C, irrespective of the date of the order. Class A comprises work under a Government contract, "certified war work," or merchant shipping work certified by the Board of Trade to be munitions work. Class B comprises the repair of existing industrial machinery where necessary to obtain continuity of work in the United Kingdom; the maintenance of reasonable stocks of materials or articles necessary as component parts of work or goods to be carried out or supplied under orders or contracts to be executed under Class A or B; and export orders and other contracts or orders certified by the Board of Trade, Admiralty, War Office, Ministry of Munitions, or Director-General of National Service, as of sufficient importance. Class C comprises all work not in Classes A or B.

The Order applies to all work carried on in establishments to which directions as to priority have already been given, also to all trades, and manufactures in or of metals and machinery, pottery and glass trades, textile trades and manufactures, linoleum, oilcloth, and table baize manufacture, the manufacture of coal tar products, dyestuffs, and other chemical products, and of lubricating oils and other lubricants, oil seed crushing, manufacture of soap, candles, fertilisers, paints, colours, varnishes, paper, leather, and coke, rubber trades and manufacture, waterproofing of fabrics and paper, and electricity, gas, and water services.

REPORTS OF THE PROGRESS OF APPLIED CHEMISTRY.

The first volume of these reports will be issued during this month. The manuscript of some of the sections not having come to hand, the volume will not be as comprehensive as was at first proposed, but it was decided to present an incomplete volume rather than delay publication any further.

CROSS AND BEVAN ESSAY PRIZE OF £20 AND LATHAM RESEARCH GRANT OF £300.

The Council have pleasure in announcing that a gift of £20 has been made by Messrs. Cross and Bevan as a prize for an essay on "The Interconnection of Economic Botany and Chemical Industry."

A further sum of £300 has also been presented by their friend, Mr. T. P. Latham, of Weybridge, to be paid in three annual instalments to such one of the competing essayists as may be judged to be of conspicuous ability, as a grant towards his expenses, on the condition that he apply himself, during three years, to research of approved character on a subject cognate with that discussed in his essay.

The immediate object of the donors is to promote the study of economic botany with special reference to its bearing on chemical industry, giving the widest possible interpretation of the relationship.

They desire, under the auspices of the Society, to assist in forming public opinion in this direction and to discover and further the career of a student of promise who may wish to devote himself to work in such a field.

The Essay Prize will be open to all members of the Society who are British subjects. The Research Grant will be limited to competitors under 25 years of age at the time of sending in the essay.

Essays are to be submitted to the Council of the Society not later than the close of the year 1917. The awards will be made promptly. Neither the prize nor the first grant will be given unless the essayist or essayists shall be deemed to have real merit. The Latham Research Student will be required to submit a report at the close of each year, to satisfy the Council that he has made and is likely to make proper use of the grant.

MR. S. B. CHADSEY IN THE CHAIR.

THE FUNCTION OF COLLOIDAL CHEMISTRY IN PAPER MAKING.

BY JUDSON A. DECEW, B.A.SC.

It is the object of this paper to point out some of those problems that are met with in the manufacture of pulp and paper, in which colloidal chemistry has an important function.

The cellulose materials of fibrous character from which paper is made are gel-forming colloids.

The only exception to this would be that paper which is made from asbestos, where crystalline material having a fibrous structure is felted into a continuous web, by paper-making processes. Even in this case, however, it is necessary to add colloidal material in order to obtain a satisfactory product.

The paper-making fibres proper consist of cellulose or ligno-cellulose, either natural or prepared. Cotton is the natural cellulose, but cellulose fibres may be produced from the various ligno-cellulose fibres, by eliminating the products of lignification.

The gel-forming properties of cellulose and its compounds are already well known from the extensive use in the arts of the solutions of nitro-cellulose, acetylcellulose, and cellulose xanthate (viscose). These products are the result of chemical treatments which eliminate entirely the fibrous structure in producing the colloidal solution. These processes have very little importance in paper-making, for there the colloidal properties required are developed by mechanical treatment, with but slight alteration in the fibre structure. Under grinding action the fibres may swell by the absorption of water until they have a greatly increased weight, the phenomenon being known as hydration.

For making many kinds of paper, fibres containing more or less water of hydration are required, for the colloidal properties of the fibre produce both transparency and increased strength in the product, and at the same time reduce the capillarity. In those kinds of papers where opacity or capillarity are desired, or where the rate of production is paramount, it is obvious that structure is the essential element and that hydration must be avoided. For illustration, book papers should have bulk and opacity. Blotting paper must have the maximum absorption or capillarity, and news paper must be made at the maximum speed. In such papers the fibres lie rather loosely upon each other, so that as a result the book paper has a soft feel and is not transparent, the blotting paper has a maximum of interstices, and the news paper has given up the water with which it was associated on the paper machine with the greatest of readiness. This is all due to the natural stiffness of fibres which may contain water to the point of saturation, but have not been swelled with water of hydration.

Those papers which have acquired special properties as a result of the development of the colloidal properties in the cellulose, such as grease-proof, writings, bonds, wrappings, etc., have greater density, hardness, rattle, translucency, and strength than those already mentioned as made from unhydrated material.

The greatest density and translucency are seen in the grease-proof or "glacine" papers. The voids in these papers have been filled by pressing tightly together in the manufacturing process the cellulose fibres which have been previously beaten until they have taken on a gel-like character. The density of these papers is such that they do not absorb oils, and they have become known as grease-proof papers. Writing and bond papers must be hard and fairly strong, and consequently the paper stock from which they are made must receive a considerable amount of hydrating beating treatment.

Wrapping papers vary considerably in character, but that which has the greatest strength and wrapping qualities, is the one which has been made from fibres that have been brought to a very colloidal state by long beating, without reducing

the length of fibre. Such paper is known in the trade as "brown" or "white kraft."

One kind of wrapping paper, known as "water finish," is made translucent by wetting the paper and crushing the fibres together by means of hot calender rolls. In this case the colloidal property of the cellulose is made evident by means of pressure alone. No increased strength, however, is obtained in this way such as results from the drying together of well hydrated fibres.

Methods of hydration. The usual method employed for making cellulose fibres more colloidal in character, is to mix, crush, or beat the fibres in cold water. The more drastic the grinding and crushing action, the more rapidly will the material become gel-like in character. This action may be accelerated by chemical means, as for instance by making the cellulose absorb a small amount of caustic alkali and then by treating with carbon bisulphide to obtain a thiocarbonate reaction. This does not dissolve the cellulose but develops a very hydrated condition in the product.

Some hydration takes place in cellulose fibres by mere contact with cold water, but the amount of hydration is limited and the time factor is long. The amount, however, is enough to cause trouble when a hydrated product is not desired. For instance, in the manufacture of news print paper, which is produced at the rate of over 600 ft. per minute, the extra amount of hydration obtained from allowing the wet pulp to be in the vats for 24 hours is sufficient to cause such sticking on the presses of the machine that considerable time and paper may be lost. This is why there is always difficulty in starting up fast machines on Monday morning, when the stock has been stagnant for 24 hours.

It has been found that lignocellulose fibre, such as jute or wood, does not gel so readily by cold mechanical treatment as does cellulose, but conversely to the cellulose, its hydration is accelerated by the application of heat. In the production of ground wood, it was soon found that the best results were obtained by just supplying enough water to the stone to carry the pulp away. As a result the friction of the grinding develops high temperatures at the grinding surface, which reduce the adhesion of the fibres, and a better product is then produced.

When wood which has been previously boiled or steamed is ground to pulp, the fibres are found to have a more pliable and hydrated character and they will make a stronger paper than that produced from untreated wood. The brownish colour of steamed ground wood suggests that some hydrolysing action had been the indirect cause of hydration.

Coating materials. Glue and casein are two well-known colloids which are used for binding white pigments on to the surface of papers known as coated papers. After being impregnated by these colloids, the dried papers are more resistant to the penetration of oils, and consequently they take clearer impressions from printing inks. These colloids are seldom used by mixing them in the wet paper stock, except in very small quantities where it is desired to increase the colloidal properties of other materials.

Fillers. Papers are often loaded with such fillers as China clay, talc, or other insoluble substances, in order to impart special properties such as opacity and a smooth surface.

It is desired in such cases that as much of the loading as possible be retained in the paper, and not carried away in the water draining from the paper machine wire. Some clays are more colloidal in character than others, but the colloidal properties may be developed in any clay by the use of a small amount of caustic soda. There is still some doubt as to whether this degree of dispersion is desirable or not, but it is probable that

the colloidal filler will give the best results if it is used in conjunction with the coagulants used for sizing the paper.

Sizing or waterproofing. To ensure that writing paper will resist the penetration of ink by capillary attraction of the fibres, and also to assist the ink to dry on the surface and thus give the line with proper depth of colour, the fibres are coated while in the heating engine with a water-repellant substance which will destroy their capillarity. The material which is universally used for this purpose is ordinary colophony rosin, and it is distributed throughout the paper-making material in the form of a colloid. In order to produce colloidal rosin it must first be brought into solution, the usual means being either a partial or complete saponification. The amount of saponification required will depend upon the means available for diluting the soap, without forcing any rosin from solution.

When ordinary means of dilution are employed, at least three-quarters of the rosin should be saponified, but there are means available for diluting a rosin soap, when but one-half of it is saponified, in such a manner that the unsaponified portion will remain in solution in a soap diluted to 50 or 100 times its volume. If this unsaponified rosin is not visible as suspensoids it must be in colloidal solution. If this product is now coagulated by means of a salt of aluminium, it will produce a highly colloidal precipitate of rosin and alumina. If this material has been deposited evenly over the paper fibres, it will destroy their capillarity and produce a resistance to the penetration of water and inks (sizing process). When rosin is in colloidal solution in a highly diluted soap, a portion of it can be taken up by the fibrous material by adsorption. The effect of rosin, deposited in this way, upon the capillarity of the fibres is very great, because its distribution will be perfect. The efficiency of the coagulated rosin will depend largely upon its bulk and degree of hydration, and we have in this an explanation of the fact that rosin in the form of coarse emulsions is ineffective for sizing purposes. It is obvious that a particle of rosin which has been floating in suspension, cannot be precipitated as a colloid.

The older methods of making and using rosin soap for waterproofing necessitate a more or less complete saponification of the rosin. From such solutions, even when greatly diluted, the fibres can adsorb but a small amount of rosin, and when the solutions are coagulated with aluminium sulphate, only about one-third of the rosin is thrown out of solution in the form of hydrated rosin acids, the rest being deposited in the form of aluminium resinate, which is often basic in character, and is but moderately efficient as a water repellent. From our knowledge of the properties of resins as compared with rosin itself, we would expect that a colloidal precipitate of rosin to hold its water of hydration more tenaciously than the colloidal resinate. If this is true then the colloidal rosin will withstand the drying action of the paper machine more effectively and will not crumble so easily by dehydration. The observed facts are very well explained on this basis.

In the past the literature on this problem has been quite confusing, because the subject has been considered entirely from the standpoint of chemical reactions, without any reference whatever to the physical state of the material.

Colloidal by-products in pulp making. *Sulphite waste.* In the production of cellulose from wood by the bisulphite process, about 60% of the wood becomes soluble, in the form of a sulphonie-lignone complex. This material is generally a waste product, but some uses have been developed for it based upon its colloidal properties. It is used as a binder in briquetting, in road-making

and in foundries in making cores. It has adhesive properties somewhat similar to those of dextrin, although it has not the same adhesive strength. If it could be bleached or decolorised, however, it would make an excellent substitute for other adhesives where only moderate strength is required. At the present time there is a great demand for this material in the concentrated liquid form or in the powder. The powdered product can be made by spraying the liquids into chambers with hot gases.

Black soda liquor. In the manufacture of cellulose from wood by the use of caustic soda, the lignin becomes dissolved in the form of sodium compounds. At the present time the organic matter is burnt off in incinerators, the alkali being recovered as carbonate and recausticised. If this organic waste is distilled instead of being calcined a fair amount of wood alcohol and acetone can be obtained from it. A distillation treatment, however, is very difficult to apply owing to the great viscosity of this colloidal mass, and most of the work in this direction up to the present time has not resulted in the establishment of a profitable process.

Losses from colloidal dispersion. In the manufacture of both chemical pulp and ground wood, there are certain mechanical losses due to the fact that some of the material has lost its original structure and exists as minute particles in the dispersion medium. In the straining or washing of the pulp this fine material will be largely carried away in the waste waters.

As regards mechanical pulp this is shown by the fact that the difference in yield between coarse and very fine grinding may be as much as 10%. The difference in yield of cellulose from the cooking processes, however, may be as much as 20% with varying treatments. When the cellulose itself is attacked by an excess of the chemicals or when these are improperly employed, a part of the cellulose may be dissolved and part lost as a structureless colloid.

In the mechanical process of making paper on a machine, there are always losses of colloidal and suspended matter in the water draining from the machine wire. It is to be hoped that means may yet be devised for recovering this material in an efficient and satisfactory manner, but its nature is such that it does not respond readily to either straining, filtration, or sedimentation systems.

A full appreciation of the physico-chemical problems involved in these various processes should aid materially in arriving at their proper operation and control, and if any of this discussion serves to make the art of paper-making a little more clearly understood the object of this paper will have been fully attained.

MR. JOHN GRAY IN THE CHAIR.

NOTES ON THE SPLITTING OF CASTOR OIL.

BY R. O. JONES.

As early as 1825 Chevreul and Gay-Lussac entrusted us with the key of the chemistry of fats and oils. The progress made since that time can scarcely be deemed satisfactory and a vast unexplored region undoubtedly still remains.

Within the last few years, however, the study of oils and fats appears to have received a sudden impulse, due probably to the introduction of butter substitutes and of hydrogenated fats. Phenomena such as the drying of oils, the development of rancidity, and polymerisation of oils, can scarcely be understood until clear insight into the constitution of the substances under investigation has been obtained. Much work has certainly been carried out, but we are not yet in a position to state that the composition of a single natural fat or oil is known with certainty.

In this paper a few of the properties of castor oil, or more correctly, perhaps, of castor oil fatty acids, will be dealt with.

This oil has several characteristics which differ in a marked manner from those of other fats or oils. Its insolubility in ether and its solubility in alcohol, its high viscosity and the transparency of its sodium soap, may be quoted as examples. These properties are attributed to its chief constituent, namely, *ricinolein*.

In order to render the latter part of these notes more explicit, I shall give a brief résumé of the investigations carried out upon ricinoleic acid. It should be noted that in all cases the fatty acid has been prepared by direct saponification of the oil.

Hazura and Grüssner* maintained that the fatty acids derived from castor oil consisted of a mixture of ricinoleic and *iso*-ricinoleic acids. This is, however, doubtful, in view of the work of Haller,† who was able to identify one acid only. Of the other constituents of the oil, 1% of dihydroxystearic acid was discovered by Juillard, together with some stearic acid. From a consideration of the iodine value and acetyl value, it is calculated that castor oil consists of about 93% of ricinolein.

The constitution of ricinoleic acid first proposed by Goldsobel,‡ namely:

has been verified by Haller and Brochet,§ who prepared the perozonides of the esters and identified the products obtained on treatment with sodium carbonate.

An acid of the above constitutional formula is likely to prove interesting from the theoretical point of view. It contains an asymmetric carbon atom and an ethylenic double bond, and is also a hydroxy acid.

We surmise, therefore that the acid should be capable of existing in two isomeric forms due both to the carbon atom and also to the double bond. This is actually the case. Castor oil itself is optically active, and similarly the ricinoleic acid prepared from it has a specific rotation $[\alpha]_D = +6.25^\circ$ to 7.5° in acetone solution (Walden).

The *lævo* acid has not yet been isolated. Again, on treatment with nitrous acid, it is converted into its geometrical isomer, ricinelaic acid, a crystalline solid, m.pt. 52° – 54° C. (Wohlenburg). These are comparable to the well-known fumaric and maleic acids.

The condensation products theoretically possible owing to the presence of both the hydroxyl and carboxylic groups are numerous, and for comparison these have been tabulated (see Table I.)|| We shall have occasion to refer to some of these later.

According to H. Meyer,** ricinoleic acid polymerises on standing into polyricinoleic acid, accompanied by a reduction in the iodine value and an increase in the specific gravity. The polymerised product is reconverted into the original

** Arch. d. Pharm., 1897, 184.

acid on boiling with alcoholic potash. Wohlenburg noticed a fall in the neutralisation value from 188.2 to 170.9 in 5 months.

The reactions occurring on treating the fatty acids and castor oil itself with sulphuric acid, forming the so-called Turkey red oil, have been the subject of various investigations.

Amongst other products, Juillard* claims to have isolated dibasic diricinoleic acid

monobasic diricinoleic acid

and dihydroxystearic acid.

He maintains also that polymerisation proceeds further, giving rise to the formation of di-, tri-, tetra-, or penta-ricinoleic acids. This view is contested by Scheurer Kestner, who believes that the highest polymerisation product of this nature is di-ricinoleic acid where the combination is due to the splitting off of water from two hydroxyl groups, whereas those of Juillard are of ester formation.

Rassow and Rubinsky† have investigated the products formed when ricinoleic acid is heated alone and in the presence of various catalysts. They come to the conclusion that under the conditions of their experiments, that is, up to a temperature of 150° C., the products obtained are the polyricinoleic acids of the ester type. Such a change was greatly accelerated in the presence of small quantities of sulphuric acid, the neutralisation value falling as low as 25%.

With the above remarks upon the extent of our knowledge of ricinoleic acid and its general properties, I shall proceed to describe the work carried out on the "splitting" or "hydrolysing" of castor oil, by two well-known methods, namely:—

Time.
FIG. I.

1. Hydrolysis by means of Twitchell's reagent.
2. Hydrolysis by water under pressure in the presence of bases, generally termed "autoclave splitting."

The results may be found of interest as no information upon the splitting of castor oil could be gathered from published literature.

(1) Twitchell's reagent, a product obtained by the action of sulphuric acid upon a mixture of oleic acid and a hydrocarbon such as benzene or

naphthalene, has an accelerating effect upon the hydrolysis of fats by steam. The oil is placed in a covered wooden vat together with a small quantity of the saponifier. Steam is then blown vigorously through the liquid for several hours. The extent of hydrolysis can be followed by a determination of the acid value in the usual manner.

Time.
FIG. II

When the desired splitting effect has been obtained, the mixture is acidified, whereby the emulsion formed is broken and the fatty acids are obtained clear on the surface.

In the case of ordinary fats and oils, the splitting effect increases with time and if the results are plotted a curve of the type shown in Fig. I. is obtained. The rate of hydrolysis is slow at the start up to the point of inflexion A. This is probably due to the influence of free fatty acids upon the interfacial tensions between the oil and water phases. A lowering of the tension aids the formation of an emulsion, thereby creating an increased surface contact between the oil and water, and this effect is obtained after the production of a small percentage of fatty acids. The hydrolysis then proceeds quite normally, the rate of splitting decreasing as it approaches 100%.

In the case of castor oil, the results which are tabulated below show the anomalous character of the hydrolysis.

Time.	% Free fatty acids calculated as ricinoleic acid.		
	A.	B.	C.
After 6 hours	51.4	55.0	55.3
After 12 hours	55.2	55.8	61.3
After 18 hours	61.6	62.0	61.9
After 24 hours	48.5	50.0	44.5

Batches A and B are the same oil—C is a different oil.

The results when shown graphically have the general form represented in Fig. II.

In this case it is obvious that secondary reactions tending to lower the acid value have taken place.

The product during "twitchelling" had darkened slightly. It was but partially soluble in cold alcohol, but totally soluble in hot alcohol. The insoluble portion dissolved readily in petrol ether. Both portions, however, were acidic and titrated readily to a definite end point in a petrol ether-alcohol mixture.

On boiling away these solvents and dissolving the soaps in water, there was no indication of the presence of either unsaponifiable substances or substances saponified with difficulty.

* Bull. Soc. Chim., 1891, 11, 280.
† Z. angew. Chem., 1913, 318.

The twitchelled product gave the following constants:—

Iodine value	88.83
Free fatty acids (calculated as castor oil fatty acids)	44.5%
Equivalent weight (by titration)	669.6
Saponification value	195.5
Glycerin content	0.1%

Saponification with alcoholic potash reproduced fatty acids having the same constants as the original ricinoleic acid. The change, however, could not be brought about with aqueous caustic soda. It is obvious therefore that they are fairly stable acids.

We shall return to a discussion of the probable products formed when the results of the splitting by the "autoclave" method have been indicated.

(2) This is a method adopted for the rapid production of fatty acids and consists in heating the oils or fats under steam pressure in the presence of small proportions of bases such as lime, magnesium oxide, or zinc oxide and zinc. In our case the splitting was effected under 200 lb. pressure per sq. inch, in the presence of 0.75% zinc oxide and 0.25% zinc. With most oils the splitting is practically complete (98–99%) within 1½–2 hours.

FIG. III.

The results given below are typical of those obtained in the case of castor oil.

Time.	% Fatty acids as ricinoleic acid.
1 hour	75.7
2 hours	69.1
3 hours	58.1
4 hours	56.0
5 hours	55.6
6 hours	55.3
7 hours	54.0
8 hours	52.9
9 hours	51.0

These are represented graphically in Fig. III. The general form of the curve obtained is seen to resemble closely the one obtained by "twitchelling." There is one difference obvious. In the autoclaving the system approaches an equilibrium when an apparent splitting of 50% has taken place, whereas in the "twitchelling" curve the equilibrium point, though not actually determined, is much below this figure. In one case the percentage of fatty acids was reduced as low as 33%.

The product obtained possessed a much darker colour than the twitchelled product. It was partially soluble in alcohol, almost entirely in petrol ether, leaving a small proportion of a semi-solid mass.

The alcohol-soluble portion was a light coloured viscous liquid similar to castor oil and which readily titrated to a definite end point. The ether-soluble portion was a deep-red coloured fluid of high viscosity. This substance proved

to be the iron salts of acids of equivalent weight 917.6, the colour being entirely due to the presence of iron derived from the autoclave. The acids derived from these salts were of a good colour. It should be noted that substances of a lactone or lactide constitution could not be isolated from this portion.

All these acids could be reconverted into the original ricinoleic acid by means of alcoholic potash. This proved impossible in aqueous solution.

The following are the constants for the original castor oil and the several products.

	Original castor oil.	Autoclaved mixture.	
Acetyl value	171.0	70.8	
Saponif. value	175.8	192.6	
Iodine value	83.6	88.0	
Free fatty acids (as ricinoleic acid)	6.0%	51.0%	
Glycerin content	—	0.05%	
		Alcohol-soluble acids.	Acids derived from iron salts.
Saponif. value		191.4	—
Iodine value		87.7	88.5
Free fatty acids as ricinoleic acid ..		63.0%	32.7%
Equivalent weight		476.7	917.6

The results have also been tabulated in Table I. for comparison with the theoretically possible products. An examination of these figures makes the following conclusions obvious:—

1. The iodine values have scarcely been affected and therefore the changes in the fatty acids are not to be attributed to the unsaturated carbon linkages.

2. The reduction in the acetyl values indicates that the phenomena are due to a condensation of some form in which the hydroxyl groups take part.

3. The reduction in the acid values can therefore only be due to a combination of a hydroxyl and a carboxylic group with the splitting off of water.

We can therefore dispose of the formation of the first six theoretically possible condensation products as highly improbable, and if formed they can be present but to a small extent.

Similarly the isolation of stable lactones or lactides was not found possible. The titrations at all stages were exceedingly sharp and it is concluded that these also are not formed.

The constants of the products prove definitely the presence of the so-called polyricinoleic acids, that is, the ester acids, both in the twitchelled and autoclaved products. These acids are formed by the elimination of a molecule of water from a hydroxyl group of one molecule and the carboxylic group of another. Thus in the case of triricinoleic acid, two molecules of water are eliminated.

The acids may be represented by the general formula:—

It has been previously pointed out that condensation of the fatty acids proceeded during autoclaving as far as 50%, at this point the system

approaching equilibrium, whilst during twitchelling, the apparent fatty acid content was reduced as low as 33%. This is exactly what would have been expected, since the conditions during autoclaving, carried out under steam pressure, are adverse to the splitting of water.

No attempt was made to isolate the several polyricinoleic acids. It is, however, evident that acids at least as high as the tetra acid were formed, as those isolated from the iron salts had an equivalent value of 917.6. These higher acids were found to be very slightly soluble in alcohol, whilst the lower acids were readily soluble, thus confirming the observations of Rassow.

The conclusions arrived at concerning the splitting of castor oil can be summarised thus:—

1. The hydrolysis of the castor oil, both by means of Twitchell's saponifier and also by the autoclave process, is practically complete, as is shown by the percentage of glycerol left in the products obtained.

2. The apparent low yield of free fatty acids is due to the formation of ester-acids, the so-called polyricinoleic acids, by the condensation of the ricinoleic acid molecules.

This work was primarily of a private nature, and I wish to express my gratitude to Messrs. Lever Brothers, Limited, and especially to Mr. J. Gray, as director, for their permission to publish these results.

Meeting held at Liverpool on Wednesday, 28th February, 1917.

PROF. E. C. C. BALY IS THE CHAIR.

THE MODERN WHALE OIL INDUSTRY.

BY WILLIAM MANSBRIDGE.

The whaling industry has, from one cause or another, experienced many fluctuations of prosperity and vicissitude, now a flourishing industry, then after a few decades not worth pursuing, Hull, Dundee, Glasgow, and the seaport towns of

TABLE I.

Condensation products of ricinoleic acid theoretically possible.

	Equivalent weight by titration.	Sap. value.	Acetyl value.	Iodine value.

the Eastern States of America, all had their period of supremacy, and now Tonsberg and Sandfjord in Norway occupy the first place as head quarters for fitting out whaling expeditions.

Just previous to 1868 whaling as an industry had languished, was in fact moribund; true, the pursuit of the Greenland whale and the sperm whale, as yielding the most valuable products, was still carried on, but as a whole the industry had reached such a point that it would soon have ceased to have had any particular importance as a source of oil.

This state of affairs was the result of a variety of circumstances. The increasing difficulty of the chase owing to the disappearance of the animals from their usual haunts, the increasing rarity of the two kinds chiefly sought, the fact of the hand harpoon having reached its limit as an effective weapon, and the great development of the mineral oil industry introducing a powerful competitor for purposes of lubrication, all combined to reduce the profits to vanishing point.

In 1868 a Norwegian whaler named Svend Foyn, of Tonsberg, introduced his gun-harpoon and from the start met with great success; the next three or four years were spent in perfecting the new weapon. Modern whaling dates from this event and soon Svend Foyn by his captures in the Varanger Fiords had demonstrated the efficiency of his methods and that whales could still be caught in numbers on the coast of Norway, the powerful sulphur-bottom and less valuable finback and humpback could now be taken and made to pay. In 1877 a competing company appeared and by 1886 there were nineteen companies with 35 whaling ships engaged in the waters adjacent to the Norwegian coasts. Coincident with the gun harpoon came the use of steam vessels; the harpoon weighing 4—5 cwt. and its heavy gun required a steady platform and a fairly large boat. Operations at this period were conducted from land stations where the captured whales were taken to be stripped of their blubber; thus the old time whaling ship with its complement of oar-propelled boats for chasing was superseded, at any rate for this kind of work.

But this prosperity was not without interruption; the cod fishermen and others, believing that the operations of the whaling fleet damaged their industry, sought and obtained a law prohibiting whaling on the coasts of Norway and in consequence the business suffered a serious setback.

During the period 1868—1904 17,745 whales were taken on the Norwegian coasts, the best year being 1885 with 1287 captures. In the earlier part of this time the blubber alone was utilised but, as it was realised that whales were becoming scarcer, other uses for the whale carcase were sought, the result being that the land stations began to make bone meal and whale guano from the parts usually thrown away.

In 1894 whalers began to visit the Faroe Islands with success, and eventually there were 6 stations with 13 to 17 whaling ships having their headquarters in the islands. Fishing in narrow seas as in Irish and Scottish waters was not very productive, although the one or two companies operating there still do very well. At the opening of the 20th century we find the Norwegians extending their methods to Newfoundland, Iceland, and Spitzbergen with considerable success.

In 1904—5 it was discovered that the South Pacific and South Atlantic were frequented by whales in immense numbers, land stations were established in South Georgia, the South Shetlands, the Falkland Islands, and Kerguelen, and at the present time these waters supply 80—90% of the whale oil production of the world.

The floating factory now becomes necessary to the economical development of the industry; it is

the modern counterpart of the old-time whaling ship, but the fires, fed with exhausted blubber, have given place to steam and the open "try-pots" to "press cookers," while on the floating factories the oil when ready is run into tanks and brought home in bulk instead of in casks.

The vast distances in the Southern oceans make such an arrangement of primary importance, and the employment of a floating factory is, in its effect, as important and far-reaching as the earlier influence of the gun-harpoon; it allows the chase to be carried right up to the edge of the Antarctic ice where the natural difficulties of maintaining a land station are practically insurmountable, and besides saves much time by following up the fishing fleet.

The usual method of working such distant waters as the South Pacific and the South Atlantic is for the floating factory to sail with supplies for the land stations towards the end of summer. This cargo consists of coal, provisions, building material, machinery and general stores, including empty barrels, the coal being carried in the oil tanks. After discharging at say South Georgia, the tanks are cleaned out ready for oil and the factory ship, accompanied by its fleet of fishing vessels, departs for the cruising ground which may be at the edge of the Antarctic ice. The actual pursuit and killing of the whale is done by small steamers of about 120 tons: the gun is mounted in the bows and naturally the skill of the gunner is an important matter. On sighting a whale the vessel is allowed to drift near enough to the animal as it rises to blow within range, the harpoon is fired into it, out goes the thick cable, and if the shot has been a good one the whale is soon alongside, wound in by the steam winch and inflated through a hollow lance to make it float easily; as many as four may be secured in this way and taken to the floating factory on to the land station for disposal. The bomb harpoon, frequently employed, has as explosive head fired by a time fuse and if well planted in the whale death quickly ensues.

The floating factory is often an old liner filled with tanks for the reception of the oil; even the ballast tanks are utilised for the same purpose; some have a few large tanks built into them, others have as many as 80 or 90 small tanks; barrels from the land stations are carried in the 'tween decks, and the upper deck amidships is occupied by the "cooker tanks," as the digesters in which the blubber is rendered or "tried out" are called. The cooker tanks are arranged in pairs; they are strong iron vessels capable of standing a pressure of 100 lb. per sq. inch, with a wide manhole at the top for charging and one near the bottom for discharging the exhausted blubber, and perhaps one pair will be fitted with extra large openings 4 ft. diam. for the reception of bones, such as ribs and vertebrae; curved iron plates are used to provide a free passage for the steam through the mass of blubber.

Arrived alongside the operation of "flensing," which consists in stripping the blubber from the dead whale, is at once commenced; huge pieces are hoisted on board, put through the chopping machine, taken up by an elevator and dropped into the cooker, steam is turned on, and after a sufficient period, generally six to eight hours, the oil is run off through a system of separating tanks to get rid of the free water, then into the store tanks in the lower part of the ship.

The process of cooking is of very great importance; upon the skill and care with which it is conducted depends whether the oil will reach the market in good condition or much depreciated in value, hence the cook shares with the gunner the honours of a successful voyage. As the largest number of cargoes arrive during March to July it follows that a large part of the season's oil is

upwards of six months old, and it may even be eighteen months old when marketed, so that unless properly cooked it will keep badly and in consequence fetch a lower price when landed. The ambition of most cooks is to produce a very pale oil; this is not an easy matter even from very fresh whales if the oil is well cooked, but unfortunately quite simple if undercooked. I have been informed that cold pressing with hydraulic presses has been tried with the object of obtaining a very pale coloured oil, but, as might be expected, the oil quickly became rancid and bad in other ways, and the idea was soon abandoned. The best cook is one who is able to get the largest yield of pale oil with the best keeping qualities; this also best fills the requirements of both parties, the producer of the oil and the merchant who buys it from him. It has always been my advice to the captains of floating factories to make a well cooked oil that will grade "No. 1" and let the superfine colour go, because if stored it always depreciates and falls to No. 1 standard or lower; they generally see the force of this, particularly as nowadays they do not get a premium for extra pale oil.

From the point of view of oil production the most valuable whale is the sulphur-bottom, *Balanoptera sibbaldii*, Gray (*sulphureus*, Cope), which belongs to the class called rorquals and known as "finners," but if other products are taken into account the Greenland Right whale, *Balaena mysticetus*, is easily first, because of the value of the whalebone obtained from its mouth, with the Sperm whale *Physeter macrocephalus*, L., which furnishes spermaceti and is also the source of the very valuable substance known as ambergris, a good second. The sulphur-bottom whale is considered to be the largest known animal, either living or extinct, of the earth; it often attains a length of 90 feet with a yield of 100 barrels of oil, the record being taken by an authentic specimen measuring 96 feet in length which gave 140 barrels of oil. The "bone" obtained from this species is harsh and brittle and, compared with true whalebone, of little value, since it only fetches £35 to £45 or even less per ton, according to condition, whereas that furnished by the Right whale brings about £2500 per ton at the present day. The "bone" from the different species of rorqual is known as "finners," which term is also extended to the animal that bears it. The humpback, *Megaptera longimanus*, Rudolphi, abounds in Southern waters and is taken up to 50 feet in length; it gives 25—40 barrels of oil, while the finback, the gamest and most sporting of whales, grows to 70 feet but is also poor in oil, yielding 25—45 barrels. The bottlenose whale, *Hyperodon rostratum*, Miller, is chiefly hunted in the North Atlantic, the oil being very similar in constitution to that of the sperm whale; the animal is only of middle size, attaining a length of 20—30 feet, but gregarious in herds of about a dozen it well repays the chase. Altogether there are upwards of seventy kinds of whales, but many of them are considered by authorities to be only varieties or geographical races of predominant species.

I have often heard the opinion expressed that if they go on killing whales at the present rate, it will not be long before the industry must again suffer a decline and be scarcely worth following. In order to obtain information on this point I have made many enquiries from captains regarding the length of time occupied in growth; most replies have been to the effect that they do not know, but the best opinion indicates that whales grow very rapidly. As one captain who had given much thought to the matter, referring to the humpback, put it, the calf just before birth is about 16 ft. long and when weaned some two months later is about 24 ft. in length, so that when two years old the whale might very well be full grown or nearly so. If this opinion be correct, and I do not doubt it myself seeing that all the conditions of

the environment are conducive to rapid growth, viz. abundance of food, warm water in the breeding grounds, and with few enemies powerful enough to do much injury combined with a fairly rapid rate of natural increase, it will be a long time, even at the present rate, before whales will be perceptibly diminished in numbers. This view is supported by the figures for 1911, as in that year we find that after 35 seasons of modern hunting in European water 1165 whales were taken; yielding an average of 35 barrels of oil per whale; in the same year the Southern Norwegian catch in the south seas is recorded as 12,635 whales giving 306,000 barrels of oil, or an average of nearly 25 barrels for the Norwegian catch in those waters. I think the above figures sufficiently indicate that we may expect a good supply of whale oil for many years to come; this is the more gratifying in view of the importance of the industrial applications of the oil, especially during the last few years. The world's production of whale oil for the last six seasons is shown in the following table, partly taken from the Anglo-Norwegian Trade Journal:

Year.	Locality.	Whales taken.	Norwegian production. Barrels.	% of total.	Total production of world.
1911.	Iceland ..	352	11,800	—	—
	Faroe Isles ..	257	6,900	—	—
	Shetland and Hebrides ..	412	13,800	—	—
	Spitzbergen ..	144	5,500	—	—
	Total Europe	1,165	38,000	—	—
	South Seas ..	12,635	306,000	—	—
			341,000	71.6	485,000
1912.	Whole world	—	—	—	875,000
1913.	"	—	600,000	77.0	775,000
1914.	"	—	575,000	78.0	735,000
1915.	"	—	475,000	75.0	630,000
1916.	"	—	367,400	58.0	634,500

The contribution of different fisheries for the last two years is as follows:—

	1915. Norway.	1916. World.
South Shetlands	195,000	216,000
South Georgia	136,700	329,400
Australia		13,000
Alaska	34,800	18,000
Faroe Islands		no data
Africa		40,000

As illustrating the magnitude of the fleet of vessels engaged in whaling in 1912, there were:—

54 floating factories of 155,174 tons total.
9 cargo ships of ... 21,098 tons total.
267 fishing vessels of ... 100/120 tons each.
A few of the last being 150 tons each.

Some of the floating factories have now been chartered for carrying other kinds of oil, and it is possible that there will be a falling off in the amount of whale oil produced because of this, but I think it will prove to be only temporary.

Crude whale oil is graded according to colour, as will have been gathered from the preceding references, but during the last few years there has been an increasing tendency to make the free fatty acid test a basis of contracts. As a matter of experience it is found that an oil which falls below the highest figure representing the limit of free fatty acid for a particular grade, will also conform to the accepted colour standard for that grade; there are exceptions, as for instance when an oil is discoloured by iron salts, but these are rare.

The accepted grades are known as No. 0, No. 1, No. 2, No. 3, and No. 4. No. 0 and No. 1 are now generally classed together, the former being regarded as a superfine No. 1; the colour varies from pale

straw colour to fine pale yellow. No. 2 is amber yellow and No. 3 pale brown, while anything too dark to be classed as No. 3 is regarded as No. 4, unless it is very bad coloured when it is referred to as "dark whale oil." In the year 1912 samples representing some 650,000 barrels, or about three fourths of the entire production for the year, passed through my hands; the colour was measured in the Lovibond tintometer and the resulting average was adopted as a standard, which has met the views of both sides of the trade so well that no suggestion for an alteration has been expressed. In conjunction with Mr. J. W. Lovibond a set of standard glasses was prepared and these have proved very useful for the rapid examination of samples so necessary when a large cargo has to be rapidly discharged.

In order to examine crude whale oil in the tintometer it is necessary to warm it slightly in order to melt the stearine; a temperature of 75°–80° F. is sufficient for the purpose. The oil as delivered by the ship, always contains moisture which should not exceed 0.5%. The sample must not be heated sufficiently to drive off water, and besides, this would probably darken the oil to some extent, neither must filtration be resorted to as thereby colour might be removed. Considerable care is therefore needed to obtain accurate results, but a little practice will soon overcome any difficulty in the preparation of the sample.

The colours in Lovibond's neutral tint series are as follows:—

	Red.	Yellow.	Blue.
No. 0	1.8	+ 5.6	+ 0.8
No. 1	5.0	+20.0	+2.0
No. 2	7.0	+30.0	+1.9
No. 3	26.0	+80.0	+1.5
No. 4	Not required.		

All in one inch standard cell.

Modern whale oil is a very different thing from the evil smelling stuff most of us have encountered in our early days; now even the dark coloured qualities are not really objectionable, while the pale kinds are quite sweet, possessing no disagreeable taste or smell.

On account of its proximity to several great soapworks and accessibility to the industrial centres of Lancashire and Yorkshire, Liverpool is especially well-placed as a port and has with commendable enterprise and foresight provided excellent facilities for handling, receiving, and distributing whale oil. As has already been stated, a large proportion of the oil arrives in bulk, being carried in tanks on board ship. This has to be analysed and graded on arrival at the port, and when, as is often the case, the ship contains a large number of tanks, this is an important matter. The oil is pumped from the ship into large storage tanks, and in spite of the difficulties connected with this class of oil, a ship carrying 30,000 barrels in bulk can be very expeditiously discharged. From the storage tanks on shore the oil is easily delivered into tank wagons or barrelled off and put on rails alongside for distribution inland, or, if desired, delivery can be given direct from the ship either in bulk or in barrels.

So efficient is the method of dealing with whale oil at Liverpool and Birkenhead that many captains prefer those ports on account of the special facilities provided for them.

Taking 1916 as an example, two-thirds of the oil imported into the U.K.—amounting to 351,000 barrels—was brought to Liverpool and a corresponding proportion in previous years.

In a future paper I hope to deal with the industrial and technical uses of whale oil more fully.

DISCUSSION.

The CHAIRMAN asked what were the uses to which the oil and its products were ultimately put.

Dr. E. F. ARMSTRONG said that whale oil was the first oil to be bought upon a chemical analysis, buyers had set up a standard for grading the oil, not by colour but by the free fatty acid content. The degree of saturation of the fatty acid in an oil depended on the climate it came from, for instance linseed oil, obtained from a mild climate, was unsaturated, but coconut oil from a tropical climate was highly saturated.

Mr. A. E. LEVEY asked for information regarding the quantity of hardened whale oil employed in margarine manufacture. He believed there was a close time when whales might not be hunted.

Mr. J. FOX thought that if the crew of a whaler were paid by results it might have considerable influence on the proportion of the different qualities brought to market. He thought the No. 2 grade was really spoiled No. 1 due to careless treatment in the rendering. Some information regarding the proportion of the products obtained by distillation would be interesting.

Mr. MANSBRIDGE replied that whale oil was used principally in soap making and in the manufacture of edible fats, oleine for the textile trades, leather dressing, and lubricating. In regard to chemical testing he recalled how a Norwegian had fitted a laboratory on his floating factory and employed a chemist to grade the oil as it was made; the result had been that they went too near the limit and on arrival in port it was found that the oil had deteriorated into the next lower grade. There was no law as to a close time for whales, but the whaler tried to avoid killing cow whales with calves. The bonus system of payment ensured the best quality of oil possible.

According to the method of distillation adopted for the treatment of the fatty acids, the yield of pitch varied from 5% to 15%, but leaving that out of the question, the yield of hard stearine (setting point about 135° C.) would be about 15%, soft stearine 25%, and the balance oleine.

Communication.

THE NATURAL ACCELERATOR OF PARA RUBBER.

BY HENRY P. STEVENS.

In various papers * I have shown that certain constituents normally present in raw rubber are necessary for the satisfactory vulcanisation of the latter. These constituents are (1) the nitrogenous complex or "insoluble" constituent which is almost wholly insoluble in benzene, chloroform, and similar solvents, (2) matters which can be extracted with acetone—mainly resins. I have also shown that the insoluble constituent can be replaced by other nitrogenous matter such as peptone, to a lesser extent by casein, and to a slight extent by non-nitrogenous substances such as starch. But I have not succeeded in satisfactorily replacing the acetone-soluble constituents (mostly natural resinous matter) by other resins such as colophony. From this it may be inferred that the active constituent contained in the acetone extract consists of matter other than resin although the latter harks largely. The removal of the nitrogenous matter has the effect of retarding vulcanisation but does not affect the stability of the caoutchouc or the vulcanised rubber. The

* This Journal, December 16, 1912, p. 1099. Also Kolloid Zeits., 1912, 11, p. 69; 1913, 12, p. 46; 1914, 14, p. 91. Reports of the 5th Int. Congress of Applied Chem., 1912, 25, p. 581.

removal of the acetone-soluble matters not only tends to retard vulcanisation, particularly when the rubber is compounded with litharge, but also reduces the stability of the caoutchouc and renders it more readily oxidisable. Numerous analyses failed to reveal any direct relationship between the percentage of nitrogen and the vulcanising properties of raw rubber.

In recent papers* Eaton and Grantham have described the effect produced by allowing wet coagulated latex to stand for a few days before washing and drying. This results in a more rapidly vulcanising crêpe rubber. From the results of tests made on rubber prepared by Mr. Morgan, chemist to the Rubber Growers' Association, in Malaya, I am able to confirm this. Eaton and Grantham also found that this rapidly vulcanising rubber contained less nitrogen than ordinary sheet or crêpe, loss of nitrogen taking place during drying and crêping. On the other hand, smoked rubber did not show a loss of nitrogen in similar circumstances. I have obtained the following results by means of duplicate determinations on samples of rubber prepared by Mr. Morgan on three consecutive days. Each vertical column represents samples prepared from portions of the same coagulated latex.

TABLE I.
Air-dried.

	1st day.	2nd day.	3rd day.	Mean.
Nitrogen %.				
(1) Dried without rolling, i.e., "slab"	0.40	0.39	0.35	0.38
(2) Dried for 14 days without rolling, then crêped and dried	0.30	0.29	0.32	0.30
(3) Dried after rolling, i.e., ordinary sheet	0.47	0.46	0.46	0.46
(4) Crêped next morning and dried, i.e., ordinary crêpe	0.47	0.46	0.45	0.46

Smoke-dried.

	1st day.	2nd day.	3rd day.	Mean.
Nitrogen %.				
(5) Smoked without rolling, i.e., "slab"	0.48	0.50	0.45	0.48
(6) Smoked for 14 days, then crêped and smoke dried ..	0.50	0.50	0.48	0.49
(7) Smoked after rolling, i.e., ordinary smoked sheet ..	0.46	0.44	0.45	0.45
(8) Crêped next morning and smoke dried, i.e., "smoked crêpe"	---	0.49	0.47	0.48

It will be seen that the results on the three days agree well with one another. The figures for ordinary sheet rubber, whether air-dried or smoke-cured, remain about the same, 0.44 to 0.47%, on all three days. Of the air-dried specimens, the slab (1) contains less nitrogen than the ordinary sheet (3) although it must originally have retained more of the nitrogenous serum. This loss is more pronounced after washing (2). The nitrogen content of crêpe (4) is practically identical with that of sheet (3). There is evidently no appreciable quantity of serum in the sheet which can be washed out by crêping.

The ordinary smoked sheet (7) contains approximately the same amount of nitrogen as the air-dried sheet (3), but the other forms of smoke-cured rubbers (5), (6), and (8) contain more nitro-

gen. This would be expected in the case of the smoked slab (5) on account of the additional serum retained, provided that the smoke curing prevented putrefaction and consequent loss of nitrogen. The slightly higher figures for nitrogen in (6) and (8) can only be explained on the assumption that a little nitrogenous matter is absorbed from the smoke.

As the air-dried slab (1) contains less nitrogen than the air-dried sheet (3) or crêpe (4), it is obvious that the loss of nitrogenous matter on "maturing" of slab is greater than can be accounted for by the decomposition of the additional serum retained through not rolling. Hence the loss of nitrogenous matter is not confined to the soluble nitrogenous matter of the serum but includes the insoluble nitrogenous matter coagulated with the caoutchouc itself.

The nitrogenous matter is not evenly distributed throughout sheet and slab rubber. During drying, a part of the serum oozes from the surface and dries down to a water-insoluble scale or varnish-like film, and the nitrogen content of the surface layer is appreciably higher than that of the interior portions. Means are now adopted for preventing the formation of this surface film, and ordinary sheet does not show the same differences in nitrogen content between the surface and interior layers that it did a few years ago. Thus, to quote from some analyses made in 1913.

TABLE II.

	Percentage of nitrogen.		
	In surface layer.	In middle layer.	Difference.
Sheet rubber, without surface scale, cured on			
Estate A	0.44	0.33	0.11
Estate B	0.43	0.39	0.04
Sheet rubber showing surface scale, cured on			
Estate A	0.60	0.33	0.27
Estate B	0.60	0.32	0.28

Or again, taking sample B 1 for the third day (Table I.), and separating into approximately equal parts consisting of outside and inside portions, the nitrogen content of the former amounted to 0.55% and of the latter to 0.35%. This slab showed a very marked surface scale, but it is evident from the figures for the first two samples, that the scale does not wholly account for the concentration of nitrogenous matter on the surface of the rubber and that part of the excess is present in the surface layers.

The above figures also show that very misleading results may be obtained for the nitrogen content of sheet and slab rubbers unless the precaution is taken of thoroughly mixing the specimen dry on the roller mill previous to removal of the sample for analysis.

I have already referred to the replacement of the protein naturally present in latex by nitrogenous substances from other sources, such as peptone and casein. Eaton and Grantham, however, as a result of certain experiments of their own, have come to the conclusion that peptone and casein have little or no effect on the rate of vulcanisation.* They used a crêpe rubber for these experiments, that is to say, a rubber washed free or almost free from natural accelerators but containing the full complement of protein matter necessary for normal vulcanisation. Peptone, in its power to promote vulcanisation, is roughly

* This Journal, July 15, 1916, p. 723. Eaton and Grantham say that my figures "do not appear very convincing" but fail to justify this statement.

* This Journal, July 15, 1916, p. 715 *et seq.*

equivalent to the natural protein matter, and consequently the addition of peptone to a rubber already containing sufficient nitrogenous matter for complete vulcanisation will have a very slight effect. Eaton and Grantham have themselves shown that the heat-coagulable proteins which separate on concentration of latex serum have, when added to ordinary crêpe rubber, little or no influence on the rate of vulcanisation.* The natural insoluble nitrogenous matter, peptone and other complex proteins, must be sharply differentiated from the simpler amino compounds produced by their putrefaction or from the synthetical accelerators. These simpler bodies are far more effective in promoting vulcanisation. Hence they accelerate vulcanisation in a rubber such as ordinary washed crêpe already containing sufficient protein matter for normal vulcanisation. On the other hand, a complex substance such as peptone is not so active and consequently does not produce appreciable acceleration. We require to distinguish clearly between (1) the complex nitrogenous substance (protein) which is necessary for normal vulcanisation but which can hardly be termed an accelerator, and (2) simpler nitrogenous derivatives (which will later be shown to consist of the simpler nitrogenous bases) which are more effective than the proteins and are true accelerators. The latter are able to produce appreciable acceleration in an ordinary raw rubber, while the former cannot. To gauge the effect of the former substances as catalysts or promoters of vulcanisation, it is necessary to start with a rubber from which the natural insoluble nitrogenous constituent has been removed. This was the method adopted in our experiments described in 1914. Work of this nature is very tedious because the removal of this natural nitrogenous constituent requires large volumes of solvents and long standing to allow the insoluble nitrogenous matter to deposit. A further series of experiments has now been made with rubber from which practically the whole of the nitrogenous material has been removed, and which carries the matter a stage further than the published work of Eaton and Grantham. The rubber was freed from nitrogenous matter by standing in the dark with cold benzene for a period of one to two years. The clear supernatant solution of rubber was then poured off and the rubber recovered from this by spontaneous evaporation without artificial heat. The original raw material was an unsmoked sheet rubber containing 0.48% of nitrogen. After removal of the insoluble matter the "protein free" rubber contained only 0.07% of nitrogen. Separation of the insoluble matter was very complete, and it is probable that this small residue of nitrogen was present in some soluble form.

The following "mixes" were made up, based on the simple formula of rubber 100 parts, sulphur 10 parts:—

- (1) Untreated sheet.
- (2) "Protein free" sheet.
- (3) "Protein free" rubber +3% of the heat-coagulable proteins which separate out as a flocculent precipitate on concentrating the serum expressed in sheet making.
- (4) "Protein free" rubber +1½% of the evaporated liquors after removal of the flocculent precipitate referred to above.
- (5) "Protein free" rubber +3% of *l*-methyl-inositol extracted from the residual liquors. This represents about the maximum amount of this crystalline substance ordinarily found in sheet rubber.†
- (6) Rubber rich in protein, being the residue of rubber and solvent after pouring off the clear benzene solution.

The following results were obtained. All samples were cured under the same conditions (3 hours at 135° C.), so as to illustrate the effect of the different constituents. The quantity at my disposal was insufficient for a series of vulcanisations:—

TABLE III.

	(1)	(2)	(3)	(4)	(5)	(6)
Breaking load (grms. per sq. mm.)*	1360	590	700	940	280	810
Final length (original length=100)	1010	1160	1040	860	1110	630
Tensile product	136	68	73	81	32	51
Coefficient of vulcanisation	3.66	1.60	3.08	5.28	1.32	6.44
Nitrogen calculated on raw rubber %	0.48	0.05	0.57	0.35	0.05	1.81

* For details of method of testing see this Journal, Aug. 31, 1916, p. 873.

In experiments of this type particular attention should be paid to the figures for the coefficient of vulcanisation. Tensile figures are more difficult of interpretation, as a low breaking load may be caused not only by under or over vulcanisation, but by the adulteration of the rubber itself.

The results clearly show the effect of the different nitrogenous constituents on the vulcanising properties of the rubber. Taking the samples in order:—

(2) Shows that the removal of the insoluble nitrogenous matter causes a greatly reduced rate of cure. The breaking load has fallen to less than one-half. On the other hand, the final length (elongation) is greater and the coefficient of vulcanisation is much lower.

(3) Shows that the addition of the insoluble matter which separates from the mother liquor or serum on evaporation causes an increased rate of vulcanisation. In fact, this insoluble matter behaves like the natural protein matter retained in ordinary crêpe rubber. This sample shows higher breaking load as against sample (2), lower final length and higher coefficient of vulcanisation. In fact, the coefficient of vulcanisation is almost equal to that of the original untreated rubber, sample (1). Eaton arrived at the conclusion that this insoluble matter had no effect on the rate of vulcanisation. His mistake arose from taking rubber already containing its full complement of nitrogenous matter instead of working with a rubber from which the latter had been removed. Although the effect of adding the insoluble matter to sample (2) is so marked, it is quite possible that the effect of adding it to sample (1) would have been inappreciable.

(4) Illustrates the effect of the addition of soluble nitrogenous matter. The effect is similar to that of the insoluble nitrogenous matter as shown in sample (3), but much more pronounced. The breaking load is higher, the final length is much less, and the coefficient of vulcanisation now much exceeds that of the original rubber, sample (1), although the percentage of nitrogen it contains is much less and the amount of this soluble matter added in sample (4) was only half that of the insoluble matter added in sample (3). The efficiency of this soluble matter is no doubt due to its containing protein decomposition products. In the main it will consist of *l*-methyl-inositol. The mother liquor from which the soluble matter was obtained was sent home* in a bottle filled to the brim. The odour was very slight and the liquor of a light brown shade which, however, darkened on evaporation. It would therefore appear that it is possible to produce

* *loc. cit.*, p. 725.

† Pickles and Whitfield, Proc. Chem. Soc., 1911, 27, p. 111.

* Supplied by Mr. S. Morgan, Chemist to the Rubber Growers' Association in Malaya.

a substance acting as an accelerator from the mother liquors of coagulated latex by keeping these in a vessel filled to the brim, the practical exclusion of air preventing the formation of putrefactive odours. Sample (1) may be regarded as artificially prepared "slab."

Sample (5) shows that the effect of the addition of the methylinositol is to retard vulcanisation. The breaking load is lower and the coefficient of vulcanisation is also lower than in the corresponding sample (2).

Sample (6) contains a large excess of the insoluble nitrogenous matter (protein) naturally present in rubber. Its effect has been to increase the rate of cure. Both samples (1) and (6) are much over vulcanised. Better results from the physical standpoint would have been obtained with shorter cures. Nevertheless the figures clearly illustrate the effect of the particular nitrogenous matter on the rate of vulcanisation. The percentage of nitrogen in sample (6) is 1.81, in sample (1) it is only 0.35. Yet the effect of the larger proportion of nitrogenous matter on the coefficient of vulcanisation and physical properties in sample (6) has not been very much greater than that of the small proportion of soluble nitrogenous matter in sample (4). This clearly illustrates the difference between the action of the insoluble and soluble nitrogenous matters respectively.

The conclusions to be drawn from these results are that complex nitrogenous matter (protein) promotes vulcanisation, and that naturally present in the rubber is necessary to secure vulcanisation within reasonable limits of time and temperature. There are, however, simpler nitrogenous substances, probably formed by the decomposition or gradual breaking up of the complex proteins by the action of micro-organisms,* which are far more active as vulcanising agents than the proteins themselves.

It has been stated that crêpe made from "slab" or matured coagulum vulcanises more rapidly than ordinary crêpe. It must therefore contain an appreciable quantity of accelerating base although the rubber has been put several times through differentially geared washing rollers in a stream of water. The figures already quoted show that loss of nitrogenous matter takes place and unwashed slab should therefore vulcanise faster than slab which has been washed and crêped. This has been put to the test.

A matured slab, prepared from unrolled latex,† was taken and divided into two parts. One part (2) was cut into thin slices with a knife and allowed to air dry. The remainder (3) was washed on a crêping machine and the crêpe air dried. The two samples were mixed in the proportion of 99 parts rubber and 10 parts sulphur and vulcanised for one, two, and three hours at 135° C. Sample (1) is a "mix" of pale crêpe rubber and sulphur in the same proportions to serve as a control. For results see Table IV.

The figures both for the physical tests and the coefficient of vulcanisation show that (2) and (3) cure much faster than the control sample (1). It must be remembered that the coagulum (slab) from which (2) and (3) were prepared was matured to the maximum extent, for the rubber was not used for some two or three months after coagulation. The results also show that the unwashed slab (2) cures faster than the washed slab (3). This is most clearly seen from the figures for the coefficient of vulcanisation, that for the unwashed slab being higher than for the washed and crêped slab in all three cures. The physical test figures also correspond, the final length being higher for the slower curing sample (3) than for (2) throughout. The breaking load figure is higher for the faster

curing sample (2) so long as the rubber is not grossly overcured, that is for the one and two hours' cure.

To carry the matter a stage further, various experiments were made for the purpose of extracting the soluble nitrogenous matter from crêpe rubber. The rubber was cut up into small pieces and digested for several days with either water or very dilute sulphuric acid. In all cases it was found possible to extract some nitrogenous matter from the rubber, even in the case of the thinnest pale crêpe which had been rapidly coagulated and converted into crêpe within three hours of adding the acid for coagulation. The amount so obtained was, however, very small in comparison with that extracted from crêpe prepared from matured coagulum or slab. Thus, in one experiment, 200 grms. of each was cut up finely and extracted with sufficient water to cover the rubber for ten days. The temperature was maintained at about 40°–50° C. during the first half of this period and then gradually raised to boiling point. The decanted liquor from the pale crêpe was almost colourless and gave only a slight precipitate with tannic acid. The liquor extracted from the crêpe obtained from the matured slab was brown in colour and gave a relatively heavy precipitate with tannic acid. The weights of the tannic acid precipitates calculated as percentages on the original rubber were 0.03% and 0.26% respectively. These figures will not represent the whole of the soluble protein matter present as repeated extractions would be necessary, but they illustrate the relative proportions retained by the rubber. After removal of the more complex nitrogenous substances (protein, etc.), by means of tannic acid and barium hydroxide, the amount of organic base remaining was determined by precipitating with phosphotungstic acid—with the usual precautions. The percentages of base weighed as phosphotungstate and isolated from the liquors were 0.0006 and 0.058 for the pale crêpe and the crêpe prepared from matured slab respectively.

In a similar manner 100 grms. each of ordinary thin pale crêpe and crêpe from matured slab were extracted for several days with 2% sulphuric acid. After removing the soluble proteins with tannic acid, and the excess of tannic acid with barium hydroxide solution, the bases were precipitated with phosphotungstic acid and gave the following amounts calculated on the raw rubber taken: for the pale crêpe 0.002% and for the crêpe prepared from matured slab 0.032%. As before, these figures apply to the first extraction only, nevertheless they are very small amounts, taking into consideration the fact that they represent a very much smaller proportion of base. The bases themselves must be very efficient accelerators if these small quantities produce the observed differences between the two varieties of crêpe. One can only suppose that long digestion with water or weak acids removes but a small part only of the bases present in the rubber.*

Some measure of the efficiency of the organic bases produced during putrefaction of latex serum results from the following experiments:—In the preparation of sheets, each from 2000 c.c. standardised latex on an estate in the East, the residual liquor from each pan, after standing, was concentrated and forwarded by Mr. S. Morgan in small bottles. The liquor was in each case made up with water to fill the bottle to the brim to prevent oxidation in transit. On arrival, the stoppers, which had been waxed, were found in good condition; the contents of the bottles varied in colour from pale yellow to brown, and contained a flocculent precipitate of coagulated proteins.

* Eaton and Grantham, *loc. cit.*

† Furnished by Mr. S. Morgan.

* With regard to the great difficulty of extracting nitrogenous substances from rubber compare D. Spence, *Koll. Zeit.*, 1914, 15, p. 268.

The contents of the bottles had little or no putrefactive odour.

Portions of 90 grms. each of the pale crêpe rubber used in the control sample (1) were mixed with 10 grms. sulphur with the addition of the substances mentioned below:—

(4) A portion of the evaporated contents of one bottle after filtering off the coagulated proteins. Weight taken 1.5 grms.

(5) The bases isolated by means of phosphotungstic acid—weight of base (crude) taken = 0.14 gm.

(6) Similar to (5), but in the place of isolating the bases the compound with phosphotungstic acid (weighing 1.29 grms.) was taken.

(7) Similar to (5), except that the base added was separated from the united contents of five bottles, equivalent to the residual liquor from 10,000 litres of standard latex. Weight of base isolated = 0.59 gm. This was soluble in alcohol.*

(8) A similar mix to those already described, but containing one gram of moist "accelerene" (paranitrosodimethylamine)† in place of the bases isolated from residual liquors. The one gram of moist accelerene corresponded to 0.92 gm. of the dry substance.

The "mixes" were vulcanised under the same conditions as before, that is to say for one, two, and three hours at 135° C., with the following results:—

product. Accelerene is said to be an exceptionally active product.

If the coefficients of the samples be compared at the three cures, it will be seen that they preserve the same order in each cure, consequently a study of the first cure alone is sufficient to illustrate the relative effect of the ingredient added to the mix, although many of the specimens are not fully vulcanised at this cure. The following conclusions may be drawn:—

(A) The artificial accelerator "accelerene" has the greatest effect. Present to the extent of 0.92%, it produces a greater degree of vulcanisation in one hour than is obtained with the control sample (3) in three hours.

(B) The samples containing natural accelerator isolated from the residual liquors (5) and (7) show an increase in the rate of vulcanisation but not in proportion to the amounts taken. It is characteristic of accelerators that smaller amounts are proportionally more effective than larger quantities. Sample (7) contains approximately four times the amount of natural base as is contained in sample (5), but the effect produced is barely doubled.

(C) It is interesting to note that the coefficient and also the physical test figures for sample (7) are very similar to those for samples (2) and (3). When it is remembered that (7) consists of ordinary pale crêpe to which has been added the natural accelerator isolated from the residual liquor, whereas (2) and (3) consist of "slab"

TABLE IV.

Sample No.	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
One-hour cure.								
Breaking load (grms. per sq. mm.)	370	950	830	560	430	160	770	1030
Final length (original length=100)	1170	1070	1090	1050	1080	990	1070	770
Tensile product	37	101	90	58	47	16	81	79
Coefficient of vulcanisation	1.16	2.73	2.42	1.93	1.57	1.28	2.69	5.31
Two-hours' cure.								
Breaking load (grms. per sq. mm.)	800	1620	1530	1030	870	600	1650	—
Final length (original length=100)	1090	960	988	1010	1000	1060	950	—
Tensile product	87	155	151	104	87	63	157	—
Coefficient of vulcanisation	2.67	5.24	5.09	3.47	3.81	2.75	5.29	—
Three-hours' cure.								
Breaking load (grms. per sq. mm.)	1710	1350	1630	1410	1660	1400	730	—
Final length (original length=100)	990	770	840	890	910	970	670	—
Tensile product	169	104	137	125	151	135	48	—
Coefficient of vulcanisation	3.86	7.02	6.80	5.41	5.09	4.29	7.16	—

The effect of the accelerator, whether the natural base in samples (4) to (7) or the artificial accelerator (accelerene) sample (8), is most easily followed by noting the figures for the coefficient of vulcanisation. The effect of the "accelerene" is so great that sample (8) is already appreciably overcured in one hour. It was not therefore included in the two and three hours' cure. It must, however, be remembered that the amount taken was 0.92 gm. whereas sample (7) with the largest proportion of natural base contained only 0.59 gm. The artificial accelerator gave a coefficient of 5.31 in one hour and the natural accelerator in smaller amount gave a coefficient of 2.69 in one hour and 5.29 in two hours. Hence we may conclude that the artificial accelerator is somewhat more powerful than the natural. 0.92 part of the former producing double the effect of 0.59 part of the latter.

Improved methods of separating the natural accelerator may, however, result in a more efficient

rubber in which the residual liquors are largely retained and allowed to putrefy, it would seem to be fairly proven that the rapid vulcanising qualities of slab are due to the bases formed during putrefaction.

(D) Sample (4) gives a higher coefficient than the control and vulcanises more rapidly. This sample contained 1.5% of residual liquors obtained merely by evaporation and consists chiefly of substances other than the natural bases. Its effect is consequently less pronounced. 1.5% produces a rubber vulcanising but little faster than (5) containing only 0.14% of natural bases.

(E) Sample (6) shows that the natural bases in the form of phosphotungstate are almost as effective as the same quantity of base in the free state.

An analysis of the figures for physical tests leads to the same conclusions as those for the coefficient, but the matter is more complicated from the fact that samples considerably overcured give low results for breaking strain similar to the undercured samples. The fully cured samples give higher results and the slightly overcured the highest of all.

* A detailed examination of the base or mixture of bases is being undertaken.

† Peachey's Eng. Pat. No. 4263 of 1914.

The organic bases separated and used in these experiments are not volatile or not readily volatile. The putrefaction of latex serum might well give rise to volatile bases and such are indeed formed. Their presence can be shown by cutting up matured slab into small pieces and distilling in steam.

In general the experimental results show that the rapid curing property of matured coagulum is due to organic nitrogenous bases formed during putrefaction, as small quantities of these bases can be extracted from the rapidly curing rubber which has undergone putrefaction, while only a trace can be extracted from the ordinary pale crêpe. Further, that similar bases can be extracted from the residual liquors and very small quantities of these bases have been shown to have very marked effect in promoting vulcanisation.

I am indebted to the Rubber Growers' Association for permission to publish the results contained in this paper, and to Mr. S. Morgan for preparation of the specimens of raw rubber.

Industrial Notes.

REFRACTORY MATERIALS RESEARCH.

A conference on research in refractory materials was held at the rooms of the Iron and Steel Institute on March 22nd, at which representatives were present from the Geological Survey, National Physical Laboratory, Ceramic Society, Faraday Society, Institute of Metals, Institution of Gas Engineers, Society of British Gas Industries, Institution of Mining and Metallurgy, Iron and Steel Institute, Society of Chemical Industry, Association of British Chemical Manufacturers, and Society of Glass Technology.

A general debate took place on the question as to what steps might be taken to organise and promote research work on refractory materials and on the raw materials used in their manufacture, and a Committee consisting of Mr. A. Cliff, Prof. J. W. Cobb, Dr. R. T. Glazebrook, Sir Robert Hadfield, Mr. Cosmo Johns, Dr. J. W. Mellor, and Dr. A. Strahan, with Mr. F. S. Spiers as Secretary, was appointed to report to a later meeting of the conference on the following subjects:—

(A) The extent of the research work on refractory materials already in progress.

(B) The facilities for research existing in this country.

(C) The facilities existing for collecting published information on refractory materials and making it generally available.

The Committee is to invite representatives of the principal industries and Societies represented at the Conference to furnish them for the purpose of their report with a schedule of the problems calling for immediate action, and a statement of the special requirements of the industry they represent.

THE WAR AND OUR SUPPLY OF DRUGS.

At a meeting of the Royal Society of Arts held on February 28th, Mr. F. A. Hocking, Pharmacist to the London Hospital, discussed this subject, basing many of his remarks upon the practice of the London Hospital, which, with its 17,000 in-patients and 170,000 out-patients annually, affords very valuable and representative data for a discussion such as the present.

The subject is considered under three sections:—
1. What drugs were in use before the war, and

to indicate to what extent we were dependent upon Central Europe for their supply.

2. The difficulties arising out of the war, and to what extent these have been surmounted.

3. The period after the war.

The drugs in use before the war and their origin.

Medicinal plants. The greatly extended use of substances of definite chemical composition derived from the mineral kingdom or prepared in the chemical laboratory has tended to reduce the use of vegetable drugs, for the constant composition of the former presents great advantages over the often varying constituents of the latter.

For these and other reasons it comes about that, of the large numbers of drugs described in a text-book of Vegetable Materia Medica, some are occasionally prescribed by medical practitioners; some are to be seen only in a museum; some are constituents of the "heal-alls" of domestic medicine; and others are in demand by the patent medicine proprietor.

The list of drugs actually used in the London Hospital in the year 1914, for the purpose of this paper regarded as a peace year, includes about eighty of vegetable origin. Of this number some, such as alkanet root, are used merely for colouring; others, as orange peel, for flavouring; and some, as orris root, for perfuming; while a few, as tragacanth, are employed for pharmaceutical, as distinguished from medical, purposes.

Very few of the most important drugs are derived from Central Europe. Several are cultivated or grow wild within the borders of the British Empire; thus cinchona bark comes from India and Ceylon, as well as from non-British parts of the world, cinnamon bark from Ceylon, Buchu leaves from South Africa, senna leaves from India, and also Egypt, quassia wood from Jamaica, Nux vomica seeds, the source of strychnine, from India, castor-oil seeds also from India, as well as sandal-wood oil, and ipecacuanha root of sound quality comes from Johore.

Many come from non-European countries outside our Empire, such as camphor, a Japanese Government monopoly, Cascara bark from the United States of America, Calumba root from Africa, Ipecacuanha root from Central America as well as from Johore, Rhubarb root from China.

Of those which are supplied by Europe, some are imported from neutral or allied countries—thus, ergot comes from Russia and Spain, squill from the Mediterranean shores.

Ultimately there is a short list of medicinal plants formerly derived from enemy countries. They are aconite root, belladonna root and leaves, colchicum corn, digitalis leaves, gentian root, henbane leaves, opium, and possibly valerian root. Of these it is generally admitted that digitalis grows wild in this country in sufficient quantity for all our needs; and it is stated that very large quantities of wild colchicum corn, i.e., meadow saffron, have been gathered in this country during the past two years; hence little difficulty seems to exist.

For opium we are not entirely dependent on Eastern Europe, Persian opium having been for long an article of commerce, and since the outbreak of war Indian opium has been imported for the production of morphine—in fact, the world's supply of this alkaloid is to-day practically all produced from Indian opium.

Gentian root is but one of a number of bitters of equal value; hence any deficiency is not of great importance.

Indian or Japanese aconite might be used probably to supply any shortage of the European article.

The real difficulties were in connection with belladonna root and leaves, hyoscyamus leaves,

and possibly valerian. There may perhaps be one or two others which have a localised use in different parts of the country. Egyptian henbane tends now to render the cultivation of other Solanaceous plants a matter of indifference, and Japanese valerian root has been used for the European article.

It is difficult to estimate accurately the real extent of the deficiency because, for instance, while some people bemoan the shortage of English belladonna root, yet others are able to obtain their requirements. The shortage of belladonna and foxglove leaves cannot be so great as is supposed, for even during the war appreciable quantities of the English-grown products have been exported.

Even if the cultivation of these few plants be necessary, much caution is required. It cannot be stated too often that the demand is and must be strictly limited.

Drugs are used only by a minority of the population and medicinal doses are generally small, so that a very little over-production will soon render these drugs a glut on the market, and reduce prices to a non-remunerative level.

In view of what has been said, it seems that too much attention has been directed to a difficulty which is scarcely so urgent as has been represented; hence, may it not be asked if the energy at present being devoted to growing medicinal drugs might not be better utilised in the production of foodstuffs?

Substances obtained from the animal kingdom. Of these one was exclusively German, namely lanolin, a very useful basis for ointments. With this exception no one country can claim a monopoly of such articles as beeswax, honey, pepsin, and dry thyroid gland.

Alkaloids. The number of alkaloids or their salts used in the London Hospital in the year 1914 was about fifteen. Of these, seven—namely, apomorphine, acetomorphine, morphine, codeine, caffeine, strychnine, and emetine—were, and of course are, manufactured in England on a large scale, not merely for home consumption, but also for export, and we may claim that for both quality and quantity the English products were easily first. It is true Germany sold these drugs, but it is not easy to determine what proportion was of German manufacture and what of English manufacture bearing a German label, for it is established that Germany imported appreciable quantities of these British-made alkaloids.

It cannot be claimed that English quinine dominated the world, for it is produced in the United States of America, France, Germany and Italy; but the home manufacturer had a good share of the world's trade, and, as regards the quality of English quinine salts, an official investigation by the Italian Government some years ago showed them to be second to none.

Cocaine and theobromine were manufactured in this country, but relatively not on a large scale.

For the remaining alkaloids in the list we were undoubtedly dependent on enemy countries, as the very small quantities that may have been made here were almost negligible. They include atropine, eserine, and homatropine, so important in ophthalmic practice, as well as some alkaloids of less frequent use.

It is of interest to note that the alkaloid, acetomorphine, was discovered by a Scotch chemist, and subsequently manufactured and put on the market by Germany, who, however, had to purchase English morphine for its production; while another, cotarnine, was also put on the English market by a British firm long before the German product was boomed under a fancy name.

Acids. Four of these, including lactic and tannic acids, were probably German; the remainder are English products, prepared in some instances

from raw materials existing here, and in other instances from raw material imported from non-European countries, but the supply of which is largely controlled by British capital and enterprise, as in the case of boric acid. The raw material for citric acid is an Italian Government monopoly.

Salts. The group includes important remedies, as calomel, corrosive sublimate, silver nitrate, bismuth carbonate, sulphate of iron, sodium bicarbonate, potassium bromide and iodide, and many others. It will suffice to state that we depend upon home production for the majority of these compounds. For many the raw material is found in England, for others, as bismuth, it is imported from America; for some, as mercury, from Spain; and for others, by no means the least important, from Germany. Reference will be made to this a little later.

Simple compounds of carbon. The majority of the twenty simple compounds of carbon are of great importance to the physician and surgeon. The group includes the general anæsthetics, ether, chloroform, and ethyl chloride; the antiseptics, carbolic acid, creosote, and iodoform, and also alcohol and glycerin. All of these were and, of course, are produced here in large quantities and of indisputable quality.

The other articles in this group are of much less importance. Three are of Teutonic origin, and the remainder English or American productions.

Complex compounds of carbon. The pre-war source of the great majority was Germany; very few of them were obtainable elsewhere, except possibly from Switzerland. France produced adrenalin (synthetic), and also digitalin. An English house made chlorbutol, and occasionally small quantities of two or three others; but for more than thirty out of the forty we were dependent on Central Europe.

The members of this group are not all of equal importance. One or two are dyes, used merely to give a distinctive colour to certain lotions, and one or two are substances whose medical value has not been fully established; but the majority comprises some very important drugs, such as antipyrin, chloral hydrate, novocain, phenacetin, resorcin, saccharin, salicylic acid, aspirin, salol, veronal, together with salvarsan and neo-salvarsan.

The difficulties arising out of the war.

With the outbreak of war there was also an outbreak of profiteering, but this difficulty may be regarded as in some sense avoidable.

The real difficulties were comparatively few, but very formidable, and became intensified as the British blockade of Germany became more stringent. They were associated mainly with the supply of raw material, particularly of potash and of bromine, and the supply of synthetic and some other drugs. The main difficulty in connection with potash lies in the direction of the supply for artificial manures, for the relatively small requirements of medicine and of the arts have been met without very great difficulty, but, of course, at a high price.

Prior to the war the world's supply of bromine was derived from the United States of America and from Germany, and the producers in these two countries had entered into arrangements whereby competition was largely eliminated, in consequence of which the Americans kept away from European markets. The blockade left the Americans masters of the situation, and at one time the price of potassium bromide was 25s. per lb., as compared with 1s. 6½d. per lb. in July, 1914.

It is instructive to set beside this enormous rise the moderate variations in respect of the prices of drugs the raw material for which is obtained within the Empire or is controlled by British enterprise and capital. Two instances will suffice

for comparison. The production of iodine from Chili saltpetre is largely controlled by Britain; hence the price of potassium iodide, which in July, 1914, was 12s. per lb., rose to 15s. per lb. only in December, 1915, and has since fallen to 12s. 2d. per lb., practically the pre-war price.

Similarly, the price of morphine in July, 1914, was 9s. per ounce. On the outbreak of war with Turkey it rose to 13s. 6d. per oz., at which price it still remains.

Bromine, however, is now being prepared in France from sea water in large quantities, and at a price which enables it to compete with the American product.

These two problems of potash and of bromine, so essential in the treatment of nervous disorders, do not seem to have attracted public attention to the same extent as the question of synthetic drugs.

A great deal of undeserved blame has been heaped on the heads of English firms manufacturing medicinal chemicals because they did not immediately undertake the production of these synthetic drugs, but it is forgotten that the resources of British firms were taxed to the utmost in their endeavour to cope with the sudden and enormous demand for essentially British products for the needs of the Allied armies and of the civil populations; hence they had neither time nor staff to devote to fresh work. The extent of these demands far exceeds the conception of all who are not directly associated with this work.

In the next place, it is not possible to raise armies of millions of men and have at the same time a surplus of labour to draw upon for new commercial enterprises, and plant and processes cannot be improvised in a day, which have occupied the enemy years of thought and labour in bringing to their present state of perfection. For these and other reasons very little was done in the early months of the war.

A start was, however, first made in the East End of London with the production of salicylic acid and its compounds, and in the early spring of 1915 the London Hospital received 1 cwt. of British-made sodium salicylate of excellent quality.

Aspirin was the next item to be tackled, and although the early attempts were not satisfactory, difficulties have now been surmounted, and more than one manufacturer is turning out tons of this article of the highest degree of purity.

Atropine sulphate, so essential in ophthalmic practice, and originally derived from Central Europe, is now being produced from Egyptian henbane in large quantities by at least two English firms.

It is unnecessary to give detailed records of recent British achievements. It will suffice to mention a few of the "German" drugs now being produced in this country: absolute alcohol, lanolin, butyl chloral hydrate, paraldehyde, lactic acid, homatropine, phenacetin, saccharin, salol, xeroform, novocain, salvarsan, and potassium permanganate.

It is interesting to note that the chemical laboratories and staffs of various university colleges throughout the kingdom have been pressed into this work.

The period after the war.

It will be generally admitted that the scientists of these islands are fully equal to the solution of all questions relating to synthetic drugs involving chemical knowledge both general and particular. And with the passing of the war there will also pass most of the difficulties with which manufacturers have at present to contend, particularly as regards provision of plant and of labour. Discussions of the turn of events after the war have centred, therefore, round what may be termed the commercial and financial aspects of the question.

It is assumed without doubt that the enemy countries will put forth the most strenuous efforts to regain the trade enjoyed by them before the war. Profiting by the lower rate of wages ruling in Germany as compared with those in this country, and aided probably by State subsidies, it is expected they will offer synthetic drugs at prices with which British manufacturers, if left entirely to their own resources, will be unable to compete.

If the production of synthetic drugs established here during the past two years is to survive the war, then some form of State aid seems to be necessary. Difference of opinion exists as to the form which Government assistance should take. Firms which have had but limited experience of chemical manufacturing on a commercial scale ask for subsidies from Parliament. They desire to buy their experience and to build up a business at the expense of the State. Firms, however, which are in possession of extended experience in the production of medicinal chemicals, having already tackled the new problem successfully, ask only for State assistance of a legislative character in order to ensure that the newer industries shall have a fair chance of surviving. Some suggest that importation of synthetic drugs from enemy countries should be entirely prohibited for a period of years following the war; others suggest the imposition of a tariff which, while sufficiently high to give British firms a reasonable chance of competing with the German, should at the same time not be so excessive as to penalise the consumer.

Public bodies which are large consumers of drugs, such as the Voluntary Hospitals and the Municipal and other infirmaries, can render much help in support of such legislative action by collectively agreeing to refuse to buy synthetic drugs emanating from Central Europe, even though such refusal may involve a slight extra cost to the ratepayer. Is British patriotism strong enough to support such a step on the part of the governing bodies of these institutions?

The question of legislative assistance is by no means a simple one. For example, how is it proposed to deal with the competition of neutral countries. The United States is already a serious competitor to be reckoned with in the English market, and, in spite of high freights and insurance, the American can sell his goods in England at a lower price than the Englishman. In some cases the difference is not great; in others there is no comparison: thus some tons of American phenacetin were recently sold in London at about one half the price of the English product.

Is then a tariff to be imposed on all non-British synthetic drugs, or only on the German article? British manufacturers and scientists recognise that legislative protection does not by itself constitute a royal road to success. Co-operation among themselves is highly desirable in arranging that too many firms are not engaged on turning out the same products; it has also been pointed out that by organisation and mutual concession the cost of manufacture can be reduced to a minimum if some firms undertake the production of essential intermediate substances for the use of other firms engaged in working up the ultimate synthetic drug. Further, it is to be noted that certain intermediate products are required very largely in the dye industry, and upon the development of the latter to some extent depends the success of the synthetic drug industry.

There is a further question upon which there has been much agitation for many years, and concerning which there is also some difference of opinion. Endeavours have been made to persuade successive Governments to grant the use of duty-free alcohol on the grounds that the high duty handicaps the Englishman to such an extent as to

make it impossible for him to think of competing with the foreigner who has the advantage of cheap alcohol. The Government has made some concession in permitting the use of a spirit known as "industrial spirit," containing a smaller quantity of the denaturing constituents, but this does not give universal satisfaction. It may be the question will be investigated once again and further concessions granted.

Another complaint for which there is some justification, and which has occasionally been levelled by home manufacturers against the medical profession, is that new drugs of English manufacture put on the market under systematic names understood by all chemists are coldly received by the physician, but when these same drugs are made in Germany and introduced under a fancy name they are received with open arms. For example, acetomorphine, already referred to, was first made and introduced in England by a Scotch firm, but little interest was manifested by the medical profession, whereas the same drug put on the market by the Germans, under the name "Heroin," was taken up with alacrity.

Furthermore, the partiality shown by some medical workers in the field of research for German reagents and solutions is difficult to understand, when it is remembered that British reagents of equal purity are easily obtainable.

One other criticism of our system of medical research is the lack of assistance sometimes accorded in physiologically testing newly discovered drugs of British origin. It is pointed out that the organisation of the German chemical and medical worlds permits of the thorough investigation of the properties of any new remedial agent by experiments on animals, and also by employing it in clinical practice, if there be sufficient ground for expecting good results. It is urged by some manufacturers that similar co-operation be established between British firms and workers in the field of medical research.

FERROCERIUM AND OTHER PYROPHORIC ALLOYS.

A recent issue of the *Engineering and Mining Journal* (1917, [5], p. 212) contains the following notes on pyrophoric alloys:—

About the year 1903 Welsbach discovered that certain alloys of the rare earths, when filed, gave off showers of bright sparks which would readily ignite inflammable gases. It was subsequently found that the best results were secured when employing an alloy containing about 65% iron. The same action takes place with these alloys as with the flint and steel, except that a spark is produced much more easily than with the primitive tinder-box.

The mixture of certain earth metals, often called *misch* metal, consists mainly of the elements cerium, lanthanum, didymium, neodymium, praseodymium, and samarium. All these metals are white to light yellow in colour and not readily oxidised in the air. The commercial *misch* metal varies in character according to the manufacture. For example, the *misch* metal produced by one large German chemical manufacturer is quite soft, whereas that produced by another manufacturer by electric reduction is quite hard and often very brittle. The brittleness in most cases is caused by the presence of silicon as an impurity. Welsbach patented his discovery and for a time monopolised the market. Subsequently the German courts limited the operation of the patent and at one time threatened to annul it entirely.

The price of ferrocereum alloys when first produced was about £12 per kg. Later this was reduced to £2 8s. per kg. and in 1913 to about £1 per kg.

While the original pyrophoric alloy (ferrocereum) manufactured by Welsbach contains nearly 10% iron, the competing products have only about 15% iron, and for the purpose of hardening, about 2% antimony or bismuth is added. Silicon is found in nearly all ferrocereum alloys, because it is either contained in the raw *misch* metal as an impurity or has been absorbed from the clay crucibles in which the alloy is often produced. To produce a low-melting and smooth-casting pyrophoric alloy, certain manufacturers add about 5% copper. Various theories have been advanced to explain the pyrophoric character of ferrocereum alloys, and various authorities claim that it is due to nitrides, hydrides, or suboxides. None of these theories has been substantiated, however.

Several alloys, interesting solely from a scientific standpoint, have been produced with mercury and platinum. The former is highly explosive. The latter alloy, when containing about 25% platinum, possesses the greatest pyrophoric properties of any of the known cerium alloys. A zinc-cerium alloy is especially suitable for the ignition of mine lamps. Cerium alloys containing boron have also been recommended for a like purpose.

By the addition of 25% aluminium or magnesium to the cerium alloys, a very brittle metal is produced, which is readily pulverised. Inferior pyrophoric alloys containing high percentages of carbides are very unstable, and unless protected from the air by a film of oil, readily oxidise and become worthless within a few weeks.

The raw material for the manufacture of ferrocereum is generally the waste from gas-mantle factories, which consume large quantities of monazite sand. After the extraction of the thorium from the sand, there is produced as a by-product what is known as rare earth residues or *misch* metal oxides. Most manufacturers produce ferrocereum by the electrolysis of the anhydrous chlorides of cerium, lanthanum, didymium, etc. A good grade of mixed anhydrous chlorides costs, under normal conditions, about 3s. per kg. The fluorides of the cerium metals have not proved satisfactory, as they produce a thick, pasty metal in which the *misch* metal separates in a fine state of distribution and not in the form of a solid mass as in the case of the chlorides. For the production of ferrocereum by the electrolytic process, it is necessary that cheap current be available. Many manufacturers use ordinary graphite or clay crucibles with large iron cathodes. Others use water-jacketed iron crucibles.

In the early days of the industry, the small pocket lighters, in which the pyrophoric alloy was employed, contained only small pieces of metal weighing from $\frac{1}{2}$ to 1 gm., and these lighters were regarded more or less as scientific toys. At the present time there are two distinct types of lighters on the market, in one of which the pyrophoric alloy is fed in the form of a small stick against a hard steel wheel with a file-like surface; this wheel, when revolved, produces a shower of sparks, which are projected on a cotton wick impregnated with benzine or gasoline. The other type of lighter consists of a long strip of pyrophoric alloy against which a hard steel pin is struck; around this is wrapped an asbestos thread, which is kept saturated, when not in use, with gasoline in a small reservoir constructed in the body of the lighter.

The largest consumption of ferrocereum in the United States is for patent gas-lighters. In Europe, where the match industry is a government monopoly, the main consumption of ferrocereum is for cigar lighters.

MUNITION FACTORY EXPLOSION.

The Committee appointed by the Home Secretary to inquire into the cause of the explosion which occurred in East London on Friday, January 19th, have presented their report, bearing date February 23rd. The report itself will not be published, but the following is a summary of the conclusions at which the Committee have arrived:

(1) The explosion was preceded by a fire which broke out either in the melt pot or in a corrugated iron structure at the top of the building immediately above the melt pot.

(2) The fire rapidly gained a fierce hold, and as the melt pot contained a large quantity of explosive material in a state of confinement, it is probable that the initial detonation took place there.

(3) The evidence available is not sufficient to determine with certainty how the fire was started, but all accidental causes presenting any degree of probability may be eliminated except the two following: (A) A detonation spark produced by friction or impact; (B) spontaneous ignition, due to decomposition, of the material in or about the melt pot.

(4) The possibility of the disaster having been maliciously caused cannot be disregarded, but searching investigation by the police and other authorities failed to discover any evidence which would warrant such a conclusion, and no suspicion fell upon any employee or other person.

The Committee made various recommendations with regard to precautions to be adopted in the manufacture and storing of the explosive in question.

OFFER OF PRIZE FOR METHOD OF DETERMINING THE HARDNESS OF METALS.

Sir Robert Hadfield has placed in the hands of the Institution of Mechanical Engineers the sum of £200, which with any income therefrom may be awarded at the discretion of the Council of the Institution as a prize or as prizes for the description of a new and accurate method of determining the hardness of metals, especially of metals of a high degree of hardness. The ordinary tests of hardness, such as are described in the report of the Hardness Tests Research Committee (Proceedings of the Institution of Mechanical Engineers, 1916, pages 677 to 778) fail to some extent when the hardness of the material exceeds about 600 to 800 Brinell. What is desired is the description of a research for or an investigation of some method of accurately determining hardness suitable for application in metallurgical work in cases in which

present methods partially fail. The Council will consider annually all communications received, and may then award a prize or prizes. But in January, 1922, the offer of prizes will be withdrawn. The Council may award the whole or any part of the sum available at any time if a communication is received which, in their opinion, is of sufficient originality and importance and satisfies the object aimed at; or they may from time to time award portions of the fund not exceeding in all £75 in any one year, for communications which do not completely solve the problem, but which appear to advance the knowledge of methods of testing hardness. A communication should be accompanied by scale drawings of any new apparatus described, or by a model or an example of the apparatus itself. If the communication describes a new invention, likely to be of commercial value, it is desirable that provisional protection should have been obtained before it is submitted for consideration. Communications should be addressed to the Secretary, the Institution of Mechanical Engineers, 11, Great George Street, Westminster, London, S.W.1, and marked "Method of Determining Hardness," and should reach him at least one month before January 1 in any year.

INDIA-RUBBER MANUFACTURERS' ASSOCIATION.

The India-Rubber Manufacturers' Association, Ltd., has recently been incorporated under the Companies Acts, 1908 and 1913, as a company limited by guarantee and not having any share capital, with not more than 100 members. The annual subscription is £10, and the objects of the Association are, *inter alia* :—

(1) To watch over, protect, and advance the interests of india-rubber manufacturers in the United Kingdom.

(2) To protect freedom of trade and liberty of action in relation to the carrying on of the manufacture of india-rubber goods and other allied industries in the United Kingdom.

The association will also deal with labour troubles and with terms of purchase of and specifications for raw rubber and other manufacturing materials. It is proposed to encourage inventions likely to be of value to the rubber trade and also fresh sources of production of raw rubber and other manufacturing materials.

Membership of the Association is confined to *bona fide* india-rubber manufacturers, whose principal works are situate in the United Kingdom.

The Secretary of the Association is Mr. W. G. Wilson, 16, Deansgate, Manchester.

Journal and Patent Literature.

PATENT SPECIFICATIONS may be obtained by post by remitting as follows:—

English.—*s.d.* each to the Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C.

United States.—*1s.* each to the Secretary of the Society, who has to furnish the U.S. Patent Office with the following data:—Patent number, date, name of patentee, and title of invention.

French.—*1 fr. 05 c.* each, as follows: Patents dated 1902 to 1907 inclusive, Belin et Cie., 56 Rue Ferou 8, Paris (3e.). Patents from 1908 to date, L'Imprimerie Nationale, 87, Rue Vieille du Temple, Paris.

I.—GENERAL; PLANT; MACHINERY.

Air drying. C. Hering. Met. and Chem. Eng., 1917, 16, 187—199.

OF the various methods for drying air, the most practical on the large scale is that of cooling until most of the moisture is deposited and then reheating to the original temperature. Although absolute dryness cannot thus be obtained, it is possible by the use of ammonia refrigerators to reduce the humidity at normal temperatures to 2—1%. In cooling the air it is advantageous

to condense and remove as much as possible of the moisture in the liquid form before the freezing temperature is reached, thereby saving the latent heat of solidification, and this is best effected by the use of a regenerative system. By this system the warm moist air is made to pass in one direction through thin-walled ducts, on the other side of which the cold dry air is passing out in the opposite direction. The saving thus effected in cooling the moist air and heating the dry air may amount to one-half the cost of the total heat. Additional economy may be obtained by cooling

the air somewhat more, while passing through the regenerator, by means of the partially spent cooling liquid or gas coming from the refrigerator. Ammonia refrigerators can be regularly worked to give a temperature of -15°F. (-26°C.); cooled to this temperature and then heated again to 70°F. (21.5°C.), the air would have a humidity of 2.95%. A common way of producing moderately dry air is to spray it with very cold water, but a large amount of spraying water is required. If the spraying water is at 32°F. (0°C.) and perfect cooling of the air to this temperature is assumed, the theoretical effect of the treatment would be a humidity of 24.5% on re-heating to 70°F. (21.5°C.). If the amount of spraying water at 32°F. (0°C.) be limited, so that the air is cooled only to 38°F. (3.5°C.), the humidity would be 31.1% at 70°F. Starting with air originally at the same temperature and 75% humidity, this result could be attained with about 167 lb. of spraying water per 1000 cub. ft. of air. A simple means for working this method on a small scale is by forcing the warm moist air through cracked ice. Assuming perfect interchange of heat units, the air could be reduced to a humidity of 24.5% by the melting of 8.9 lb. of ice per 1000 cub. ft.—J. F. B.

Colloidal solutions; Effect of centrifugal force on —. E. E. Ayres, jun. Amer. Inst. Chem. Eng., Jan. 12, 1917. *Met. and Chem. Eng.*, 1917, 16, 190—196. (See this J., 1916, 676.)

PARTICLES of uniform size suspended in a liquid medium will settle by gravity when the product of their mass in grms. multiplied by 3×10^{13} is as large as 10. When the product is less than 10, a partial subsidence will occur until an equilibrium is established. The only considerable force opposing complete subsidence in this case is osmotic pressure. By the use of a law of distribution which takes into account the opposing forces, it is possible to compute the concentration at any level when the system is in equilibrium. When a particle will not settle completely by gravity, it is possible to cause complete subsidence by the application of centrifugal force when the product of the mass in grms., the force in dynes, and the constant 3×10^{13} is greater than 10. Partial subsidence with the establishment of equilibrium will occur when the product is less than 10. The time required to establish this equilibrium can be computed from a modification of Stokes' law. The highest commercial centrifugal force, 40,000 times gravity, can completely remove particles as small as the lower limit of ultramicroscopic observation, but such a separation will require 33 hours when the suspending medium is water. For less viscous media the time will be shorter; smaller particles can never be separated by this force. Particles just too small to be retained by a fine porcelain filter can be removed in a few seconds. Gases of different densities cannot be separated completely by any force less than about 100 million times gravity. The same applies to true solutions, but gases should be partially separated by a much lower force within a reasonable time, whereas solutions in liquid media would require several weeks.—J. F. B.

PATENTS.

Centrifugal machines and the like. J. Hamill. Wolverhampton. Eng. Pat. 102,407, Feb. 14, 1916. (Appl. No. 2144 of 1916.)

THE machine shown is specially adapted for the clarification of sugar juice. The liquid is supplied by the pipe, f , to the annular chamber, f^1 , from which it passes by the pipe, f^2 , to the lower part, a^2 , of the rotating drum, a , in which blades, a^3 , are provided to rotate the liquid. The lighter impurities are forced toward the inner surface

of the liquid annulus and are collected under the ring a^4 . The heavier impurities collect at the outermost part of the drum, and the liquid escapes continuously by the orifice, a^1 , to the receptacle a^5 . The lighter impurities are periodically ejected through the valve, c , which is operated by admitting water by the pipe, d^2 , to the space, d , from which it passes to a cylinder, e , having a

piston attached to the valve rod, e^2 , which is forced inward by the pressure due to centrifugal force, thus opening the valve. A slow leakage device is provided so that the valve closes again by centrifugal force. This may be done by making the piston movable on the hollow valve rod, so that it uncovers a small escape orifice in the rod when forced inward against a shoulder on the valve rod. A similar axial orifice is placed in the valve head for the discharge of the water. A similar valve, c , is provided for the escape of solid matter as shown. In a modified machine suitable for china clay or sewage sludge, the escape orifice is placed midway along the hollow valve rod, so that the water does not mix with the discharged solid matter. When used for the collection of solids which will not "flow," an escape valve is provided for the lighter material only, and the solid matter is removed by a scraper. The surplus water escapes through a perforated tube surrounding the stem of the valve for the escape of lighter material.—W. F. F.

Separating liquids from solids; Method of —. H. A. Herr, Philadelphia, Pa. U.S. Pat. 1,212,638, Jan. 16, 1917. Date of appl. Dec. 23, 1915.

A MIXTURE of solid and liquid is placed in a vessel rotating at high speed, the liquid being removed by centrifugal force. The speed of the vessel is then reduced, and the solid material removed from the sides by a scraper and discharged by its own force through a port in the bottom which is opened when the speed is reduced.—W. F. F.

Centrifugal separator. M. R. Spehnan, Hyde Park, N.Y. U.S. Pat. 1,212,831, Jan. 16, 1917. Date of appl. July 30, 1915.

A CYLINDRICAL basket is suspended from a vertical, rotating shaft, and a vertical, concentric pipe, movable axially, and provided with radial nozzles, extends downward into the basket. A mixture of liquid and solid to be separated is admitted by the pipe and distributed over the wall of the basket by the vertical movement of the pipe. The solid matter which collects on the inner surface of the basket is removed by jets of fluid directed inwards

from nozzles arranged around the outside of the basket in such a way that the lateral pressures are balanced.—W. F. F.

Water cooling towers and the like. A. G. Evans, North Finchley, Middlesex, Eng. Pat. 103,691, Feb. 5, 1916. (Appl. No. 1752 of 1916.)

WATER to be cooled trickles over a series of inclined wood or metal laths or battens supported at their ends on rails and arranged in trellis form with the short transverse axes of their flat surfaces horizontal. A second series of laths is arranged between the first series with its supporting rails midway between the rails of the first series, so that water dripping from the rails is received on the cooling surface of the laths below. The lower ends of the laths are notched and bevelled, the bevelled portion of the notch directing the greater part of the water on to the lath below instead of on to the supporting rail.—W. F. F.

Packing and jointing material. E. T. Williams, London, Eng. Pat. 103,776, Aug. 1, 1916. (Appl. No. 11,056 of 1916.)

A PACKING or jointing material for hydraulic, steam, pneumatic, or other pipes, glands, bulk-head or watertight doors, hot water or steam tips, valves, boiler fittings, or other water-tight or gas-tight fittings, is composed of indiarubber, 50%, and mineral oxides such as zinc oxide, zinc white, or silica, 50%.—W. F. F.

Mills; Pulverising.—The Raymond Brothers Impact Pulveriser Co., Assignees of J. Crites, Chicago, Ill., U.S.A., Eng. Pat. 103,963, Sept. 20, 1916. (Appl. No. 13,361 of 1916.) Under Int. Conv., July 3, 1916.

The beaters in a conical pulverising chamber through which a current of air is passed, are made to slide along the shaft to enable the distance between the beaters and the fixed conical grinding surface to be adjusted. The chamber is flared towards the discharge end and is provided with a second interior conical surface inclined to the first, and with rotating arms for retarding the outward movement of the material.—W. H. C.

Rotary-beater mill. T. J. Sturtevant, Wellesley, Mass., Assignor to Sturtevant Mill Co., U.S. Pat. 1,212,018, Jan. 16, 1917. Date of appl., July 27, 1916.

THE mill consists of a vertical casing in which a vertical shaft rotates. The casing is provided with fixed grinding faces and the shaft with grinding beaters, which rotate in horizontal planes. The uppermost beaters are of a heavy type and the lower ones of a lighter type.—W. H. C.

Rotary-beater mill. T. J. Sturtevant, Quincy, Mass., Assignor to Sturtevant Mill Co., U.S. Pat. 1,212,119, Jan. 16, 1917. Date of appl., July 27, 1916.

A MILL similar to that described in the preceding abstract is provided with a receiving and detaining table mounted on and rotated with the vertical shaft below the upper heavy beaters.—W. H. C.

Rotary-beater mill. T. J. Sturtevant, Wellesley, Mass., Assignor to Sturtevant Mill Co., U.S. Pat. 1,215,075, Feb. 6, 1917. Date of appl., Mar. 16, 1916.

THE mill has a cylindrical and a conical portion, and beaters to correspond in shape with the mill are suspended from and rotated by a horizontal shaft. The conical part of the mill is provided with a corrugated liner and the corresponding beaters have stepped faces. The beaters can be moved horizontally on the shaft to vary their distance from the liner.—W. H. C.

Impact-pulveriser. R. C. Newhouse, Milwaukee, Wis., Assignor to Allis-Chalmers Manufacturing Co., U.S. Pat. 1,212,991, Jan. 16, 1917. Date of appl., Oct. 20, 1911.

A PULVERISER of the disintegrator type has a number of beaters suspended from the central shaft. The beaters consist of arms having detachable bars at their outer ends. The bars of successive beaters are of different thickness, but the bars of opposite beaters are of like thickness.—W. H. C.

Drying apparatus. J. B. Watson, Willington, Derbyshire, Eng. Pat. 101,139, Oct. 21, 1916. (Appl. No. 15,114 of 1916.)

TWO horizontal chambers are placed end to end and each contains a revolving drum formed of steam-heated tubes mounted in end plates carried by a common shaft. The shaft is directly driven by gearing arranged between the drums. The material is fed into one chamber at the top and is distributed by small plates projecting radially from the drums, and by a conveyor in a side pocket connecting the two chambers. The chambers are also connected at the top by a ventilating passage. One chamber may have an outlet at the top with a suction fan for ventilation, and both chambers may have removable covers at the top, so that both chambers may be ventilated by suction, or one by suction and the other by being open to the atmosphere, or both by being open to the atmosphere. When both are under suction, hot air may be used for ventilation.—W. F. F.

Desiccating apparatus. W. R. Clayton, Evanston, Ill., U.S. Pat. 1,215,316, Feb. 13, 1917. Date of appl., Dec. 2, 1915.

A DESICCATING chamber is built of hollow porous tiles, which are filled with a desiccating material such as calcined gypsum. A false floor is formed above the bottom layer of tiles and a trapped drain is provided to allow the egress of liquids and gases. The chamber is enclosed in an outer sealed chamber with an intermediate layer of waterproof cement.—W. F. F.

Desiccating fluid substances; Process and apparatus for.—R. W. G. Stutzke, Assignor to G. A. Buhl, Chicago, Ill., U.S. Pat. 1,215,889, Feb. 13, 1917. Date of appl., Dec. 28, 1915.

LIQUIDS containing solid substances are sprayed into the tangential inflow portion of a cyclone collector, while a circulation of superheated vapour of the liquid is maintained under pressure from the outlet back to the inlet of the collector. Heat is continuously supplied to the circulating vapour, which is vented from the system, and the desiccated solids are collected within the cyclone collector.—W. F. F.

Evaporating apparatus. J. H. Federler, New York, U.S. Pat. 1,212,469, Jan. 16, 1917. Date of appl., Nov. 26, 1909. Renewed June 9, 1916.

A HORIZONTAL cylinder carrying on its outer surface the substance to be evaporated, rotates within a casing having plates projecting inwards in planes containing the axis of rotation, their inner edges being close to the rotating cylinder. The plates are so arranged with respect to one another that a current of air may be passed transversely backwards and forwards over the substance to be evaporated.—W. F. F.

Evaporator. W. L. DeBaufre, Annapolis, Md., U.S. Pat. 1,213,596, Jan. 23, 1917. Date of appl., Nov. 23, 1915.

A SOLUTION is evaporated, and the vapour dried, and compressed by means of a vapour-actuated

compressor. The solution is heated by the compressed vapour and the exhaust from the compressor combined, and uncompressed vapour from the solution is condensed.—W. F. F.

Vaporising, concentrating, or drying solutions: Method of and apparatus for — G. A. Krause, Munich, Germany. U.S. Pat. 1,213,659, Jan. 23, 1917. Date of appl. Nov. 29, 1916.

THE solution is sprayed into a chamber and passes thence by a wide conduit into a drying chamber. Hot gases are admitted into the conduit near its junction with the drying chamber.—W. F. F.

Evaporator. W. J. Giller, Warsaw, Ill. U.S. Pat. 1,215,140, Feb. 6, 1917. Date of appl. Mar. 10, 1916.

LIQUID is drawn from the bottom of an evaporator by a pump, and passed through a preheater and returned to the upper part of the evaporator in the form of spray. The evaporator has a vapour outlet pipe provided with rows of baffles to keep back any liquid.—W. H. C.

Filter-press; Continuous — D. B. Sweeney, Bayonne, N.J. U.S. Pat. 1,212,844, Jan. 16, 1917. Date of appl. Mar. 22, 1916.

A LONG perforated cylindrical casing is built up of segments and lined with canvas. Feed and discharge pipes are provided at opposite ends, and a screw conveyor within the casing is held out of contact with the sides by strips placed between the segments.—W. F. F.

Filtering apparatus. A. L. Genter, Assignor to Kelly Filter Press Co., Salt Lake City, Utah. U.S. Pat. 1,212,932, Jan. 16, 1917. Date of appl. Mar. 11, 1916. Renewed Dec. 16, 1916.

THE material to be filtered is fed through the pipe, 9, into the trough, 5, which is provided with an

agitator, 6, and is open at the upper part to the casing, A. The latter forms the filter chamber proper and is provided with a hollow shaft, 1, carrying filter leaves, 12. The shaft passes through the end, A¹, which, together with the shaft, slides in and out of the casing. The shaft is rotated by the pulley, 4, and the clutches, 3, 3'. The solid material collects in the casing, A, and the liquid passes through the filter leaves and is discharged through the hollow shaft. When the casing is full of solid matter the feed is stopped, and the end, A¹, together with the shaft and filter leaves, is removed from the casing, carrying the solid matter with it.—W. H. C.

Filtering apparatus. A. L. Genter, Assignor to Kelly Filter Press Co., Salt Lake City, Utah. U.S. Pat. 1,212,933, Jan. 16, 1917. Date of appl. Mar. 11, 1916.

A RECTANGULAR casing with a pyramidal bottom has one side hinged to allow access to the interior. The hinged side is provided with a locking device and a counter-balance. Filter leaves are provided within the casing, each having a valved outlet pipe.—W. H. C.

Furnace. F. Doerinkel, Essen, Germany. U.S. Pat. 1,213,082, Jan. 16, 1917. Date of appl. June 17, 1916.

A CUP-SHAPED vessel, comprising an outer jacket with a refractory lining, is provided with numerous fine perforations and is contained within an outer concentric casing spaced from it at the bottom and sides. The annular space thus formed is closed at the top, and hot gases are injected tangentially into it. The inner vessel is provided with a stand for a crucible.—W. F. F.

Liquid composition [for heating and refrigerating]. H. Hilbert, Pittsburgh, Pa. U.S. Pat. 1,213,368, Jan. 23, 1917. Date of appl. Jan. 10, 1916.

A COMPOSITION, which is relatively non-volatile and remains liquid at low temperatures, is prepared by mixing 60 to 65 parts of water with 35 to 40 parts of glycols of the 1,2-glycol type, such as ethylene-, propylene-, and butylene-glycols.—J. N. P.

Liquids; Apparatus for heating — J. O. Lundberg, Torp Brug, Norway. U.S. Pat. 1,215,011, Feb. 6, 1917. Date of appl. Feb. 28, 1916.

A VERTICAL cylindrical chamber is provided with a series of vertical heating coils, side by side, around the inner periphery of the cylinder, so that a central space is left having a diameter not less than that of the heating coils. The upper ends of the coils are connected to a common stand-box suspended in the top of the chamber, which is supplied by a pipe passing through the side wall of the chamber. A manhole is provided in the top of the chamber having a diameter not less than the diameter of the heating coils.—W. F. F.

Extracting values from bodies; Apparatus for — R. L. Ogden, Rahway, N.J. U.S. Pat. 1,215,182, Feb. 6, 1917. Date of appl. Sep. 22, 1916.

THREE vessels are arranged to contain respectively the solvent, the material undergoing extraction, and the resulting solution. The vessels are connected by pipes provided with check valves, so as to control the flow and allow it to proceed in one direction only. The liquid is forced through the three vessels in succession and back into the first one by increasing or diminishing the pressure of air in the enclosed space in the first vessel. The change of pressure is brought about by alternately admitting water to and withdrawing it from an auxiliary tank, the alternation being effected automatically by means of a valve operated by a float in the water tank.—J. N. P.

Levigation of vegetable, animal, or mineral substances; Method of — Elektro-Osmose A.-G. (Graf Scheyerin Ges.), Berlin. Ger. Pat. 291,667, Jan. 10, 1915.

ELECTRICALLY active bodies are washed out of the material by causing the washing liquid to travel to and fro through perforated electrodes. Electro-negative constituents migrate towards the anode, and electro-positive constituents towards the cathode, and the withdrawal of constituents migrating towards an electrode, against the flow of liquid, is effected by allowing a portion of the liquid to flow away continuously at the electrode concerned.—F. SOPN.

Furnace-gases; Filtering medium for cleaning — F. E. Kling, Youngstown, Ohio, Assignor to L. B. Weidlein. U.S. Pat. 1,215,385, Feb. 13, 1917. Date of appl. Dec. 11, 1915.

DUST is filtered from hot furnace gases by passing them through "steel wool."—W. F. F.

Low temperatures; Method of attaining — H. Mewes, Berlin. Ger. Pat. 291,516, Sept. 6, 1915.

LIQUEFIED gas flowing from the condenser of the

refrigerating apparatus, before utilisation, is cooled further in a surface cooler by the cold expanded gas from an expansion machine which may utilise waste gas from the liquefier.—F. SODX.

Catalytic agent. A. Mittasch, C. Schneider, and H. Morawitz, Assignors to Badische Anilin und Soda Fabr., Ludwigshafen, Germany. U.S. Pat. 1,215,396, Feb. 13, 1917. Date of appl. June 1, 1911.

SEE Eng. Pat. 8162 of 1911; this J., 1915, 822. Special claim is made for catalysts containing a platinum metal.

Absorption refrigerating apparatus of the reversing type. H. E. Willsie, Cranford, N.J., U.S.A. Eng. Pat. 104,151, Feb. 10, 1916. (Appl. No. 18,410 of 1916.)

Centrifugal machine. T. E. Brown, New York. U.S. Pat. 1,215,337, Feb. 13, 1917. Date of appl. Apr. 22, 1911.

SEE Eng. Pat. 102,281 of 1916; this J., 1917, 74.

Disintegrating, pulverising, or mixing apparatus; Rotary. J. W. Spensley, Manchester. U.S. Pat. 1,215,424, Feb. 13, 1917. Date of appl. Dec. 23, 1915.

SEE Eng. Pat. 1331 of 1915; this J., 1915, 1195.

Drying apparatus. E. J. M. Martini, Paris. U.S. Pat. 1,215,951, Feb. 13, 1917. Date of appl. July 5, 1913.

SEE Fr. Pat. 157,298 of 1912; this J., 1913, 998.

Gas cooling apparatus. Eng. Pat. 103,917. See IIA.

Process of compressing, purifying, drying, and cooling gases. U.S. Pat. 1,213,796. See IIA.

Apparatus for organic chemical reactions. U.S. Pat. 1,213,143. See III.

Apparatus for concentrating sulphuric acid and other liquids. Eng. Pat. 101,034. See VII.

IIA.—FUEL; GAS; MINERAL OILS AND WAXES.

Coal; Water content of— with some ideas on the genesis and nature of coal. E. Mack and G. A. Hulet. Amer. J. Sci., 1917, 43, 89—110.

It is known that the determination of the moisture in air-dried coal, as usually carried out, does not necessarily give the true moisture content of the coal (see Huntly and Coste, this J., 1910, 62). Even drying *in vacuo* with phosphorus pentoxide at air temperature does not remove all water. Considering the development of coal from peat it seems probable that coal is essentially colloidal in character, the constituent particles increasing in size with the ageing of the substance from peat to anthracite. It is generally recognised that there is a concentration layer at the boundary of heterogeneous phases, and where colloid substances are concerned, with relatively large surfaces of contact, such "adsorption" effects may become important. The true moisture of coal is regarded as adsorbed by the colloidal constituents, and even if the condensed moisture layer is only a few molecules thick, it may represent a considerable proportion, by weight, of the coal substance. Such a moisture layer would have an unusually low vapour pressure and hence the apparent dryness of a coal which contains several per cent. of moisture. The true moisture content of a coal may be regarded as a measure of colloidal humic matter present. Owing to the small vapour pressure, no low-temperature method can effectively remove all adsorbed moisture. At the

critical temperature of water (365° C.) all the moisture should be driven off. It was shown, however, that below 250° C. *in vacuo*, the removal of water from coal was nearly complete, while the small evolution of gases indicated that no appreciable decomposition took place. Most probably the gases evolved were also adsorbed. Methods were devised to carry out such moisture determinations. The coal was heated *in vacuo* to 230° C. and the water driven off was condensed and weighed.—H. J. H.

Sardinian lignites in gas manufacture. A. Pacchioni. Bull. Assoc. Ital. Ind. Gas e Acqua. Gas J., 1917, 137, 467—468.

THE author gives results of tests in inclined retorts on lignites from Bacu-Abis and Caput-Acquas. The former appeared to contain two components, one brilliant, black particles similar in appearance to ordinary coal, containing 16.7% ash and 1.62% nitrogen, and having little tendency to agglomerate; the other of dull opaque colour, rich in volatile matter (15.15%), sulphur (7.81%), and nitrogen (3.15%). The author considers the coke produced of little commercial value, and advocates the use of the lignite for production of enriching gas or producer gas. Suitable coke may be made from a mixture of 35% of lignite and 65% of coal, the mixture, though swelling, not giving rise to any insuperable difficulty in distillation. With Caput-Acquas lignite the coke produced is of a light spongy quality, more fragile than that from ordinary coal. The gas obtained from both lignites, when purified, is comparable in quality and quantity with that from English coals, whilst the high content of nitrogen should give a high yield of ammonium sulphate. The analysis of purified gas from Caput-Acquas lignite is given as CO₂ nil, C₂H₄ 8.3%, CO 14.8%, H₂ 31.7%, CH₄ 42.2%, N 2.9%, whilst the yield of benzol and its homologues is given as 8.18 kilos. per ton (practically 2 galls. per ton). The content of sulphur (8.23%) is unusually high, and it is suggested that the lignite be mixed with iron oxide or that the gas be washed with a solution of sulphurous acid.—J. E. C.

Benzol and toluol: Apparatus for determination of— in coal gas. H. E. Copp. Gas J., 1917, 137, 595.

THE series of four wash-bottles used in the ordinary benzol test is replaced by a scrubbing system consisting of a calcium chloride tower filled with glass beads over which oil gravitates from a 3-litre aspirator. Results from 20 cu. ft. of gas by the scrubbing method showed 2.965 galls. per ton as against 2.722 by the older wash-bottle method.—J. E. C.

Ignition [of gases]; "Stepped" —. R. V. Wheeler. Chem. Soc. Trans., 1917, 411, 130—138.

THE researches of Thornton (this J., 1916, 682) appear to show that the curve connecting the minimum igniting current with the pressure in a given mixture of combustible gas and air, consists of a series of vertical and horizontal portions which he terms steps. The present author has carefully determined for a mixture of methane and air (9.5% CH₄) at varying pressures the minimum current passing through the primary circuit which just causes ignition when the spark gap and the rate of break in the primary circuit are both kept constant. His results lead to a perfectly smooth hyperbolic curve, suggesting that Thornton's results are due to some peculiar conditions of experiment. Mathematical analysis of the curve (by A. Greenwell) suggests that the quantities "observed igniting current" and "observed degree of compression" are mutually involved

and that for the true interpretation of the curve the axes of co-ordinates should be inclined parallel to the asymptotes of the hyperbola.—W. H. P.

Tar dehydrating and debenzolising plant. Mottram.

Silica bricks and some new uses for them. Gray.
See VIII.

PATENTS.

Briquettes; Manufacture of—, F. A. Vogel.
Assignor to General Briquetting Co., New York.
U.S. Pat. 1,212,991, Jan. 16, 1917. Date of appl., July 22, 1916.

AN oily material is heated to and maintained at 250° F. (about 120° C.), while sulphite pitch solution is added and the whole thoroughly mixed. The product is then incorporated with the finely-divided particles of the fuel to be briquetted.—H. J. H.

Washing coal and other minerals; Apparatus for—, P. Habets, Montegnée, and A. France, Liège, Belgium. Eng. Pat. 104,132, Oct. 4, 1916. (Appl. No. 11,099 of 1916.) Addition to Eng. Pat. 22,655 of 1912.

THE troughs of a number of washers in series are arranged at a decreasing inclination between the washers and are provided with interchangeable filling pieces to reduce the effective cross-section of the channel in stages.—J. E. C.

Coal; Treatment of—for use in domestic grates or furnaces. A. Rollason, Long Eaton. Eng. Pat. 103,873, Feb. 17, 1916. (Appl. No. 2536 of 1916.)

FROM 1 to 2% by weight of finely ground calcium carbonate or magnesium carbonate is added to the coal. It is claimed that its thermal conductivity is thereby reduced and that a more rapid and complete combustion occurs in the fire with resultant economy.—H. J. H.

Coke; Increasing the heating power of—, A. Rollason, Long Eaton. Eng. Pat. 103,893, Mar. 3, 1916. (Appl. No. 3196 of 1916.)

FROM 1 to 3% by weight of calcium or magnesium carbonate is added to coke. It is claimed that the coke then burns better and more completely in stoves, furnaces, or forges.—H. J. H.

Coke oven. L. Wilputte, New York. U.S. Pat. 1,212,865, Jan. 16, 1917. Date of appl., July 31, 1912.

THE oven has vertical flues below each of which is a separate regenerator for preheating its own air supply. The air and gas supply to each flue are capable of independent regulation. Each set of flues is divided at the middle into two similar parts, one of which takes the products of combustion from the other. At regular intervals this is reversed.—H. J. H.

Coke oven and method of operation of same. L. Wilputte, New York. U.S. Pat. 1,212,866, Jan. 16, 1917. Date of appl., Apr. 26, 1913.

IN regenerative coke ovens, with vertical flues, the flues in each heating wall are divided into two groups, and the flues of each group are connected with different regenerators or sets of regenerators, whilst both groups are connected with a common gas supply main. Regulating devices are provided to facilitate control of the distribution of air and gas supplied for heating and also of the removal of the products of combustion.—H. J. H.

Coke from pitch; Method of manufacturing—, C. R. Eckerl, Chicago, Ill., Assignor to The Barrett Co., New York. U.S. Pat. 1,213,763, Jan. 23, 1917. Date of appl., Sept. 10, 1915.

IN manufacturing coke from pitch, solid carbonaceous material non-liquefiable by heat is added to prevent foaming; 10% of coke breeze may be added for this purpose.—J. E. C.

Motive fluid; Apparatus for the generation of—, G. M. Clark, London. From Keller Mechanical Engraving Co., New York. Eng. Pat. 103,885, Feb. 26, 1916. (Appl. No. 2911 of 1916.)

FUEL and air are supplied under pressure to a mixing chamber and the mixture passes through a number of passages of gradually decreasing area into a combustion chamber in which it is ignited by a sparking plug or other suitable means. A cooling fluid is sprayed into the combustion chamber, and means are provided for regulating the amount of cooling fluid supplied, by utilising the differential expansion of the outlet tube and a rod of dissimilar metal. In case of higher temperatures the greater coefficient of expansion of the outlet tube, by means of levers and the like, opens an adjusting valve admitting a greater flow of water to the combustion chamber to reduce the temperature to the required extent, and thereby maintain a fairly constant temperature of the motive fluid.—J. E. C.

Gas from liquid hydrocarbons; Apparatus for making—, W. C. Dayton, Buffalo, N.Y., U.S.A. Eng. Pat. 104,023, Feb. 18, 1916. (Appl. No. 2111 of 1916.)

LIQUID hydrocarbons are gasified by heating them, admixed with a suitable proportion of air, to a high temperature in an oil- or gas-fired retort. To maintain uniformity of composition and calorific value in the gas produced when the output fluctuates, a device is provided for causing the oil feed to vary automatically with the air supply.—H. J. H.

Liquid fuel; Apparatus for burning—, C. Ellis, Montclair, N.J., Assignor to Radiant Heating, Ltd., Leeds. U.S. Pat. 1,216,096, Feb. 13, 1917. Date of appl., Apr. 22, 1912. Renewed July 11, 1916.

LIQUID fuel, along with a limited supply of supporter of combustion, is injected into a series of gas-forming chambers containing a porous filling of refractory material. A vaporising temperature is maintained by the partial combustion, and the vapours from each gas-forming chamber are mixed with air under pressure to form an explosive mixture which is caused to pass at high velocity into a combustion bed of granular refractory material. The amount of gas burnt in the combustion devices is regulated by controlling the fuel supply to the gas-forming chamber.—J. E. C.

Gas producers. A. H. Lynn, London. L. A. Riley, New York, and N. E. Rambush, London. Eng. Pat. 15,167, Nov. 2, 1915.

IN an agitating device for gas producers of the rotary grate type, the whole or part of the superficial area of the grate is of an incomplete spiral, screw-propeller, or like form, having gradually rising surfaces terminated by abrupt shoulders of considerable depth. The sides of the grate have the shape of two vertical half cylinders, laterally displaced along their dividing surfaces, which on revolving force the charge towards the producer shell. The ash is deflected by a number of ash ploughs to the exterior annular section of the revolving bowl, whence it may be removed by conveyors, elevators, or the like. The top of the charge is levelled by an agitating device, and

the portion below the surface, tending to agglomerate, is broken up by a similar device, both devices being attached to a water-sealed rotary top.

—J. E. C.

Producer-gas-engine system. C. S. Bradley, New York, U.S. Pat. 1,212,891, Jan. 16, 1917. Date of appl., Feb. 3, 1914.

THE system comprises a combination of a gas producer, an engine, means for introducing fresh air into the producer, means for transferring heat from the producer gas to the fresh air and delivering the cooled gas to the engine, means for introducing burnt gas from the engine into the producer, and means for controlling the proportion of burnt gas to fresh air supplied according to the temperature of the producer gas.—J. E. C.

Producer gas or water-gas mixed with distillation gases; Generator for producing — from bituminous fuels, such as coal, lignite, etc., by alternating working. E. Dolensky, Frankfurt, Ger. Pat. 294,333, July 6, 1915.

THE lower part of the shaft, occupied by coke, is divided vertically by a fire-bridge which terminates below the dividing zone between coal and coke. A hot-air blast is introduced at the base of each compartment in turn, and travelling upwards through the coke, passes over the bridge and downwards in the other compartment to an exit flue. Steam enters at the base of the hotter compartment, following each air-blast, and the resulting water-gas, after undergoing partial combustion with air introduced at the dividing zone, so as to heat this region, passes upwards with the distillation products, to be withdrawn at the top of the generator.—F. SOPX.

Gas cooling apparatus. J. E. Christopher, Hindley, Eng. Pat. 103,917, Apr. 28, 1916. (Appl. No. 6087 of 1916.)

THE gas is conducted through a series of inner tubes, G, and openings, J, to concentric spaces, N, and passing down these concentric spaces in the form of thin layers or films, is brought into intimate contact with the inner surface of the outer tubes, H. The outer tubes are cooled by water, which may be run off at various levels. The total sectional areas of the inner tubes of the concentric spaces, and of the main gas inlet and outlet passages respectively, must be approximately the same, so that the gases may be equally distributed.—J. E. C.

Heavy hydrocarbons: Method of using — as fuel in internal combustion engines. R. Vidal, Asnières, France, Eng. Pat. 103,831, Jan. 3, 1916. (Appl. No. 99 of 1916.)

A MIXTURE of heavy hydrocarbons (e.g., methyl-naphthalenes and ethylnaphthalenes) boiling within 60° C. of one another is used as a fuel for internal combustion engines, the mixture being heated to and used at a temperature of 100° C., i.e., 140° to 150° C. below the mean boiling point of its constituents.—C. A. M.

Distilling oil. G. E. Heyl, London, Eng. Pat. 104,067, Apr. 7, 1916. (Appl. No. 5135 of 1916.)

THE oil gravitates through a series of chambers internally heated by electric arcs to different temperatures, each being connected to a separate condensing plant maintained under reduced pressure. In this way the oil is fractionally distilled continuously.—H. J. H.

Hydrocarbons: Method of and apparatus for distilling —. H. A. Frasch, New York, U.S. Pat. 1,212,620, Jan. 16, 1917. Date of appl., Apr. 16, 1915.

HEAVY hydrocarbons are heated to the decomposition temperature in a retort within a distilling apparatus containing a heating medium (a melted fusible substance) in which the open lower end of the retort is immersed. Heat is applied to the distilling apparatus to melt the heating medium and to bring it to a sufficient temperature to decompose the hydrocarbons. The pressure of the vapour within the retort forces the vaporised hydrocarbon and the non-volatilised residue through the melted heating medium into the distilling apparatus, where they are distilled under reduced pressure and condensed.—C. A. M.

Hydrocarbons: Process of separating — from natural or other gas. Process of compressing, purifying, drying, and cooling gases. W. O. Fell, Bradford, Pa., Assignor to Petroleum Products Co. U.S. Pats. (A) 1,213,795 and (B) 1,213,796, Jan. 23, 1917. Dates of appl., (A) Oct. 3, 1908 and (B) Sept. 26, 1908. (B) Renewed May 5, 1916.

(A) GAS containing condensable hydrocarbons is compressed in the presence of a heat-absorbing material (glycerin) and then cooled, whereby the condensable hydrocarbons are liquefied and can be separated. (B) Gases are purified by compression in the presence of Turkey-red oil, which may be introduced in the form of a fine spray or mist. The Turkey-red oil may be reduced to a temperature considerably below that of the gas. Subsequently it is recovered and used again.—C. A. M.

Purifying [hydrocarbon] oils: Process for —. W. O. Snelling, Pittsburgh, Pa., Assignor to J. T. Milliken, St. Louis, Mo. U.S. Pat. 1,215,732, Feb. 13, 1917. Date of appl., Apr. 8, 1915.

SULPHUR-CONTAINING low-boiling hydrocarbon oils are freed from sulphur by heating or distilling them in the presence of a high-boiling cracked oil capable of absorbing sulphur.—H. J. H.

Coal washing mechanism. E. G. Burks and N. Hayes, Birmingham, Ala., U.S.A. Eng. Pat. 101,121, Sept. 11, 1916. (Appl. No. 12,855 of 1916.)

SEE U.S. Pat. 1,201,143 of 1916; this J., 1916, 1209.

Coke ovens. L. Wilputte, New Rochelle, N.Y., U.S.A. Eng. Pat. 101,127, Sept. 26, 1916. (Appl. No. 13,678 of 1916.)

Distilling coal. G. E. Heyl, London. Eng. Pat. 104,066, Apr. 7, 1916. (Appl. No. 5134 of 1916.)

PULVERISED coal is fed by an extrusion apparatus into a chamber containing an electric heater, e.g., an electric arc or resistance. The coal in rod form traverses the floor of the chamber and is rapidly distilled. The products passing into a condensing system maintained under reduced pressure. By subdivision of the heating chamber, compartments kept at different temperatures are provided, so that distillation and condensation may be carried out fractionally.—H. J. H.

Distillation of shale. G. E. Heyl, London. Eng. Pat. 104,065, Apr. 7, 1916. (Appl. No. 5133 of 1916.)

THE device described in the preceding abstract may be applied to the distillation of shale and the like.—H. J. H.

Kelp and the like: Distilling apparatus for —. J. C. W. Stanley, Santa Cruz, Cal. U.S. Pat. 1,212,579, Jan. 16, 1917. Date of appl., Mar. 7, 1916.

BOXES are arranged at each end of a furnace, and connected by a series of tubes arranged in a common horizontal plane. The material is carried by a series of conveyors back and forth through the tubes, following a sinuous path, and is discharged at the opposite end to the inlet, gases passing away through vents in the boxes. — J. E. C.

Distilling wood: Apparatus for —. A. W. Quattlebaum and B. S. Mooney, Statesboro, Ga. U.S. Pat. 1,215,990, Feb. 13, 1917. Date of appl., June 3, 1913.

THE wood is distilled in a vertical cylindrical retort, which is charged and discharged from above, and is supported on a pier inside a furnace of beehive form. The products of distillation pass out of the retort from below to a condensing system.—H. J. H.

Carbon electrode [for arc lamps] and method of manufacturing same. R. D. Pike, San Francisco, Cal. U.S. Pat. 1,215,700, Feb. 13, 1917. Date of appl., Mar. 13, 1916.

III.—TAR AND TAR PRODUCTS.

For dehydrating and debenzolising plant. A. E. Mottram, Manchester District Inst. of Gas Eng., Mar. 3, 1917. Gas J., 1917, 137, 164—167.

THE author describes a Wilton tar-dehydrating plant having a capacity of 100 galls. per hr. Tar from an overhead storage tank is pumped through an economiser in which it is heated by the outgoing hot tar. It then enters a coil still at the bottom, being heated during its passage upwards by a Wilton coke-breeze furnace. Leaving the still through a pipe fitted with gauge, thermometer, and safety-valve, it enters a vapour-box near the middle. From the vapour-box the tar flows down into the economiser, whilst the vapours rise and are condensed, the condensed liquid passing into a separator from which liquor is conducted to the liquor well and light oils to a storage tank. The temperature of the still may be controlled by means of the furnace or by the speed of the pump. When making tar for the No. 1 specification of the Road Board, a temperature of 160 to 180 °C. is aimed at and for No. 2 specification, 220 to 240 °C. When the plant is used for debenzolising creosote oil, the latter follows the same course as the tar but at a lower temperature (110 to 115 °C.). The working cost is about 6d. per ton of tar; the total cost of the plant, including storage tanks and barrels, is about £600 to £800. In working up benzolised creosote, a good supply of water is necessary in the condenser, and the addition of a fractionating column after the vapour-box has given improved results.—J. E. C.

Benzol: Rectification of —. W. N. Drew, Midland Inst. Min., Civil and Mech. Eng., Mar. 8, 1917. Gas J., 1917, 137, 514.

THE modern practice in rectifying benzol is to distil unwashed crude benzol, separating it into unwashed fractions of benzol, toluol, and solvent naphtha, the residue being run into a pan where the naphthalene solidifies on cooling. The partly rectified fractions are separately agitated with acid and with caustic soda. 90% benzol has been superseded by standard benzol, giving 95% distillate below 90 °C.; 90% benzol contains about 84% of benzene, 15% of toluene, and 1% of xylene, whilst standard benzol contains about 96% benzene and 4% toluene. The final products are usually standard benzol, 90% toluol, and solvent naphtha, and in working up benzol products "topping up" is frequently adopted. In this case after expulsion of the benzol fraction, the still is allowed to cool and a further supply of crude benzol added. The process is repeated until the still is nearly full of residue, the still then being run for toluol and naphtha fractions. Not more than 5% toluol is permissible in solvent naphtha. The pressure of steam should be constant, preferably not less than 75 lb.—J. E. C.

2-Acetyl-amino-3,4-dimethoxybenzoic acid and 3-acetylaminoveratrole: Nitration of —. C. S. Gibson, J. L. Simonsen, and M. G. Rau, Chem. Soc. Trans., 1917, 111, 69—85.

2-ACETYLAMINO-3,4-DIMETHOXYBENZOIC acid gives on nitration the 6-nitro compound, which on hydrolysis loses carbon dioxide and yields 5-nitro-3-aminoveratrole. 3-Acetylaminoveratrole on nitration gives the 5-nitro derivative, which in turn readily converted into 5-nitro-3-aminoveratrole. The latter compound on diazotisation

and treatment with cuprous cyanide yields the nitrile of 5-nitro-2,3-dimethoxybenzoic acid which readily yields the corresponding acid (m.pt. 171—175° C.), on hydrolysis. 6-Nitro-2,3-dimethoxybenzoic acid, prepared by two different methods, was found to melt at 185°—186° C. (corr.). Under a slight variation of conditions 2-acetylaminio-3,4-dimethoxybenzoic acid gives in addition to the 6-nitro compound a quantity of 4,5-dinitro-3-acetylaminoveratrole, which is also formed when 3-acetylaminoveratrole or its 6-nitro derivative is nitrated with fuming nitric acid.—W. H. P.

Apparatus for determination of benzol and toluol in coal gas. Coppr. See IIIA.

PATENTS.

Cresols: [Electrolytic] oxidation of —. [Preparation of salicylic acid.] U. Pomilio, Francavilla, Italy. Eng. Pat. 103,709, Apr. 18, 1916. (Appl. No. 5687 of 1916.)

Is the oxidation of cresols for the production of the corresponding hydroxy-acids or their salts, an electric current of 5—8 amps. per sq. dm. is passed through a fused mixture of the cresol and an alkali at 200° to 270° C., using electrodes of nickel, nickel-steel, iron, etc. For example, in the production of salicylic acid, a mixture of 3—5 parts of caustic soda and 1 part of water at 110—120° C. is treated with 1 part of 85%—95% *o*-cresol, added in small quantities at a time; the mixture is then heated to 240—250° C., and a current of 5—8 amps. per sq. dm. at the anode passed through.—B. V. S.

Benzenesulphonic acid: Separating — from sulphuric acid and converting the benzenesulphonic acid into a salt. L. M. Dennis, Hhaca, N.Y. U.S. Pat. 1,212,612, Jan. 16, 1917. Date of appl., Dec. 18, 1915.

The mixture of acids is treated with a solvent, such as benzene, which dissolves only the benzenesulphonic acid, and this solution is then treated with a suitable substance to form a salt not soluble in the solvent.—B. V. S.

Diphenylamine: Process of manufacturing —. B. J. Flürscheim, New York. U.S. Pat. 1,212,928, Jan. 16, 1917. Date of appl., June 21, 1916.

ANILINE is heated with ferric chloride, finely divided copper, and iodine.—W. H. C.

Phenol and other substances: Production of —. *Apparatus for organic chemical reactions.* J. W. Aylsworth, East Orange, N.J.; A. M. Aylsworth, and The Savings Investments and Trusts Co., Exors. U.S. Pats. (A) 1,213,112 and (B) 1,213,113, Jan. 23, 1917. Date of appl., Jan. 21, 1916.

(A) PHENOL is obtained by heating a mixture of chlorobenzene and caustic alkali solution, under pressure higher than that of the vapour tension of the mixture, at about 360° C. Chloride and phenoxide are produced, and phenol is liberated from the latter by the action of acid. Where caustic soda is used the proportions are about 1 mol. of chlorobenzene, 2 to 3 mols. of caustic soda, and about 20 mols. of water. (B) An apparatus suitable for the above and similar reactions, arranged for continuous operation, the reacting liquids being mixed in one coil and then pumped through a heated reaction coil.—B. V. S.

Phenol: Manufacture of —. D. Tyret, Stockholm-on-Tees. Eng. Pat. 101,220, Feb. 29, 1916. (Appl. No. 3021 of 1916.)

IV.—COLOURING MATTERS AND DYES.

PATENTS.

o-[Hydro]aryazo dyestuffs: Manufacture of copper compounds of substantive — in substance and on the fibre. O. Inray, London. From Soc. Chem. Ind. in Basle, Switzerland. Eng. Pat. 12,932 of 1915; date of appl., May 31, 1916.

SUBSTANTIVE *o*-hydroxyazo dyestuffs (c.g., those described in Eng. Pats. 12,250 of 1915, 101,601 and 102,881; this J., 1916, 1008, 1101, and 1917, 210) are converted into complex copper compounds or prepared in presence of copper salts to obtain the copper compounds direct, in substance or on the fibre. The fastness to washing, and especially to alkali and to acid, is better than that of the parent dyestuffs, and the fastness to light is in certain cases as good as is obtainable with the best vat dyestuffs.—F. W. A.

[Azo] dyes and process of dyeing. J. Flachslaender and P. G. List, Leverkusen, Germany, Assignors to Synthetic Patents Co., New York. U.S. Pat. 1,215,359, Feb. 13, 1917. Date of appl., July 29, 1916.

DIAZO-COMPOUNDS, c.g., diazotised *p*-nitro-*o*-toluidine, are coupled, in solution or on the fibre, with a hydro-*α*-naphthalide, c.g., the tetrahydro-*α*-naphthalide of 2,3-hydroxynaphthoic acid.—F. W. A.

[Anthracene] vat dyes: Green — and process of making them. M. Kardos, Charlottenburg, Assignor to Badische Anilin und Soda Fabr., Ludwigshafen, Germany. U.S. Pat. 1,216,134, Feb. 13, 1917. Date of appl., June 30, 1913.

SEE Fr. Pat. 458,949 of 1913; this J., 1913, 1101.

[Anthracene] vat dye: Yellowish-brown —. O. Bally and H. Wolff, Mannheim, Assignors to Badische Anilin und Soda Fabr., Ludwigshafen, Germany. U.S. Pat. 1,216,921, Feb. 20, 1917. Date of appl., Jan. 23, 1915.

SEE Fifth Addition, of Apr. 2, 1910, to Fr. Pat. 365,920 of 1906; this J., 1910, 1197.

o-[Hydro]aryazo dyestuffs: Copper compounds of — and a process of making same. B. Wuth, B. Mayer, C. Jagerspacher, and E. Anderwert, Assignors to Soc. Chem. Ind. in Basle, Switzerland. U.S. Pat. 1,216,760, Feb. 20, 1917. Date of appl., Aug. 3, 1915.

SEE Eng. Pat. 1611 of 1915; this J., 1916, 301.

o-[Hydro]aryazo dyestuffs: Copper compounds of — and a process of making same. C. Jagerspacher and B. Wuth, Assignors to Soc. Chem. Ind. in Basle, Switzerland. U.S. Pat. 1,216,812, Feb. 20, 1917. Date of appl., Oct. 7, 1915.

SEE Eng. Pat. 12,249 of 1915; this J., 1916, 922.

o-[Hydro]aryazo dyestuffs: Metal compounds of — and a process of making same. C. Jagerspacher, Assignor to Soc. Chem. Ind. in Basle, Switzerland. U.S. Pat. 1,216,813, Feb. 20, 1917. Date of appl., Dec. 31, 1915.

SEE Eng. Pat. 16,916 of 1915; this J., 1917, 78.

Monoazo dyes. C. Mensching, Birkenhead, Assignor to W. E. Mounsey, Liverpool. U.S. Pat. 1,217,042, Feb. 20, 1917. Date of appl., Jan. 29, 1916.

SEE Eng. Pat. 10,716 of 1915; this J., 1916, 301.

V.—FIBRES; TEXTILES; CELLULOSE; PAPER.

Methyl alcohol and acetone as by-products of the soda pulp industry. A. H. White and J. D. Rue, Tech. Assoc. of Pulp and Paper Ind., New York. Feb. 7, 1917. Met. and Chem. Eng., 1917, 16, 182—186.

IN laboratory tests with the concentrated black liquor from the digestion of wood by the soda process, favourable results were obtained on destructive distillation by feeding the liquor gradually into an inclined, preheated tubular retort. The liquor entered the retort through a side arm at the middle, and the gases were led off at the upper end, while the carbon accumulated at the lower end. The best results were produced at 550°—600° F. (288—316° C.) with liquors from the digestion of beech and bass woods concentrated to 41·3° B. (sp. gr. 1·37). The average yields were 3·81% of methyl alcohol and 0·56% of acetone by vol. on the aqueous distillate, which was 65·5% of the black liquor treated; the rate of feeding was such that the gases remained in the retort for 15—30 secs. An experimental plant on a larger scale, consisting of 24 retorts constructed of steel well-casing, 12 ft. long and 9·6 in. in diam., with a fall of 3 ft. from end to end, was operated continuously for 3 weeks without serious trouble, but owing to leaks the yields were only about 75% of those obtained in the laboratory. The capacity of the plant was about 1 gall. of thick black liquor per hour; the success was limited by the fact that the feeding of the liquor and the removal of the black ash had to be controlled by hand. The black liquor used had the composition: water, 31·7; organic matter, 40·0; ash, 28·3%. The firing of the retorts was effected by gas, but it could be efficiently carried out by the combustion of the black ash produced, or better of the "carbon" obtained from the black ash after leaching. The methyl alcohol and acetone were practically free from tar and could be readily purified. The quantity of tar obtained amounted to about 11·2% by vol. on the black liquor, and it contained about 50% of phenolic constituents. The loss of soda which takes place in rotary incinerators is eliminated by this process, and the carbon recovered from the ash is sufficient to provide fuel for the whole by-product plant. The net saving by the treatment is estimated at \$1·86 (7s. 9d.) per cord of wood.—J. F. B.

PATENTS.

Lignified vegetable materials; Treatment of — for preserving or restoring their colour. C. F. Cross, London. Eng. Pat. 101,032, Feb. 23, 1916. (Appl. No. 2721 of 1916.)

LIGNIFIED materials, such as paper pulp, textiles, or straw plait, are treated with a solution containing 0·2—0·5% of hydroxylamine or hydroxylamine acetate in order to restore their colour or to make them capable of resisting discoloration under the influence of atmospheric exposure.

—J. F. B.

Drying and conditioning materials [yarn]; Process and apparatus for —. W. W. Sibson and T. Allsop, Assignors to The Philadelphia Drying Machinery Co., Philadelphia, Pa. U.S. Pat. 1,213,519, Jan. 23, 1917. Date of appl., July 28, 1913. Renewed June 20, 1916.

YARN is loosely suspended and subjected to heated air at a relatively high temperature, then to air at a lower temperature, and finally to moist air. These operations are carried out in a chamber which is divided into compartments so that the material may be passed from the drying to the conditioning compartment without coming into contact with cold air.—W. P. S.

Size; Manufacture of — and its application to paper and paper pulp. G. H. Gemmell and S. Milne, Edinburgh. Eng. Pat. 101,012, Feb. 12, 1916. (Appl. No. 2108 of 1916.)

ROSIN is dissolved in a solution of borax or ammonia or a combination of both, with or without the addition of soda. In engine sizing, the diluted size is preferably decomposed with aluminium sulphate before adding to the pulp; the size may also be applied to the surface of the paper, which is subsequently dried at a temperature sufficient to fuse and dry the size.—J. F. B.

Cellulose derivatives; Manufacture of —. J. Koetschet, Lyon, and M. Theumann, St. Fons, France, Assignors to Soc. Chim. Usines du Rhône (anc. Gilliard, P. Monnet, et Cartier) Paris. U.S. Pat. 1,216,162, Feb. 20, 1917. Date of appl., June 19, 1915.

SEE Eng. Pat. 7773 of 1915; this J., 1916, 302.

Film and process of producing same. Manufacture of artificial textile material. L. Lilienfeld, Vienna. U.S. Pats. 1,217,027 and 1,217,028, Feb. 20, 1917. Date of appl., Oct. 20, 1913.

SEE Fr. Pat. 459,972 of 1913; this J., 1913, 1153.

Process for bleaching textile fabrics or like material. Eng. Pat. 101,048. See VI.

VI.—BLEACHING; DYEING; PRINTING; FINISHING.

PATENTS.

Bleaching textile fabrics or like material; Process for —. A. Poulson, Widnes, Eng. Pat. 104,048, Mar. 15, 1916. (Appl. No. 3842 of 1916.)

RAW cotton, wool, flax, textile fabrics, paper, or like material is bleached by steeping in a boiling solution of about equal parts of sodium carbonate crystals and sodium bicarbonate and subsequently adding a solution of sodium hypochlorite.—F. W. A.

Chrome colours; Dyeing with artificial —. T. L. Whitehead, London. From Chemical Works, formerly Sandoz, Basle, Switzerland. Eng. Pat. 101,083, Apr. 27, 1916. (Appl. No. 6065 of 1916.)

A CHROMIUM alkali oxalate is added to the dye-bath instead of chromic acid compounds to avoid oxidation of the dyestuff in dyeing wool in one bath with chrome colours such as Indochromine, Gallocyanine, or an *o*-hydroxyazo dyestuff. The chromium alkali oxalate dissociates slowly but completely at the boil, and the chrome lake of the dyestuff is developed on the fibre without premature formation in the dye-bath, as occurs if an organic salt of chromium is used (Eng. Pat. 11,077 of 1894; this J., 1894, 881); the handle of the fibre is not impaired, as is the case after treatment with chromium fluoride.—F. W. A.

Multi-colour printing: Production of azo dyestuffs from nitrosamine colours in —. A. G. Bloxam, London. From Chem. Fabr. Griesheim-Elektron, Frankfurt, Germany. Eng. Pat. 101,108, July 12, 1916. (Appl. No. 9817 of 1916.)

IN multi-colour printing in which steaming is necessary, azo dyestuffs are produced from mixtures of nitrosamines and naphthols or their derivatives (except 2-naphthol-1-carboxylic acid and 2-naphthol-1-sulphonic acid), to which has been added a normal chromate, which forms lakes fast to steaming. By this process it is possible to print simultaneously with tannin dyestuffs and chrome dyestuffs, or sulphurised dyestuffs and vat dyestuffs with nitrosamine colours. After steaming, the colour is developed in a boiling bath containing acetic acid and sodium sulphate, or in a bath containing acetic acid and a dichromate, to which an antimony salt is added in the case of tannin dyestuffs. — F. W. A.

Iron mordants: Firing on textile fibres. P. Schmid, Basle, Switzerland. U.S. Pat. 1,216,847, Feb. 20, 1917. Date of appl., May 23, 1916.

SEE Eng. Pat. 102,310 of 1916; this J., 1917, 80.

Manufacture of copper compounds of substantive α -(hydroxy-azo dyestuffs in substance and on the fibre. Eng. Pat. 12,932. See IV.

[Azo] dyes and process of dyeing. U.S. Pat. 1,215,359. See IV.

Process for making cleaning compounds. U.S. Pat. 1,212,442. See VII.

VII.—ACIDS; ALKALIS; SALTS; NON-METALLIC ELEMENTS.

Kelp for the recovery of potash: The carbonisation of —. J. W. Turrentine, Met. and Chem. Eng., 1917, 16, 196—199.

IN the United States the giant kelps of the Pacific coast offer the best promise for the establishment of a domestic potash industry. Considerable progress has been made as regards the cheap harvesting of the kelp. Drying in the open air, even in the dry climate of S. California, is scarcely feasible on a sufficiently large scale, though it might be assisted by some suitable mechanical device for turning over the material on the floors. Of the artificial drying processes, the use of the direct-heated rotary kiln appears the most promising, preferably when operated on the counter-current principle, with the drying effected in stages. Dry kelp is a powder, weighing about 50 lb. per cub. ft., and containing about 15% of K_2O , and is comparable with the low-grade potash salts formerly imported. The question of freights to distant markets demands the elimination of the organic matter, e.g., by incineration, and if this method be adopted it must be carried out at a temperature below the fusing point of the potash salts (750° C.). Burning in the air does not fulfil these conditions, and all the circumstances point to the method of destructive distillation with the production of gas and possibly the recovery of other useful by-products. It is considered that an adaptation of the continuous vertical coal-gas producers, in which the heat units are carefully preserved, would afford a suitable apparatus for the distillation of kelp. The temperature of working would be lower than that required for coal, and the expansion of the charge would not have to be provided for. Kelp charcoal is porous and easily leached and the reduction in freight rates on the potash salts would fully cover the expenses of treatment. — J. F. B.

Ammonium molybdate solutions: Yellow deposit found in —. A. R. Pentfold, Austral. Pharm. Notes and News, 1917, 13, 17.

THE yellow crystals sometimes deposited from solutions of ammonium molybdate on keeping, have been shown to be hydrated molybdic acid of the formula, $H_2MoO_4 \cdot H_2O$. — B. N.

Oxides of iron: Some problems of the —. R. B. Sosman, J. Wash. Acad. Sci., 1917, 7, 55—72. (See also this J., 1916, 536, 736.)

IN considering the phase ruled diagram of the system iron-oxygen, it is pointed out that the solubility of oxygen in solid iron, although certainly not large, has not been accurately determined. The assumption that FeO is the lowest oxide in equilibrium with metallic iron is based on unsatisfactory data; and the methods commonly given for the preparation of this oxide do not yield pure FeO but mixtures which sometimes have an average composition approximating to it. Analogy with iridium oxide (IrO) suggests that, over some particular range of temperature, FeO may have a higher dissociation pressure than Fe_3O_4 , thus permitting the occurrence of the reaction, $4FeO = Fe_3O_4 + Fe$, which would explain many experimental results and possibly account for the known occurrence of metallic iron in basic rocks such as diabase and gabbro. Magnetite, Fe_3O_4 , melts sharply, at 1580° C., to a mobile liquid which crystallises in octahedra on cooling; the dissociation pressure of this oxide is extremely low, being less than 0.01 mm. of mercury at 1200° and less than 0.005 mm. at 1100° C. The oxides, Fe_2O_3 and Fe_3O_4 , recently investigated by the author at 1100° and 1200° C., seem to form a continuous series of solid solutions, but the melting temperatures (solidus and liquidus curves) have yet to be determined. The dissociation pressure rises so rapidly with increase of temperature that at the melting temperature of the solid solution the pressure of oxygen is probably several atmospheres for compositions which depart much from Fe_3O_4 . The melting point of Fe_2O_3 can be determined only under sufficient oxygen pressure to prevent its dissociation, and it is impossible to predict whether the melting point will be higher or lower than that of magnetite. This type of solid solution presents the special feature of one of the constituent oxides being produced by direct dissociation of oxygen from the other, and raises questions relative to internal structure, the transition of one class of crystal into another (hematite being hexagonal and magnetite isometric), and the factors determining the equilibrium pressure of the oxygen dissociated for a given composition of the solid solution. As regards magnetic properties and polymorphism, the similarity of the temperature-magnetism curves for the magnetic inversions occurring in iron, magnetite, hematite, and various ferrites suggests a common fundamental basis for all. It is quite possible, and appears to be the case with the oxides of iron, that the rapid, reversible type of polymorphic inversion hitherto regarded as denoting merely a molecular rearrangement involving slight changes in crystalline form or symmetry, and therefore less fundamental than the slow and sometimes irreversible type, is in reality the fundamental inversion occurring within the atomic nucleus and thus necessarily producing a corresponding change in the spacing of the atoms. The facts suggest that the magnetic properties and the inversions of iron and its compounds are bound up with the spacing and arrangement of the iron atoms, almost without regard to the other atoms present. The bearing of the above and other considerations on geological questions relating to the oxides of iron is also discussed. — W. E. F. P.

Manufacture of polish [and cement] from felspar.
See XVI.

PATENTS.

Sulphuric acid: Apparatus for manufacture of — H. E. Macadam, Woodford Green, and H. Walker, London. Eng. Pat. 103,877, Feb. 17, 1916. (Appl. No. 2107 of 1916.)

ONE or more towers or structures lined and packed with acid-resisting material are interposed between the Glover tower and the first of the series of lead chambers, and a solution of sodium nitrate is sprayed into the gases as they pass through the tower or towers. At the bottom of the tower, means are provided for drawing-off the denitrated solution. A convenient size for the towers is 9 to 12 ft. high by 4 ft. diameter.—J. B. C. K.

Sulphuric acid and other liquids: Apparatus for concentrating — A. G. Duron, Paris. Eng. Pat. 104,034, Feb. 21, 1916. (Appl. No. 2789 of 1916.)

HOT gases are passed through horizontal flues situated immediately above a series of parallel channels containing the acid to be concentrated, and thence over the surface of the acid itself in the reverse direction. The gases lose heat as they traverse the flues, but they keep their temperature as they pass over the acid owing to contact with the heated under-surface of the flue. The reheating of the gases producing the evaporation is greatest at the point of exit, where the reduction of temperature would otherwise be greatest. The width and surface of the channels, the distance between the acid surface and the lower part of the flue, and the flow of acid, are varied according to the extent of evaporation required, the arrangement being such that there is the largest surface of evaporation, together with the minimum speed of flow and the greatest volume of hot gases, at the point where the acid is weakest. By using four channels, acid of 65–67% concentration can be gradually brought up to 98.3%.—E. H. T.

Lead monoxide: Manufacture of — Patent Corporation, Ltd., Assignees of W. P. Thompson, Liverpool. Eng. Pat. 100,069, Feb. 5, 1916. (Appl. No. 1738 of 1916.) Under Int. Conv., Feb. 6, 1915.

METALLIC lead is heated above its melting point, and is stored in a raised tank, from which it descends to an aspirator under considerable pressure. It flows into the aspirator through a row of small openings, in the form of a fine even spray, and meets many hundreds of times its own volume of highly heated air introduced through slits parallel and at right angles respectively to the row of openings. The resulting dust and hot air are kept in contact with each other at a high temperature until the whole of the lead is oxidised. The chamber which receives the oxidised lead dust for cooling purposes, is surrounded by an air chamber, through which the air supply for the process is aspirated, and the heat of the effluent gases from the lead melting furnace is similarly utilised to heat the pipe or conduit which conveys the molten lead to the aspirator or atomiser. Lead monoxide prepared in this way is specially suitable for the manufacture of white lead by the dry process.—J. B. C. K.

Vitre cake: Utilisation of — I. P. Jewell, Stockport, and P. Spence and Sons, Ltd., Manchester. Eng. Pat. 103,689, Feb. 4, 1916. (Appl. No. 1691 of 1916.)

NITRE cake is heated with a suitable reducing agent, as for instance 25% of iron sulphide in the form of ground pyrites, in a closed iron vessel provided with a mechanical agitator. Sulphur dioxide is evolved, together with some sulphur, which is readily condensed, and a residue of norma-

l sodium sulphate and iron oxide remains. If finely divided iron be substituted for iron sulphide, no free sulphur is liberated, but a steady evolution of sulphur dioxide occurs.—J. B. C. K.

Chromates: Manufacture of — G. N. Vis, Paris. Eng. Pat. 103,696, Feb. 9, 1916. (Appl. No. 1926 of 1916.)

AN ore containing chromium in the form of oxide is heated in a metal vessel with sodium hydroxide (with or without addition of sodium carbonate) to a temperature of 600° to 800° C., the higher temperature being required when sodium carbonate is employed in the mixture. The corresponding compounds of potassium may also be employed. Lime may be added to the mixture, and also chlorides to serve as a flux. Oxygen or air is blown through the molten mass. Examples: A mixture of 300 grms. of chromite and 300 grms. of sodium hydroxide, heated to dull cherry redness and treated with air for 1 hrs., gives a 90% yield of sodium chromate; and a mixture of 200 grms. of chromite, and 280 grms. of sodium hydroxide gives a yield of 97½%.—J. B. C. K.

Formates: Manufacture of — S. H. Katz and E. K. Oritz, Pittsburgh, Pa. U.S. Pat. 1,212,350, Jan. 6, 1917. Date of appl., May 16, 1916.

FORMATES are produced by the interaction of a caustic alkali solution, carbon monoxide, and a volatile alkali such as ammonia. A descending, finely divided stream of the alkali solution meets an ascending stream of mixed ammonia and carbon monoxide in a closed vessel under a pressure of 10–20 atmospheres and at a temperature of 150°–200° C.—B. V. S.

Cleaning compounds: Process for making — A. W. Bishop, St. Louis, Mo. U.S. Pat. 1,212,442, Jan. 16, 1917. Date of appl., Aug. 9, 1916.

A CLEANING solution is obtained by treating a solution of sodium sulphide (20 parts) and sodium hydroxide (3 parts) in water (120 parts) with manganese dioxide (21 parts), and agitating until the sulphurous smell disappears; sodium chlorate (3½ parts) and sifted coal ashes (3 parts) are then added, the liquid allowed to settle for a predetermined time until free chlorine is liberated, the clear liquor decanted off, and mixed with nitrobenzene (4 parts).—B. V. S.

Alkaline-earth metal compounds: Process for producing — E. W. Huber and R. W. Poin-dexter, jun., Los Angeles, Cal. U.S. Pat. 1,213,375, Jan. 23, 1917. Date of appl., July 6, 1914.

AN alkaline-earth sulphate, e.g., strontium sulphate, is subjected to the action of a reducing flame at a temperature of 1200° to 1300° C., and the sulphide produced by this treatment is then exposed while still hot to the action of super-heated steam. The process may be made continuous and carried out in a revolving type of furnace. The hydrogen sulphide evolved in the second stage of the process is employed in the first stage to assist in maintaining a reducing atmosphere.—J. B. C. K.

Cyanogen and sulphur-compounds from fluids: Recovering — F. W. Sperr, jun., Oakmont, Pa. U.S. Pat. 1,213,429, Jan. 23, 1917. Date of appl., Oct. 20, 1915.

A SOLUTION of cyanide and sulphide, or a gas containing hydrocyanic acid, is treated with a solution of a zincate so as to form insoluble zinc sulphide and a soluble cyanide. The precipitated sulphide is separated and cyanide extracted from the solution.—B. V. S.

Cyanogen compounds: [Electrolytic] process of making —. H. Foersterling and H. Philipp, Perth Amboy, N.J., Assignors to The Reessler and Hasslacher Chemical Co., New York. U.S. Pat. 1,211,770, Feb. 6, 1917. Date of appl., June 21, 1910; renewed June 21, 1916.

A METALLIC compound, containing a metal capable of forming cyanogen compounds, is electrolysed and alloyed with another metal. The first metal is vaporised by blowing an inert gas, such as nitrogen, through the molten alloy, and the vaporised metal is treated with nitrogeous and carbonaceous matter. B. N.

Acetate of lime: Purifying crabs —. O. T. Zinkeisen, Assignor to Fore Chemical Works, Inc., New York. U.S. Pat. 1,213,724, Jan. 23, 1917. Date of appl., Jan. 21, 1914.

ORGANIC impurities are precipitated from a solution of crude calcium acetate by boiling with lime, an iron salt, and a bleaching agent. B. V. S.

Alumina and potassium sulphate: Production of — from alundite. E. Blough and T. McIntosh, Assignors to Aluminium Co. of America, Pittsburgh, Pa. U.S. Pat. 1,211,991, Feb. 6, 1917. Date of appl., Feb. 1, 1916.

ALUNITE is mixed with common salt and heated until the latter is decomposed. The sulphates of sodium and potassium produced by the reaction are dissolved out by water, and the potassium sulphate is separated from the solution. The residue from the lixiviation is then heated with the solution of sodium sulphate that remains. The sodium sulphate is thus decomposed and sodium aluminate is obtained. Sulphur dioxide is evolved during the last stage of the process and may be collected and utilised. — J. B. C. K.

Aluminium hydrate (hydroxide): Process for producing —. C. A. Doremus, New York. Assignor to J. S. Hoyt, Darien, Conn. U.S. Pat. 1,215,351, Feb. 13, 1917. Date of appl., Feb. 27, 1911.

A SOLUTION of aluminium fluoride is purified from iron by oxidation and then treated with calcium hydroxide, whereby aluminium hydroxide and a fluoride are precipitated. The former is converted into sodium aluminate by the addition of caustic soda, and the solution is separated and decomposed to re-precipitate the aluminium hydroxide. — E. H. T.

Hydrogen: Retorts used in the manufacture of —. R. and J. Dempster, Ltd., and R. Dempster, Manchester. Eng. Pat. 101,115, Aug. 12, 1916. (Appl. No. 11,113 of 1916.)

THE disintegration of the iron ore caused by the manner of charging it into the retorts (where it is subjected alternately to the action of reducing gases and steam) is obviated by providing the retort with a perforated platform or plate, which is mounted on a vertical shaft and can be raised and lowered from top to bottom of the retort for charging and discharging. The movement is guided by projections or buttresses on the internal walls of the retort, and the platform can be revolved as well as moved vertically. — E. H. T.

Hydrogen [from activated aluminium and water]: Preparation of —. L. Elkan Erben G.m.b.H., Charlottenburg. Ger. Pat. 291,910, Jan. 27, 1916.

ACTIVATION of the aluminium is partially or wholly effected under the influence of heat, which brings about a considerable increase in the yield of hydrogen obtained when the product is subsequently treated with water. — F. SODN.

Lead sulphate: Process of preparing —. International Color and Chemical Co., and A. S. Ramago, Detroit, Mich., U.S.A. Eng. Pat. 190,391, Mar. 2, 1916. (Appl. No. 3176 of 1916.) Under Int. Conv., Apr. 16, 1915.

SEE U.S. Pat. 1,168,118 of 1916; this J., 1916, 309.

Ammonia: Absorbing — and apparatus therefor. C. Bosch, Assignor to Badische Anilin und Soda Fabrik, Ludwigshafen, Germany. U.S. Pat. 1,216,959, Feb. 13, 1917. Date of appl., July 7, 1913.

VIII.—GLASS; CERAMICS.

Glass furnaces: Development of — on the Continent. T. Teisen. Soc. Glass Tech., Mar. 15, 1917.

WOOD and peat are used for heating furnaces in Scandinavia in some works, whilst natural gas is used in the United States to some extent. The chief fuel in use for furnaces, however, is either coal or gas. When coal is burned direct, a large excess of heat is necessary to complete the combustion, and if this excess be cut down the waste gases contain a large proportion of carbon monoxide. In the complete combustion of 1 kilogram of coal to carbon dioxide, 8000 calories are set free whilst only 2500 calories are freed if the coal only is burned to carbon monoxide. Thus the presence of carbon monoxide in the waste gases represents a considerable loss of heat. The use of producer gas allows much better combustion to be obtained, so that a large excess of air is unnecessary. A higher temperature results, therefore, particularly if the gas and also the incoming air are delivered hot to the combustion chamber. This preheating of air and gas can be accomplished either by regeneration or by recuperation. In the latest pattern of the Siemens regenerative furnace there are four chambers lined with fire bricks, two of which are being heated by the waste gases whilst the other two are warming up the incoming air and gas. By reversing the direction of flow of air and gas, the chambers which were being heated now supply heat to the air and gas, whilst the others are in their turn heated by the waste gases. This method of regeneration is very useful for large furnaces but is expensive and takes up considerable floor space. In the Hermanssen system of recuperation the air and gas always pass in the same direction and are sufficiently preheated by passing through flues, which are surrounded by the hot waste gases. In 1906—7 the first Hermanssen furnace used for glass melting was burning wood and

melted a batch of 4 cwt. in 10 hours. So perfect is the combustion in the Hermannsen furnace that, at the Costa Works, crystal glass is made in open pots. Furnaces of this type will melt glass during the night for next day, and so the capacity of a furnace should not be judged by the number of pots, but by the amount of glass it will melt. From this point of view the continuous recuperative furnace is more efficient than the regenerative furnace.

Glass: Effect of small amounts of impurities, in particular chlorides and sulphates, in producing turbidity or opacity in —. W. E. S. Turner and J. D. Cauwood. Soc. Glass. Tech., Mar. 15, 1917.

LEAD glass made with Russian potash, though found at first to be quite clear, gradually became milky as it stood at a lower temperature in the pot, or if after the glass had been worked the articles in course of formation were re-heated. Analysis indicated that the three impurities in Russian potash to any extent were phosphate, chloride, and sulphate. Of these three phosphate was not active in producing milkiness, at least up to 1% of the batch mixture, but chloride and sulphate caused opacity. Of the two, sulphate, to the extent of 1% of the batch, produced opacity, when melting at 1300° was carried out until the glass was clear, followed by several hours' heating at 950°–1000°. Under the same conditions, to give opacity, chloride must be present to an extent exceeding 1% of the batch. It is possible to prevent or retard the appearance of milkiness by the addition of borax. The most effective agent, however, is high temperature, by which chloride is volatilised or sulphate decomposed. The results emphasize the need of the introduction of more efficient furnaces, capable of reaching a high temperature. Especially is this so when dealing with the new types of glassware that now have to be produced in this country.

In the discussion that followed, it was pointed out that whilst borax removed the milkiness, on the glass being reheated it again appeared. Thus the best means of removing this defect was to employ a high temperature.

Silica bricks and some new uses for them. W. Gray. Met. and Chem. Eng., 1917, 16, 209–216.

SILICA bricks are manufactured from a sandstone or quartzite of sedimentary origin. In the United States suitable deposits are restricted to certain parts of Pennsylvania, Wisconsin, and Alabama. The ganister rock when crushed should appear splintery, sharp, heterogeneous in form and size, and slightly translucent. A suitable quartzite would contain approximately 97.5% of SiO_2 , 1–1.5% of Al_2O_3 , and 0.75% of other impurities; it should melt at cone 35–36, expand, and swell without perceptible cracking. The total fluxes should not exceed 3%. Two kinds of silica brick are manufactured: ganister or lime-bond brick, rich in silica, in which the bonding agent is lime, and quartzite brick manufactured from about one part of finely ground clay to two of crushed quartz, and containing 21–26% of Al_2O_3 . In the manufacture of lime-bond brick, the crushed rock is ground in mills with about 2% of good lime; the bricks are moulded, dried for 10–20 hours, and very carefully fired. The first stage of kilning, to drive off the moisture occupies three days with plenty of air, in the course of which the temperature rises to 300° F. (150° C.); the intermediate stage lasts for four days with gradually increasing temperature and less draught; the burning proper, with the formation of the clinker owing to the combination of the lime with the silica, lasts for three or four days, the temperature being forced up to 2800°–3000° F. (1540°–

1650° C.). In cooling, draughts of cold air must be avoided, and the operation extended over seven days. The composition of silica brick will be approximately as follows:— SiO_2 , 96.0%; Al_2O_3 , 0.90%; Fe_2O_3 , 0.70%; CaO , 1.75%; MgO , 0.14%; alkalis, 0.39%. It is an acid brick, used in metallurgical furnaces operating with acid slags to form a stable lining; it is very soluble in strong alkali solutions, easily attacked by metal oxides and flue dust. It is an ideal material for a high and constant temperature where the chemical action of the slag is not detrimental, but it possesses the drawback of "sprawling" or disintegrating if subjected to blasts of cold air or irregular cooling when hot; it is also essential to approach the working temperature slowly and evenly until the brick has become properly annealed. Compared with other refractories, silica brick possesses the important advantage of supporting pressures of 75 lb. per sq. in. well above 2800° F. (1510° C.) without deformation; the softening and melting points are almost identical at about 3400° F. (1870° C.). The bricks expand considerably in kilning owing partly to the conversion of the silica into tridymite, but show a relatively small expansion after the first burning. Silica brick is coming largely into use for the construction of the checkerwork of open-hearth furnaces, with the most satisfactory results. For boiler furnaces it is not so well adapted unless protection from draughts of cold air can be ensured. For the crowns of beehive coke ovens the advantage in structural properties imparted by the expansion properties of silica brick has established its supremacy under exceptionally adverse conditions of cooling. For the lining of lime-kilns, both vertical and rotary, and for cupolas in steel casting, the use of silica brick has resulted in prolonging the normal life of the refractory structures several times over. Similarly in by-product coke ovens and gas-retorts, the advantages derived from the superior properties of silica brick have enabled the industry to reach a stage of development not otherwise attainable, the expansion properties of the silica being particularly valuable in sectional retorts and long coking chambers.—J. F. B.

PATENTS.

Glass furnaces. C. F. Price, Birmingham. Eng. Pat. 101,136, Oct. 17, 1916. (Appl. No. 14,726 of 1916.)

THE furnace is an adaptation of that described in Eng. Pat. 100,819 of 1916 (this J., 1916, 930) and consists of a combustion chamber containing the glass pots or crucibles, mounted above a semi-producer, the sides of the latter being surrounded by flues which heat the air required for combustion. The gas and air are mixed and enter the base of the combustion chamber through an annular flue surrounding the top of the producer. Uniformity in the distribution of the hot air is secured by the use of several damper-controlled air inlets on each side of the producer. The waste gases are taken down flues which partially surround the combustion chamber and producer, and so act as heat insulators, before they proceed to the chimney.

—A. B. S.

Quartz glass: Process of producing articles of —. O. C. Trautmann, Assignor to Sidio Co. of America, Inc., New York. U.S. Pats. (A) 1,215,432 and (B) 1,215,433, Feb. 13, 1917. Date of appl., Aug. 10, 1916.

(A) THE quartz is packed around a resistance core constricted at its middle and heated in an electric resistance furnace until plastic. The core is then broken by twisting one end of it, and the two parts, together with the surrounding plastic quartz, are drawn apart until the latter forms a

tube. (B) An electric resistance furnace is shaped so as to form a mould, a resistance core is placed in it and surrounded by quartz which is then heated electrically until plastic. Any unfused quartz is removed, the core is broken as in (v), and the furnace is then transformed into an arc furnace whereby gases are generated which "blow" the plastic quartz and cause it to take the shape of the mould. —A. B. S.

Drying means of tender clay; Apparatus.

R. O. Perrott, Bucyrus, Ohio, Assignor to American Clay Machinery Co., Chicago, Ill. U.S. Pat. 1,215,819, Feb. 13, 1917. Date of appl., Aug. 11, 1913.

A MULTITUNNEL dryer is so arranged that one end of it is highly heated, whilst at the other end a "low primary curing heat" is applied to the goods by means of a transverse conduit with suitable openings. A forced draught is used throughout, the temperature and pressure of the air being controlled in each section of the dryer. —A. B. S.

Enamels for enamelling iron. R. Koepf and Co., Oestrich, Germany. Eng. Pat. 101,802, Feb. 18, 1916. (Appl. No. 11,121 of 1916.) Under Int. Conv., July 1, 1916.

NATURAL "borate of lime," e.g., borocalcite, colemanite, etc., may be used for the production of high-class enamels for iron if it has previously been melted with a relatively large quantity of boron-glass, lead-glass, or boron-lead-glass. The glass also lessens the injurious action of any chlorides or sulphates present. Two satisfactory mixtures are: (a) 10 parts of sand, 8 of felspar, 25 of ruby glass, 15 of borate of lime, 1 of saltpetre, 4 of soda, and 2 of fluorspar; (b) (for white enamel) 35 parts of glass, 25 of felspar, 15 of clay, 12 of borate of lime, 12 of sodium fluosilicate, 12 of soda, and 2 of saltpetre. Calcium compounds (other than borate) should be replaced by corresponding compounds of other metals. —A. B. S.

Refractory materials; Preventing disintegration of — M. Barrett, and The Leeds Fireclay Co., Leeds. Eng. Pat. 103,953, Aug. 18, 1916. (Appl. No. 11,751 of 1916.)

Blocks intended for use in coke-ovens, gas retorts, and the like, immediately they are made and whilst of a leather-like consistency, are polished on the surfaces to be treated, by soft leather, etc. They are then dried, and submitted, whilst in an incandescent state, to the hot vapour of an alkali chloride, such as sodium chloride, for about 30 mins. The parts not requiring protection may be coated with a wash of barium sulphate if desired or placed in close contact with each other. —J. E. C.

Centrifugal machines and the like. Eng. Pat. 102,107. See 1.

IX.—BUILDING MATERIALS.

Timber; Preservation of — from boring organisms. Engineering, 1917, 103, 171.

RESULTS are given of tests made in Australia on the Carbo-Teredo process for the preservation of timber from marine and land boring organisms (see Eng. Pat. 781 of 1915; this J., 1915, 1056). The timber is impregnated with a hydrocarbon and the surface is then charred by means of a high-pressure gas flame. If the continuity of this charred surface is broken in subsequent working, it must be restored by a further treatment before submerging. This treatment was very effective against *Sphaeroma gigantea* and other borers prevalent in Australian harbour works, and, on land, against the attack of white ants. —H. J. H.

Silica bricks and some new uses for them. Gray. See VIII.

Manufacture of polish (and cement) from felspar. See XVI.

PATENT.

Artificial stone slabs; Manufacture of — E. Iner-Schneider, Geneva, Switzerland. Eng. Pat. 101,151, Feb. 5, 1917. (Appl. No. 1824 of 1917.) Under Int. Conv., Feb. 16, 1916.

See Ger. Pat. 295,268 of 1916; this J., 1917, 219.

X.—METALS; METALLURGY, INCLUDING ELECTRO-METALLURGY

Committee on light alloys.

THE Advisory Committee for Aeronautics, Teddington, have appointed a light alloys sub-committee with a view to the co-ordination of the work which is now being done in connection with the use of light alloys in the construction of aircraft and aircraft engines. The functions of this sub-committee will be to advise Government departments on questions relating to light alloys, to institute research for the development and improvement of such alloys, and of the methods of working, and to assist in the removal of difficulties which may arise in practice in their production and use. The sub-committee will be in close touch with the experimental work on light alloys, and hope to be able to give advice and assistance to manufacturers undertaking the production of light alloys, and to founders engaged in the manufacture of engine parts, cylinders, pistons, crank cases, etc. They trust to have the co-operation of firms who have undertaken such work, and will be glad to receive suggestions and to give any help that may be possible in answer to inquiries. The members of the Committee are: Mr. Henry Fowler, Lieut.-Comm. C. F. Jenkin, R.N.V.R., Prof. F. C. Lea, Capt. H. P. Philpot, Mr. A. W. Johns, and Dr. W. Rosenhain, together with the Chairman of the Advisory Committee for Aeronautics, *ex officio*.

Basic lining; Reinforced — for Martin furnaces. H. Godfroid. Rev. Mét., 1916, 13, 359—360.

MAGNESITE or dolomite (100 parts) is well mixed with hot tar (15 parts) and steel turnings (23 parts). The mixture is applied in 4 in. layers which are compressed by means of red-hot tools; or a layer of the mixture of tar and refractory material (2—3 in.) may be made to alternate with a layer of one-fifth of its weight of steel turnings. —W. R. S.

Steel; Effect of annealing on overheated — S. Smolensky. Rev. Soc. russe Mét., 1916, 1, 31—37. Rev. Mét., 1916, 13, Extraits, 211—212.

THE effect of overheating steel is the more pronounced the higher the carbon and manganese content. Heating to 900° C. and allowing to cool in the furnace does not materially improve the structure of overheated steel. By keeping the articles at a temperature of 1000° C., cooling them slowly, and subjecting them to a second annealing process, a uniform structure and greatly improved mechanical properties are obtained. —W. R. S.

Carbon steels; Temperature of the reversible A1 transformation in — K. Honda. Sci. Reports, Tôhoku Imp. Univ., 1916, 5, 285—295.

TWELVE carbon steels, containing C 0.14—1.50, Si 0.05—0.31, Mn 0.30—0.67, P 0.01—0.051, S 0.014—0.044, Cu 0.05—0.13%, and one specially pure low-carbon steel containing C 0.29, Si 0.05, Mn 0.01, P 0.011, S 0.003%, were heated and cooled at normal and extremely slow rates, and the A1 transformation investigated magnetically. In every case the magnetic transformation of cementite was observed, the critical temperature being about 210° C.; the author proposes to designate this the A0 point. It is concluded that,

however slowly the heating and cooling processes are conducted, the A1 transformation cannot take place reversibly except in carbon steel free from impurities. For pure carbon steel the critical temperature is $727^{\circ}\text{C}.$ and the transformation is reversible, or nearly so, when the rate of heating is extremely slow. With impure carbon steel, whatever the rate of heating and cooling, the A1 point is much lower than the Acl point, the difference depending on the quantity of impurities, other than carbon, in the metal. The A1 point is independent of the maximum temperature previously attained by heating.—W. E. F. P.

Carbon in iron alloys; Rapid determination of —. S. Zinberg. Rev. Soc. russe Met., 1915, 1., 710—712. Rev. Mét., 1916, 13, Extraits, 193-194.

THE powdered alloy is heated with sodium peroxide in a test-tube, the bottom of which is covered with a thin layer of magnesia, until the mixture becomes incandescent and fuses. After cooling, the tube is dropped into 160 c.c. of sulphuric acid (sp.gr. 1.5), with or without 3 c.c. of chromic acid, and the assay finished according to Wiborg's method (this J., 1887, 748). A determination may be made in half an hour. The following mixtures are recommended: ferrochrome 0.2, peroxide 1.2, and magnesia 0.2 grm.; ferrotungsten 0.5, peroxide 1.2, and magnesia 0.1 grm.; ferromolybdenum 0.3, and peroxide 1.2 grm. A blank test must be made for each series of assays.—W. R. S.

Tin ores; Method for assaying —. G. M. Henderson. Eng. and Min. J., 1917, 103, 267. INSTEAD of using nickel crucibles, the fusion of tin ores with sodium peroxide may be carried out in small scorifiers in a muffle, with satisfactory results. The scorifier should not be left in the muffle too long after the mass is liquefied, or an incrustation will be formed which is insoluble in hydrochloric acid.—W. R. S.

Silica bricks and some new uses for them. Gray. See VII.

PATENTS.

Steel furnace; Electrically heated —. *Electric steel furnace.* J. L. Dixon, Detroit, Mich. U.S. Pats. (A) 1,214,763 and (B) 1,214,764, Feb. 6, 1917. Date of appl., Oct. 14, 1916.

(A) THE furnace is supplied with current from a two-phase transformer having two primary windings, and a pair of secondary windings for each primary, the secondary windings being interconnected so as to produce a delta connection expressed by a rectangular vector diagram. Four electrodes are arranged over a crucible, two of which are connected respectively with the right and left terminals of the left-hand member of one of the pairs of secondary windings, while the other two electrodes are similarly connected with the right-hand winding of the same pair. (B) The crucible, which forms no part of the circuit, is provided with two pairs of arcing electrodes, each pair being supplied with current from a primary and secondary of a two-phase transformer. The neutral points of the two secondaries are connected, and independent controlling devices of the ammeter type are connected in the respective leads to the electrodes.—B. N.

Ferrous metals [steel]; Process for deoxidising and refining —. E. H. Schwartz, Chicago, Ill. U.S. Pat. 1,215,065, Feb. 6, 1917. Date of appl., Jan. 6, 1916.

A DEOXIDISED and refined steel of relatively high carbon content is obtained by mixing carbon-steel scrap with spiegeleisen, and pig iron of high silicon content, adding limestone, and melting the charge in presence of carbonaceous material.—J. N. P.

Iron ores; Process of treating —. E. F. Goltra. St. Louis, Mo. U.S. Pat. 1,216,109, Feb. 13, 1917. Date of appl., Apr. 26, 1910.

IRON ore having a clayey gangue is calcined and tumbled in an inclined, rotary cylinder to expel moisture, etc., and loosen the gangue. The calcined material is then subjected to a strong blast by which the lighter particles are carried away; and the residual concentrate is smelted as usual.—W. E. F. P.

Precious metal alloy. W. J. Mellersh-Jackson. London. From G. H. Whiteley, jun., York, Pa., U.S.A. Eng. Pat. 101,025, Feb. 18, 1916. (Appl. No. 2459 of 1916.)

As substitutes for platinum and the platinum alloys employed hitherto for dental purposes, claim is made for alloys (of the general composition Pt 15—20, Pd 30—35, Au 45—55%) containing much less platinum than palladium or gold but sufficient for the melting point to be above that of gold or porcelain as required.

—W. E. F. P.

Aluminium or its light alloys; Method of protecting — *from corrosion by sea water and other liquids.* R. Seligman and P. Williams. London. Eng. Pat. 101,128, Sept. 28, 1916. (Appl. No. 13,831 of 1916.)

STRIPS or plates of an aluminium alloy (e.g., Al-Zn), which is electropositive to the metal or alloy to be protected, are placed in electrical contact with the latter.—W. E. F. P.

Aluminium, its alloys, and other lighter metals; Apparatus for and process of die-casting pure —. F. H. Borst, Artesian, S.D. U.S. Pat. 1,215,243, Feb. 6, 1917. Date of appl., June 22, 1916.

A BAR mounted so that it can be rotated, and having a stop at each end, carries on opposite sides a slide and a counterweight adapted to move outwards against the respective stops. Attached to the slide is a die with a crucible adjacent to its inner end. By the rotation of the bar, molten metal from the crucible is delivered by centrifugal force into the die, the air from the latter being discharged in a direction opposite to that of the flow of metal.—W. E. F. P.

Sulphur dioxide from metallurgical smoke and similar gases; Method of removing —. F. A. Eustis, Milton, Mass. U.S. Pat. 1,212,139, Jan. 16, 1917. Date of appl., May 14, 1915.

THE gases are caused to pass upwards through an absorption tower against a descending stream of water. By means of horizontal, perforated partitions, the tower is divided into superposed compartments, of which the lowest is empty, the next two nearly filled with broken coke, and the remainder charged with crushed dolomite. The quantity of water used is sufficient for physical solution of the sulphur dioxide.—W. E. F. P.

Sintering apparatus. F. A. Eustis, Milton, Mass. U.S. Pat. 1,212,333, Jan. 16, 1917. Date of appl., Aug. 18, 1915.

A SINTERING pan has a hinged cover to which an air-delivery pipe is attached; and the latter is connected with an air-supply pipe by means of a swivel joint. The space below the grate of the pan communicates with a stack, the arrangement being such that, when the pan is closed by the cover, air under pressure is caused to pass downwards through the charge on the grate.

—W. E. F. P.

Nickel ores: Treatment of —. F. A. Eustis, Milton, Mass., U.S. Pat. 1,212,331, Jan. 16, 1917. Date of appl. Aug. 21, 1915.

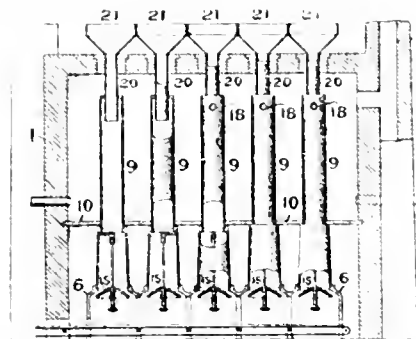

Oxidised nickel ore containing iron and alumina, is mixed with a small proportion of pyrites, and roasted at 400–500° C., whereby the nickel and alumina are converted largely into soluble sulphates, while the iron is not appreciably affected. —W. E. F. P.

Puddling furnace. E. L. Ford, Youngstown, Ohio, U.S. Pat. 1,212,929, Jan. 16, 1917. Date of appl. Sept. 22, 1915.

A CUP-SHAPED puddling furnace mounted so that it can be rotated and tipped on different axes, has its open end closed by a cover which is removed when the finished puddle ball is to be taken out of the furnace. Gaseous fuel is supplied to the interior of the furnace through a pipe, which projects into a hole formed in the centre of the cover, and the waste gases escape through the annular space between the pipe and the cover. —W. H. C.

Retort apparatus [for metals]. E. Fink, Milwaukee, Wis., Assignor to H. W. Seaman, Clinton, Iowa, U.S. Pats. (A) 1,213,316, and (B) 1,213,317, Jan. 23, 1917. Dates of appl. May 9, 1914, and June 10, 1915.

(A) A NUMBER of long, high, and narrow retorts are arranged in a combustion chamber so that

flues are formed between them. Each retort is provided with a vertical feed pipe at the top into which material is fed through a horizontal pipe by a conveyor, so that the retort is sealed from the air, and metallic vapour issuing from the retort is condensed. Vapour from the retort passes through a reduction chamber at one end and thence by a pipe to a condenser placed in a chamber adjacent to the combustion chamber and communicating with it, so that the condenser is heated by combustion products. (B) A series of retorts, 9, are supported on a partition, 10, in a combustion chamber, 1, and a zone of high temperature is maintained just above the partition. Material is fed from the hoppers, 21, through preheating tubes, 20, projecting into the top of each retort so as to leave a space free of material from which vapour is fed by a pipe, 18, to a condenser. The retorts are supported on members, 6, open at the bottom, and the material is retained by supports, 15, through each of which an agitator projects into the retort for breaking up crusts of material. —W. E. F. P.

Manganese: Method of improving the alloying qualities of — with brass and bronze. H. Goldschmidt and O. Weil, Essen, Germany, Assignors to Goldschmidt Thermite Co., New York, U.S. Pat. 1,211,539, Feb. 6, 1917. Date of appl. Dec. 5, 1914.

MANGANESE or ferromanganese is first alloyed with phosphorus and copper, and then added to the metal bath containing the other ingredients. —J. N. P.

Castings: Process of making tight —. R. B. Wolf, Berlin, N.H., U.S. Pat. 1,214,630, Feb. 6, 1917. Date of appl. Mar. 1, 1914.

THE casting is cleaned by treatment with a suitable acid, and a salt is then added which precipitates an insoluble sulphate or other compound in the pores and interstices. During the treatment the metal is subjected alternately to a vacuum and to pressure. —J. N. P.

Magnetic or inductive separation of substances. S. W. Osgood, Chicago, U.S. Pat. 1,214,817, Feb. 6, 1917. Date of appl. Sept. 18, 1914. Renewed June 30, 1916.

THE material is fed through a hopper on to an endless belt which travels horizontally around two supporting wheels. A direct-current electromagnet is suspended above the centre of the belt, in close proximity to the material. The magnet consists of a coil wound round a drum which is placed parallel to the belt. The ends of the drum are provided with extended circular flanges, to the lower ends of which are fixed flat metal plates serving as pole pieces. A shield of non-magnetic metal is interposed to prevent actual contact of particles with the poles. The magnetic field is applied intermittently by means of a revolving armature. Any magnetic substance in the material under treatment is thus raised from the main channel and deposited in an adjacent layer on the belt. —J. N. P.

Furnace: Electric — for fusing metals. Electric zinc distilling furnace and condenser for producing blue powder. J. Thomson, New York, Assignor to John Thomson Press Co., Jersey City, N.J., U.S. Pats. (A) 1,214,811 and (B) 1,214,812, Feb. 6, 1917. Date of appl. Jan. 28, 1916.

(A) THE sides and ends of the furnace are lined with refractory material, and a radiating carbon resistor is suspended in the chamber beneath a melting tank open at the top. The edges of the melting tank rest on the chamber walls, thus closing the chamber, and leaving a space between the tank and the walls, so that the tank is exposed to the heat emitted by the radiator and that reflected by the walls. The furnace is mounted on a rocker, and the tank is provided with a spout for pouring the metal. (B) The furnace is heated by a radiating resistor suspended above the bath, and the fumes pass through channels formed by two septum plates above, viz., through ports on the outside of the lower plate and a central port in the upper one, thus directing the fumes against the roof. The radiation of heat from the latter may be controlled, whereby the temperature of the hot fume is reduced before the gases enter the condenser. —J. N. P.

Zinc-bearing materials: Method of treating — and apparatus therefor. C. A. H. de Saulles, New York, U.S. Pats. (A) 1,215,006 and (B) 1,215,007, Feb. 6, 1917. Date of appl. June 19 and 28, 1915.

(A) MOLTEN zinc-bearing material is fed continuously into a retort heated to about 1350° C., part of the resulting zinc vapour being condensed to liquid metal and the remainder caused to expand rapidly at a relatively low temperature to form "blue powder." (B) The apparatus consists of a cylindrical retort, mounted in a furnace and sloping downwards towards the feed end, which is provided with an external charging funnel. The outlet of the retort communicates with a short, horizontal condenser (for the liquid metal) and the latter with a relatively large vertical pipe or chamber in which the blue powder is deposited. —W. E. F. P.

Reducing and metallising ores: Apparatus for —, H. N. Tracy, Los Angeles, Cal. U.S. Pat. 1,214,844, Feb. 6, 1917. Date of appl. Oct. 12, 1915.

A RESERVOIR for liquid metal is composed of a horizontal portion and a vertical arm at each end; a high vertical ore-reducing stack forms a continuation of one of the arms, whilst the other is provided with a means for discharging the spent ore. The horizontal portion is provided with a spiral conveyor, and the reservoir is adapted to hold liquid metal to a level above the horizontal part, so that the weight of the charge will force the ore beneath the level of the molten metal as it enters the horizontal portion.—B. N.

Brazing material. T. S. Fuller, Schenectady, N.Y., Assignor to General Electric Co. U.S. Pat. 1,215,138, Feb. 6, 1917. Date of appl. Jan. 29, 1915.

COPPER parts are united by an intervening metallic film of a malleable tenacious alloy, containing 57 to 65 parts of silver, about 38 to 29 parts of cadmium, and some copper, the alloy having a melting point about 750° C.—B. N.

Metallic alloys [ferro-nickel]: Process of producing —, M. A. Robert, York, Pa. U.S. Pat. 1,215,857, Feb. 13, 1917. Date of appl. Apr. 8, 1914. Renewed May 23, 1916.

CALCIUM fluoride is melted in an electric furnace and electrolysed in the presence of nickel-bearing iron ore or a nickel compound and metallic iron.—W. E. F. P.

Metals and other materials: Method of treating — by heat. J. H. L. de Bats, Assignor to A. G. Zehner, Zehlendorf, and T. de Wolf, Pittsburgh, Pa. U.S. Pat. 1,216,086, Feb. 13, 1917. Date of appl. Mar. 19, 1914. Renewed July 11, 1916.

THE material is heated in a crucible or in direct contact with solid fuel in a closed chamber from which the gaseous products are withdrawn by suction while a limited quantity of air is admitted to the lower part of the fuel bed. The interior of the chamber is thus maintained under reduced pressure and the heat confined to the zone containing the material under treatment.—W. E. F. P.

[Crucible] furnace apparatus. W. W. Doolittle, Assignor to Crane Co., Chicago, Ill. U.S. Pat. 1,216,090, Feb. 13, 1917. Date of appl. Mar. 31, 1914.

IN a gas-fired crucible furnace, each crucible is contained in a separate heating chamber consisting of a lower section, which can be tilted, and above which the top of the crucible projects, and a removable upper section or cover. The lower section has an inclined pouring face opposite the crucible lip, and is adapted to seat a coping member by which the crucible is maintained in position, and the pouring facilitated, when the section is tilted.—W. E. F. P.

Electric furnace. H. de Nolly, St. Chamond, Assignor to Soc. Electro-Métallurgique de St. Bérón, Lyon, France. U.S. Pat. 1,216,961, Feb. 20, 1917. Date of appl. Jan. 31, 1914.

SEE Fr. Pat. 466,116 of 1913; this J., 1914, 599.

Apparatus for extracting values from bodies. U.S. Pat. 1,215,182. See 1.

Filtering medium for cleaning furnace-gases. U.S. Pat. 1,215,385. See 1.

XI.—ELECTRO-CHEMISTRY.

Silver voltmeter: Volume effect in the —, E. B. Rosa and G. W. Vinal. Bull. U.S. Bureau of Standards, 1916, 13, 447—457.

THE volume effect, consisting of the deposition of an excess weight in the large size voltmeters, in

the cases of the porous cup, Kohlrausch, siphon, and filter-paper forms, has been shown to be due to the presence of impurities in the electrolyte. Using the same cathodes, anodes, and porous cups, the volume effect may be made to appear and disappear according as the electrolyte is contaminated or not. Very high results have been obtained by contaminating the solutions with impurities, such as colloids. With the same cathode and solution, the volume effect may be increased by increasing the volume of electrolyte, i.e., increasing the amount of colloid present, as in the case of the siphon voltmeter.—B. N.

PATENTS.

Oxygen and hydrogen gases: Apparatus for the [electrolytic] production of —, W. Jones, New York. U.S. Pat. 1,212,229, Jan. 16, 1917. Date of appl. Oct. 16, 1913.

THE apparatus is provided with a number of electrodes, and a diaphragm between adjoining electrodes forming chambers for the separation of the evolved gases, with gas ducts leading from them and separate conduits connected with the gas ducts. The electrolyte is conveyed to the several chambers by supply ducts connected to a supply conduit, the various conduits being located beyond the electrodes, and so arranged as to be outside the path of the electric current through the apparatus.—B. N.

Electrolytic apparatus. W. E. Greenawalt, Denver, Colo. U.S. Pat. 1,211,775, Feb. 6, 1917. Date of appl. Aug. 18, 1913.

THE apparatus is provided with an electrode cell, the sides of which are formed from top and bottom pieces bolted together with a diaphragm between them, and the bolts in the bottom piece are protected from the corrosive action of the electrolyte. Means are provided in the bottom piece for the escape of the gases from the under side of the diaphragm. The cell contains a perforated electrode, with a hood over it, and with a liquid seal between the electrode and the hood. The perforated electrode on its outside edge is provided with a flange projecting in a downward direction, to collect the gases on the under side of the electrode and direct them through the perforations into the hood.—B. N.

Electrolytic gas-generator. I. H. Levin, New York. U.S. Pat. 1,211,934, Feb. 6, 1917. Date of appl. Dec. 20, 1915.

A CLOSED receptacle is formed from two similar dished casing members, the edges of which are placed adjacent to each other, and a partition is located in the upper portion of the receptacle, whereby the interior is divided into two gas chambers. A diaphragm projects downwards from the partition, with one electrode on each side. The receptacle is provided with means for filling and for conveying the gases from the gas chambers.—B. N.

Storage battery. W. Gardiner, Chicago, Ill. U.S. Pat. 1,213,182, Jan. 23, 1917. Date of appl. May 22, 1915.

THE electrolyte, of the consistency of jelly, is composed of sulphuric acid (sp. gr. 1.30) mixed with a "solution" of a half-pint of water, 2 oz. of sodium silicate, and 1 to 8 oz. of infusorial earth. This is covered with porous material and then with absorbent material.—B. N.

Impregnated [electrical] coil and method of making the same. L. H. Bakeland, Yonkers, N.Y., Assignor to General Bakelite Co., New York. U.S. Pat. 1,213,726, Jan. 23, 1917. Date of appl. Dec. 1, 1907.

THE windings of the coil are spaced apart, and are

provided with a fibrous covering, the interstices between the windings being filled, and the fibrous covering simultaneously impregnated, with a fluid and mobile phenolic condensation product, combined with a substance capable of increasing the flexibility of the final product. The product is transformed, whilst in position, into a solid, homogeneous, impervious, insoluble, and infusible body, serving both as a support and as an insulator for the windings.—B. N.

Method of liriciation of vegetable, animal, or mineral substances. Ger. Pat. 291,667. See I.

[Electrolytic] oxidation of cresols. Eng. Pat. 103,739. See III.

[Electrolytic] process of making cyanogen compounds. U.S. Pat. 1,214,770. See VII.

Process of obtaining a hard fully-burnt, high-grade coke as by-product in the manufacture of lamp-black. Ger. Pat. 291,701. See XIII.

XII.—FATS; OILS; WAXES.

Lumbang and perilla oils. H. A. Gardner. Oil, Paint, and Drug Rep., Feb. 5, 1917, 91, 55.

Lumbang oil is obtained from the fruit kernels of *Alcurites moluccana*, which is indigenous to Polynesia and is now cultivated in many parts of Asia and in tropical islands. The oil is almost colourless and has a purgative action. It closely resembles tung oil in its characters, but has not the polymerising property of the latter. The pressed cake is prized by the natives as a fertiliser. A sample of the nuts contained 32.1% of kernels which on expression yielded 60.3% of oil with the following characters:—Sp. gr. 0.927; acid value, 1.3; saponif. value, 192.3; iodine value, 162.0; and refractive index, 1.475. The press-cake when freed from oil by extraction with petroleum spirit, and dried, had the following composition:—Nitrogen, 7.34; phosphoric acid (P_2O_5), 3.95; sodium oxide, 0.47; and potassium oxide, 1.42%. *Perilla oil*:—A sample of perilla seed from Yokohama yielded 33.73% of oil with the following characters:—Sp. gr. 0.937; acid value, 4.3; saponif. value, 193.4; iodine value, 193.3; and refractive index, 1.4870. The press-cake had the following composition after extraction of the residual oil:—Nitrogen, 5.28; phosphoric acid (P_2O_5), 2.58; sodium oxide, 0.56; and potassium oxide, 1.50%.—C. A. M.

Spinacene: a new hydrocarbon from certain fish liver oils. A. C. Chapman. Chem. Soc. Trans., 1917, 141, 56—69.

AS oil obtained from the livers of *Centrophorus granulosus* and *Seymouria licha*, both belonging to the *Spinacidae* or sharks, which are caught off the Moroccan coast, had the following characters:—Sp. gr. at 15°/15° C., 0.8666; saponification value, 22.5; iodine value (Wijs), 358; unsapon. matter, 89.1%; iodine value of unsapon. matter, 376.2; free fatty acid (as oleic acid), 0.12%; and bromine precipitate insoluble in ether, 76.5%. The unsaponifiable matter when distilled under a pressure of 10 mm. yielded a small amount of cholesterol, whilst the main fraction, distilling between 268° and 269° C., was a colourless mobile oil, with a faint odour suggestive of limonene (see also Mastbaum, this J., 1916, 316). It boiled at 280° C. under a pressure of 17 mm., and its elementary composition corresponded with the formula, $C_{30}H_{50}$. On the other hand, the depression of the freezing point gave a molecular

weight agreeing more closely with the formula $C_{27}H_{44}$ or $C_{28}H_{44}$. It was optically inactive, did not solidify at -20° C., had a sp. gr. of 0.8611 at 15°/15° C., and a refractive index, $n_D^{20} = 1.4987$. When exposed in a flat dish for two months to an atmosphere of oxygen it absorbed 23.8% of oxygen and became very viscid. Thin films of the hydrocarbon exposed to the air yielded hard skins similar to that given by linseed oil. Dry hydrogen chloride when passed into an ethereal solution of "spinacene" yielded a crystalline hexahydrochloride, $C_{30}H_{50}.6HCl$, beginning to melt at 110° C. and decomposing at 110° C. with the liberation of hydrogen chloride. After separation of the hexahydrochloride, a pale yellow viscous trihydrochloride, $C_{30}H_{50}.3HCl$, could be obtained from the filtrate. Bromine not only saturated the double bonds of the hydrocarbon, but also formed substitution derivatives. A dodecylbromide, $C_{30}H_{50}Br_{12}$ was obtained as a white crystalline product. Trinitroso- and hexanitrosochlorides were also prepared. Hydrogenation of spinacene, with platinum black as catalyst, reduced the iodine value to 18, and a hydrocarbon, $C_{30}H_{62}$, boiling at 271° to 275° C. (18 mm.) was obtained. This was a colourless odourless oil not solidifying at -20° C., and having a sp. gr. of 0.8172 at 20°/20° C. The unsaturated hydrocarbon "sequene" separated by Tsujimoto (this J., 1916, 609, 1121) from the livers of certain Japanese sharks, closely resembles spinacene and may be identical therewith.—C. A. M.

Soaps; Specifications for and methods of testing—. Circular No. 62, Dec. 16, 1916. Bureau of Standards, Dept. of Commerce, U.S.A., 1—25.

1. *Milled soaps.* The following are suggested as the maximum permissible limits:—Matter volatile at 105° C., 15% (in case of excess, deliveries to be rejected); free alkali as NaOH, 0.1%; alkali as alkaline salts (as Na_2CO_3), 0.3%, of which not more than half shall consist of sodium silicate; sulphate as Na_2SO_4 , 0.4%; chloride as NaCl, 0.3%; substances insoluble in water, 0.1%; unsaponified saponifiable matter, 0.1%. No rosin, sugar, or foreign matter is to be present. The mixed fatty acids must solidify (titertest) not below 37° C., and have a neutralisation value falling within the limits 203 and 212. Apart from moisture, the constituents are to be calculated on the basis of material containing 10% of volatile matter. A deduction of 2% from the weight of the soap delivered shall be made for each 1% of volatile matter in excess of 10%. 2. *White floating soap.* Matter volatile at 105° C., 34% (in case of excess, deliveries to be rejected); free alkali as NaOH, 0.1%; alkali as alkaline salts (as Na_2CO_3), 0.5%; chloride as NaCl, 1%; substances insoluble in water, 0.1%; no rosin, sugar, or foreign matter shall be present. The mixed fatty acids shall melt at not less than 35° C., and have a neutralisation value of not less than 212. The odour and character of the cake shall be as specified. Constituents other than moisture are to be calculated on the basis of material containing 28% of volatile matter, and a deduction of 2% from the weight of the soap to be paid for shall be made for each 1% of volatile matter in excess of 28%. 3. *Liquid soap.* This should consist of a clear solution of pure vegetable oil-potash (or potash and soda) soap, with or without alcohol or glycerol, suitably perfumed, and free from foreign matter. It must be free from objectionable odour, other than that of coconut oil, must lather readily, and contain not less than 20% of soap. Free alkali, as KOH, must not exceed 0.05%; alkali as alkaline salts (as K_2CO_3), 0.3%; chloride as KCl, 0.3%, whilst no sugar or sulphates must be present. 4. *Salt-water soap.* This must have been made exclusively from pure coconut oil, without removal

of glycerol. It should dissolve completely in both sea water and fresh water, lather well, and be free from filling materials. Matter volatile at 105° C. shall not exceed 55% (in case of excess, deliveries to be rejected); free alkali as NaOH, 0.5%; alkali as alkaline salts (as Na_2CO_3), not less than 2 nor more than 3%, of which not more than a quarter shall be sodium silicate; chloride as NaCl, not less than 2.5 nor more than 3.5%; mineral matter including sodium sulphate, substances insoluble in water, etc., 0.5%. No rosin, sugar, or foreign matter shall be present. The mixed fatty acids separated from the soap must have a neutralisation value of not less than 256. All non-volatile constituents are to be calculated on the basis of material containing 55% of volatile matter. In calculating the weight of soap to be paid for, $\frac{1}{2}$ lb. of matter not volatile at 105° C. shall be considered 1 lb. of soap. 5. *Special grade laundry soap.* This is intended to be used with soft water for cleaning and laundry purposes, where the presence of sodium silicate or carbonate may be objectionable. It should contain not more than 20% of water. Matter volatile at 105° C. must not exceed 34%; free alkali as NaOH, 0.2%; alkali as alkaline salts (as Na_2CO_3), 1%; chloride and sulphate, together, 1%; substances insoluble in water, 0.1%; and rosin, 15%. The mixed fatty and rosin acids shall solidify at not less than 35° C. Substances other than volatile matter are calculated on the basis of 28% of volatile matter. In calculating the weight to be paid for, $\frac{3}{8}$ lb. of matter not volatile at 105° C. shall be considered 1 lb. of soap, a deduction of 2% from the weight of the soap being made for each 1% of volatile matter in excess of 28% up to the limit of 34%. 6. *Ordinary grade laundry soap.* This soap is intended for use with moderately hard waters where there is no objection to the presence of rosin or sodium carbonate. It should contain not more than 20% of water. Matter volatile at 105° C. must not exceed 31%; free alkali as NaOH, 0.5%; alkali as alkaline salts (as Na_2CO_3), not less than 2%, nor more than 6%, and not more than half shall consist of sodium silicate; chloride as NaCl, 1%; sulphate as Na_2SO_4 , 1%; substances insoluble in water, 0.5%; rosin, 25%. The mixed fatty and rosin acids shall solidify at not less than 33° C. Constituents other than volatile matter are to be calculated on the basis of 28% of volatile matter. The weight of soap to be paid for is calculated in the same way as in the case of No. 5. 7. *Chip soap.* This must be suitable for use with soft water for high-grade laundry work. Matter volatile at 105° C. must not exceed 15%; free alkali as NaOH, 0.5%; alkali as alkaline salts (as Na_2CO_3), 0.5%; chloride as NaCl, 0.5%; and substances insoluble in water, 0.1%. Constituents other than volatile matter are to be calculated on the basis of material containing 10% of volatile matter. In calculating the weight, 9/10 lb. of matter not volatile at 105° C. shall be considered 1 lb. of soap, a deduction of 2% from the weight of soap being made for each 1% of volatile matter in excess of 10%, up to the limit of 15%. *Sampling deliveries.*—(a) *Cake soap.* One cake, weighing not less than 1 lb., is to be taken at random from each 1000 cakes. If the cake weighs less than 1 lb. additional cakes (not less than 3) to make up a sample of not less than 1 lb. shall be taken. The samples shall be placed in an air-tight container. (b) *Liquid soap.* After thorough admixture a sample of 1 qt. for each 100 galls. shall be taken and placed in a dry quart glass bottle. (c) *Chip soap.* Not less than 1 lb. shall be taken at random from each 1000 lb. or less of a shipment. This shall be placed in a dry air-tight container, which it must fill completely. *Preparation of laboratory sample.*—*Cake soap.* After reserving two cakes of medium weight in their air-

tight containers, a cake also of medium weight is divided diagonally and thin layers are cut from the fresh surfaces in such a way as to get a fair proportion of the inner and outer portions. *Liquid soap.* In cold weather the sample should be allowed to stand for at least 1 hour at 20° to 30° C., before taking samples for analysis. *Chip soaps.* The sample should be rapidly mixed before weighing the portions for analysis. *Methods of analysis.*—(a) *Matter volatile at 105° C.* Two grms. is spread evenly over the bottom of a porcelain dish 3 in. in diameter. After drying for 1 hour at 60° C., 50 c.c. of absolute alcohol is added, the liquid evaporated, and the residue dried for 1 hour at 60° C. and then for 2 hours at 105° C. (b) *Free alkali or acid (method for all except liquid soaps).* 5 grms. is dissolved in about 200 c.c. of freshly-boiled neutral 95% alcohol, with the aid of heat, the solution filtered through a weighed Gooch crucible, and any insoluble matter washed with hot freshly-boiled neutral alcohol. The filtrate and washings are cooled, and titrated with standard acid or alkali, with phenolphthalein as indicator. Free alkali is calculated as sodium hydroxide and free acid as oleic acid. (c) *Free alkali or acid (method for liquid soaps).* 10 grms. of the sample is dissolved in about 200 c.c. of freshly-boiled neutral absolute alcohol, the solution filtered, and the insoluble matter washed with freshly-boiled neutral alcohol. The filtrate and washings are titrated as described, free alkali being calculated as potassium hydroxide and free acid as oleic acid. (d) *Alkali as alkaline salts.* The residue insoluble in alcohol from (b) or (c) is extracted with hot water, and the solution is titrated with standard acid (HCl), with methyl orange as indicator. The result, which is calculated into sodium carbonate, includes carbonates, borates, and silicates. (e) *Silicate.* The solution which has been titrated for (d) is evaporated to dryness with excess of hydrochloric acid, and the silicate determined in the usual way, and calculated into the equivalent sodium carbonate. (f) *Sulphate.* The filtrate from (c) is treated with barium chloride. The barium sulphate is calculated into sodium sulphate except in the case of liquid soaps in which it is calculated into potassium sulphate. (g) *Substances insoluble in water.* The Gooch crucible containing the insoluble matter in (d) is dried for 2 hours at 105° C. and weighed. (h) *Unsaponified saponifiable matter.* 5 grms. of soap is dissolved in about 100 c.c. of 50% alcohol, any free fatty acids present being neutralised with standard alkali, and washed into a separating funnel with 50% alcohol. The solution is extracted with 100 c.c. of ether, the ethereal extract washed with water, and the unsaponified matter weighed. It is then boiled for an hour beneath a reflux condenser with 25 c.c. of alcoholic potassium or sodium hydroxide solution, the liquid evaporated to dryness, and the residue dissolved in water, and shaken with ether. The ether is washed free from alkali, and evaporated, and the residue of unsaponifiable matter dried and weighed. This is deducted from the unsaponified matter, and to the difference is added the amount of free fatty acids previously determined, the result giving the total unsaponified saponifiable matter. (i) *Preparation of total fatty acids (method for milled-toilet, white floating, or salt-water soaps).* 50 grms. of the soap is dissolved in 300 c.c. of hot water, and the solution transferred to a separating funnel, treated with 150 c.c. of about 2 N-sulphuric acid, and, after cooling, shaken with 120 c.c. of ether. The ethereal layer is washed until free from acid, with a strong solution of sodium chloride, and transferred to a flask, shaken with 20 to 30 grms. of anhydrous sodium sulphate, and allowed to stand until clear. It is then filtered and evaporated by means of a current of dry air at a temperature not exceeding 50° C. (j) *Fatty and rosin acids (method for*

laundry or chip soaps). About 50 grms. is dissolved in 500 c.c. of hot water, and the solution treated with 100 c.c. of 30% sulphuric acid and heated until a clear layer of fatty matter is obtained. This is washed with hot water, filtered through a hot-water funnel, and dried for 20 mins. at 100° C. (*b*) *Solidification point of fatty acids (ther test)*. About 25 c.c. of the fatty acids cooled to about 50° C., is introduced into a glass tube about 1 mm. thick, 25 mm. in diam., and 100 mm. in length. This is fitted by means of a cork into a bottle about 70 mm. in diam. and 150 mm. in height, and the fatty acids are slowly stirred with a thermometer until the mercury remains stationary for 30 secs., when the thermometer is suspended with its bulb in the centre of the mass, and the point to which the mercury rises is noted. (*c*) *Neutralisation value of fatty acids*. From 2 to 5 grms. of the fatty acids is heated with 50 c.c. of neutral alcohol (free from carbon dioxide), and the solution is titrated with standard alcoholic alkali, with phenolphthalein as indicator. (*m*) *Total alkali (method for all except liquid soaps)*. 5 grms. is dissolved in 100 to 150 c.c. of hot water, 40 c.c. of N/2 sulphuric acid added, and the mixture heated on the water bath until a clear layer of fatty acids is obtained. The beaker is cooled in cold water, the aqueous layer filtered, and the beaker, fatty acids, and filter washed with water. The united filtrate and washings are titrated with N/5 potassium hydroxide solution with methyl orange as indicator. The total alkali is calculated as sodium oxide. (*n*) *Total alkali (method for liquid soaps)*. The acid aqueous liquids obtained in the determination of total soap are heated to remove ether, and the excess of acid titrated as in (*m*). The result is calculated as potassium oxide. (*o*) *Chloride*. The neutral solution from the titration of the total alkali is titrated with N/10 silver nitrate solution, with potassium chromate solution as indicator. The chloride is calculated as sodium chloride (potassium chloride in the case of liquid soaps). (*p*) *Rosin*. As a qualitative test a small quantity of the fatty acids is heated with acetic anhydride, and a few drops of the liquid brought in contact with a drop of sulphuric acid (sp. gr. 1.83). A fugitive violet coloration indicates rosin. For a quantitative determination 5 grms. of the sample is dissolved in 100 to 200 c.c. of hot water, and the fatty acids separated by the addition of 40 c.c. of N/2 sulphuric acid, washed with ice-water, dried for an hour at 105° C., and dissolved in 20 c.c. of absolute alcohol. The solution is treated with 10 c.c. of a mixture of 1 vol. of strong sulphuric acid and 1 vols. of absolute alcohol, and boiled for 4 mins. beneath a reflux condenser. It is next treated with about 5 times its vol. of 7 to 10% sodium chloride solution, and extracted with ether. The aqueous layer is shaken two or three times with ether, and the united ethereal extracts are washed with sodium chloride solution until free from acid. The rosin acids are titrated with standard alcoholic sodium hydroxide solution (1 c.c. N/1 alkali = 0.346 gm. rosin). (*q*) *Total soap (method for liquid soaps)*. 10 grms. is dissolved in 100 c.c. of water, and the solution heated with 10 c.c. of N/2 sulphuric acid until a clear layer of fatty acids is obtained. The acid aqueous layer is twice shaken with 20 c.c. portions of ether, the fatty acids dissolved in the same ether, and the solution washed until no longer acid to methyl orange. The aqueous washings are united and shaken with 20 c.c. of ether. This ether is washed free from mineral acids and added to the other ethereal solutions, which are then evaporated at a temperature below 50° C. The residue is dissolved in neutral alcohol (free from carbon dioxide), the solution neutralised with standard alcoholic potassium hydroxide solution, and evaporated to dryness, and the residue of soap dried at 105° C. and

weighed. Any unsaponified or unsaponifiable matter is deducted from the result. (*r*) *Sugar*.—*Qualitative test*. A solution of the soap is heated on the water bath for 15 mins. with an excess of hydrochloric acid; and then cooled and filtered from fatty acids. The filtrate is boiled for 2 mins. with an equal volume of Fehling's solution.

—C. A. M.

Emulsification: Theory of — based on pharmaceutical practice. L. Roon and R. E. Oesper. J. Ind. Eng. Chem., 1917, 9, 156–161.

EXPERIMENTS are described in which gum arabic and soap solution were used as emulsifying agents for mixtures of water with cottonseed oil, mineral oil, oil of turpentine, benzene, chloroform, carbon tetrachloride, or hexane as internal phases. In the case of gum arabic the volumes of internal phase (10 c.c.) and water (7.5 c.c.) were kept constant, whilst the amount of gum arabic was varied to determine the minimum quantity required for emulsification. In the case of the soap solution 1 c.c. was used with 10 c.c. of the internal phase, and the minimum addition of water was determined. It was found that an excess of water produced much frothing, whilst insufficient water produced streaks on the sides of the tube due to incomplete emulsification. The critical point between these extremes could be determined within 0.1 c.c. of water. Systems containing a few tenths of a c.c. below the critical proportion formed emulsions if allowed to stand for 10 mins. before shaking. In general, the critical volume of water decreased relatively with the increase in the total volume of emulsion to be formed. The results obtained in the two series of experiments supported Fischer's theory (Science 1916, 43, 168), that the presence of a hydration compound is an essential in emulsification. The best results are obtained when this hydration compound is formed at the moment of dispersion of the internal phase, the globules produced by the shaking then becoming coated with the hydrated colloid. For example, better and more rapid emulsification is effected by adding all at once 7.5 c.c. of water to 10 c.c. of mineral oil and 5 grms. of gum arabic, than by the addition of 11.5 c.c. of water in successive small quantities. An excess of water (more than 7.5 c.c.) added all at once gives a less satisfactory emulsion than that obtained by diluting a previously prepared "nucleus" with the same excess of water. This is in accordance with the results of pharmaceutical practice. Slight variations from the critical proportions of the three constituents (water, internal phase, and emulsifier), or in the procedure lead to the formation of a less stable emulsion or of none at all. The critical proportions vary with the quantities and nature of the constituents. It was also found that "nuclei" of one system would tend to render stable incomplete emulsions of another system, and that a "nucleus" of one composition would act as an emulsifying agent for other internal phases.

The Shreveburg and Knapp process for the determination of coconut oil [in butter and margarine]. Elsdon and Bagshawe. See XIXA.

PATENTS.

Solutions containing oil, fat or wax: Distillation of solvents from — H. J. Pooley, and G. Scott and Son, Ltd., London. Eng. Pat. 103,682, Jan. 31, 1916. (Appl. No. 1466 of 1916.)

DISTILLATION is effected in a series of stills, the partially distilled contents of the top still passing at a regulated rate to the next lower one, and so successively to the bottom still, in which the heating is wholly or mainly effected, and thence to the discharge pipe. The vaporised solvent

(for solvent with steam, etc.) rises successively through the stills to the top one, whence it is conducted to a condenser. (Reference is directed, in pursuance of Sect. 7, Sub-sect. J, of the Patents and Designs Act, 1907, to Eng. Pats. 2900 of 1897 and 2847 of 1900; this J., 1897, 602; 1900, 437.)—C. A. M.

Oil-soaps; Process of making soft, transparent sodium —. J. W. Ryder, Assignor to Specification Soap and Oil Co., Inc., New York. U.S. Pat. 1,212,818, Jan. 16, 1917. Date of appl., July 12, 1915.

ABOUT 100 lb. of a vegetable oil is heated to 100 to 110° F. (38°—43° C.), about 3 lb. of denatured alcohol added, and the mixture saponified with about 50 lb. of caustic soda lye of 35° B. (sp. gr. 1.332) having a temperature of 60° to 90° F. (15.5°—32° C.). After the addition of 30 to 60% of water the mass is boiled until a transparent soap of the desired consistency is obtained.—C. A. M.

XIII.—PAINTS; PIGMENTS; VARNISHES; RESINS.

Resin of fir and pine. C. G. Schwalbe. Z. Forst- u. Jagdwesen, 1916, 92—103. Z. angew. Chem., 1916, 29, Ref. 186.

THE yield of resin from fir and pine, obtained by successive extractions with ether and alcohol, was considerably higher from new than from seasoned wood, especially with the former solvent. The ether extractive was yellow and oily and bitter to the taste, whilst alcohol yielded brown, almost brittle resins. The extractives contained a considerable proportion of unctuous fat, chiefly glycerol esters of oleic acid, and in smaller amounts esters of other unsaturated acids, such as linolic and linolenic acids; the pure resins were hard and brittle. From new wood resins were obtained with lower acid values and appreciably higher iodine values than from seasoned wood. The resins yielded no turpentine when distilled with steam, but turpentine was produced on heating either the fresh or extracted wood with caustic soda, under pressure, at 170° C.—F. SOBN.

Coumarone resin in the manufacture of lacquers. Krumhaar. Farben-Zeit., 1916, 21, 1086—1088. Z. angew. Chem., 1916, 29, Ref. 187.

COUMARONE resin is a neutral substance, indifferent towards saponifying agents. It is best dissolved in solvent naphtha I or II to which benzene may be added. Drying is due to volatilisation of the solvent, polymerisation of the paracoumarone, and autoxidation of the paraindene; the last is the most important factor, and good drying is chiefly dependent therefore on a high proportion of paraindene. The film of dried resin may exhibit a glossy or matt surface and for a time increases both in toughness and hardness, but ultimately it becomes brittle and develops cracks. When unsuitable, the consistency of the resin may be modified by the addition of solid resins or of linseed oil or linoxyn.—F. SOBN.

PATENTS.

Putty; Manufacture of —. E. Harkko, Kotka, Finland. Eng. Pats. (A) 15,248 and (B) 15,249, Oct. 28, 1915.

(A) PUTTY with a considerable degree of elasticity is obtained by using instead of ordinary oil, a mixture prepared by boiling rosin oil, 700 grms., until it ceases to froth and then stirring into it petroleum, 300 grms. (B) Animal glue, 50 grms., is dissolved and boiled in water, 200 grms. Bolted (rye) meal, 50 grms., is made into a paste with boiling water, 300 grms., and this paste is stirred into the glue solution; the whole is then mixed

hot with petroleum, 50 grms., and rosin oil, 350 grms., after which chalk or whiting may be added.

—E. W. L.

Paint and process of making same. A. G. Betts, Asheville, N.C. U.S. Pat. 1,213,330, Jan. 23, 1917. Date of appl., Apr. 27, 1915.

THE paint contains precipitated, dehydrated barium phosphate and a drying oil.—E. W. L.

Paint composition. G. C. Hicks, Chicago, Ill. U.S. Pat. 1,215,022, Feb. 6, 1917. Date of appl., Aug. 6, 1915.

A PIGMENT is incorporated with a mixture of glucose (less than 50%) and linseed oil (more than 50%), with or without filling material.—C. A. M.

Pigment powder and process of making the same. S. M. McMurray, Smyrna, and J. R. Parrish, Nashville, Tenn. U.S. Pat. 1,215,293, Feb. 6, 1917. Date of appl., Feb. 3, 1916.

A COMPOSITION intended to render inked impressions proof against the action of petroleum spirit, and to intensify such impressions, consists of a mixture of a saccharine substance (1 part of glucose) with a pigment (3 parts of lampblack), and an inert filling material (5 to 20% of starch). The glucose and lampblack may be mixed with water to render the mixture plastic, and then dried, powdered, and incorporated with the filling material.—C. A. M.

Water-glass paints which in use quickly become waterproof; Preparation of —. W. Gallenkamp, Grosshesselohe. Ger. Pat. 291,339, Apr. 1, 1916.

ORDINARY water-glass paints are mixed with an aqueous solution of an alkali bicarbonate or similar substance yielding carbon dioxide on heating, and the mixture is heated shortly before use. On heating, a uniform separation of very finely divided silicic acid takes place which renders the mixture more viscous without affecting its covering properties and renders the paint waterproof and weatherproof within twelve hours of its application.—F. SOBN.

Coke as a by-product in the manufacture of lamp-black; Process of obtaining a hard, fully-burnt high-grade —. A. Wegelin A.-G. für Russfabrikation u. Chem. Industrie, Cologne. Ger. Pat. 291,701, Mar. 27, 1915.

LIQUID fuel containing free carbon is submitted to distillation and imperfect combustion in a short cylindrical furnace which is kept in motion (preferably by rotation about a horizontal axis), in such manner that every part of the internal wall is moistened at intervals by the liquid charge and each successive film completely carbonised in turn by the heat of the flame. The coke produced yields very little ash and is suitable for making carbons for electrical work.—F. SOBN.

Gums or gum-resins; Preparation and purification of certain —. H. C. Miller, London, and H. A. Irlam, Mill Hill. Eng. Pat. 103,006, Jan. 11, 1916. (Appl. No. 639 of 1916.)

THE purification of gums or gum-resins, e.g., acaroid, grass tree, black boy, and Botany Bay gums—and their preparation in a granular or pulverulent form is effected by precipitating them from their solutions in alkali by means of an acid or acid salt. As alkalis, caustic soda, caustic potash, or ammonia may be used, and as acids, sulphuric, hydrochloric, or oxalic acid, or the acid salts of the first and last. Nitre cake may be used with good results. For example crude gum or gum-resin, 100, is dissolved in water, 500, containing in solution caustic soda (96—98% NaOH) 17 parts, at 80° C. The solution is filtered, and to the filtrate a mixture of sulphuric acid, 1, and water 10 parts is added, the temperature being main-

tained at 40°–60° C., preferably between 50° and 55° C. The precipitated gum is separated by filtration.—E. W. L.

Coaling composition; *Liquid* —, A. L. Brown, Wilkinsburg, Pa., Assigning to Westinghouse Electric and Manufacturing Co., U.S. Pat. 1,212,738, Jan. 16, 1917. Date of appl. Dec. 30, 1911.

THE composition contains a phenolic condensation product, a drying oil (Chinese wood oil), and a lead-manganese drier. The drying oil is present in greater proportion than the condensation product. — E. W. L.

[Resinous] *condensation product*, C. P. Steinmetz, Schenectady, N.Y., Assignor to General Electric Co., U.S. Pat. 1,215,072, Feb. 6, 1917. Date of appl. Jan. 2, 1915.

THE product described is a non-inflammable resin consisting of the condensation product of a halogenated phenol (monochlorophenol) and a substance containing an aldehyde group (formaldehyde).—E. W. L.

Condensation products from phenol, formaldehyde, and the like; *Manufacturing* —, K. Tarassoff, Moscow, Russia, U.S. Pat. 1,216,515, Feb. 20, 1917. Date of appl. Feb. 21, 1914.

SEE Eng. Pat. 528 of 1911; this J., 1911, 557.

Aldehydes and phenols; *Manufacture of hard compositions of matter from* —, K. Tarassoff, Moscow, Russia, U.S. Pat. 1,216,516, Feb. 20, 1917. Date of appl. May 7, 1911.

SEE Fr. Pat. 470,810 of 1911; this J., 1915, 187.

Condensation products; *Method of producing* — and *product thereof*, F. Pollak, Berlin, U.S. Pat. 1,216,728, Feb. 20, 1917. Date of appl. Sep. 11, 1910.

SEE Fr. Pat. 420,401 of 1910; this J., 1911, 373.

Manufacture of lead monoxide, Eng. Pat. 100,069. See VII.

Impregnated [electrical] coil and method of making the same, U.S. Pat. 1,213,726. See XI.

XIV.—INDIA-RUBBER; GUTTA-PERCHA.

Vulcanisation; *Coefficient of* — and *state of cure*, P. Schidrowitz and H. A. Goldsbrough, India-rubber J., 1917, 53, 327–328.

THE authors point out that the figures referred to by Stevens (India-Rubber J., 1917, 53, 17–19) as given by them for combined sulphur do not necessarily represent their final opinion on the subject. It is quite possible that some of the rubbers referred to are exceptional. The question at issue is whether state of cure is to be judged by chemical or mechanical properties of the vulcanised article, that is by the amount of sulphur combined with the rubber, or by the stress-strain curve. The authors re-state the case for the latter, with reference to the papers by Spence (this J., 1917, 92), and de Vries (this J., 1917, 296).—E. W. L.

PATENTS.

Rubber waste; *Process for recovering* —, R. F. Kinsley, East Cleveland, J. D. Morron, Lakewood, and C. R. Haynes, Cleveland, Ohio, Assignors to Mechanical Rubber Co., U.S. Pat. 1,215,911, Feb. 13, 1917. Date of appl. Feb. 1, 1915.

RUBBER waste containing fibrous material is comminuted, and the fibrous material disintegrated by treatment with acid. Excess of an alkaline-earth base is then added and the mass worked

until homogeneous. The excess of alkali is subsequently neutralised by the addition of a saponifiable oil, with or without a separate devulcanising agent. The whole of the added ingredients and their products, except water, are allowed to remain in the mass thus obtained.—E. W. L.

Washing and disintegrating raw rubber and materials containing raw-rubber or the like; *Machine for* —, A. A. Thornton, London, From United Engineers, Ltd., Singapore, Eng. Pat. 104,210, Feb. 23, 1916. (Appl. No. 2716 of 1916.)

XV.—LEATHER; BONE; HORN; GLUE.

PATENTS.

Quebracho or other like tanning solutions; *Apparatus for the preparation of* —, G. van de Wyer, and Association Internationale d'Agences, Ltd., London, Eng. Pat. 104,115, Nov. 16, 1916. (Appl. No. 16,119 of 1916.)

A VAT in which liquid can be heated by means of a doubly-wound spiral steam-coil at the bottom, is provided with a central vertical shaft, carrying propeller-like stirrers at its lower end, and driven by bevel-wheel gearing at its upper end; a sleeve or hollow shaft fits over the central shaft, and is attached to a framework carrying four (or other number of) perforated baskets, the whole being capable of rotation by means of bevel-wheel gearing—in a direction opposite to that of the central shaft. The quebracho or other tanning material is placed in the baskets, and the vat is filled with liquid to near the top of the basket. When the apparatus is set in motion a current of heated liquid is driven upwards by means of the propeller-like stirrers through the baskets. At the same time liquid is forced up by the motion through bell-mouthed pipes, with swan-necks leading into the top of the baskets, good circulation of the extracting liquid through the tanning material being thus secured, and the process of extraction hastened.—E. W. L.

Tanning agents; *Producing soluble* —, O. Schmidt, Assignor to Badische Anilin u. Soda Fabrik, Ludwigshafen, Germany, U.S. Pat. 1,216,612, Feb. 20, 1917. Date of appl. July 2, 1914.

SEE Eng. Pat. 18,250 of 1913; this J., 1914, 877.

Leather; *Artificial* — and *composition used in the manufacture thereof*, L. Lilienfeld, Vienna, U.S. Pat. 1,217,123, Feb. 20, 1917. Date of appl. Dec. 11, 1912.

SEE Fr. Pat. 456,261 of 1913; this J., 1913, 953.

XVI.—SOILS; FERTILISERS.

Soil fertility; *Measurements of* —, W. H. Jordan, New York Agric. Exp. Station, Geneva, Bull. No. 121, 1916, 21 pages.

WITH the object of determining relationships between soil fertility and chemical composition, nine different soils from New York State were selected for investigation. They were put into wooden boxes, 15 in. square, with a layer of sand beneath, and sown with barley during two successive seasons, the grain, straw, and total dry matter being determined after each harvest. In the chemical investigation, the soils were analysed completely, and determinations were also made of the matter dissolved by hydrochloric acid (sp. gr. 1.115) during 10 hours at 100° C., of the substances rendered soluble by continuous leaching for 10 days with water, N/200 HCl, and N/25 HCl, and of the soluble matter obtained by shaking

with the same solvents for 5 hours. By no one of these methods was it found possible to correlate the crop-producing power of a soil with its content of nitrogen, phosphoric acid, and potash, either total or soluble. In some cases there appeared to be a connection between the fertility and the total soluble matter (particularly the organic) of a soil, e.g., two soils that gave a very low crop yield were also deficient in soluble matter, but on the other hand, yields of 11·1 and 96·8 grms. of dry matter were obtained from two of the boxes containing soils showing the same amount of soluble matter.—E. H. T.

Rice plant ; Study in the assimilation of nutrients by the —. J. N. Sen. Agric. Res. Inst., Pusa. Bull. No. 65, 1916. 13 pages.

A PLOT of non-calcareous clay rice-land (kewal) which had given uniform crop results in previous years was sown on May, 21, 1915, with seed ("kalamdan") which was regularly grown on this soil. The young plants were not transplanted, but the usual cultural operations were carried out, irrigation being performed only once—during an exceptionally dry August. Seedling samples were taken on June 30 and July 22nd; adult plants were gathered in the pre-flowering stage on Aug. 21, on Oct. 27 when flowering had begun, on Nov. 29, when the harvesting stage was reached, and on Jan. 7 (1916) when the plants were dead-ripe. Analyses of these samples showed that the nitrogen content steadily diminished from the first to the last period of growth, the greatest decrease taking place in the second period. In the roots there was a very slight gain during the last stages. The phosphoric acid content of the aerial parts remained constant except in the first stage and in the flowering period, when it was slightly higher. In the roots there was a continuous steady decline. The potash in the parts above ground increased up to the pre-flowering stage and then declined. In the roots it was the same during the first two stages after which it fell steadily. These three nutrients became concentrated in the grains as the ears formed and matured; their assimilation from the soil was practically finished by the flowering stage—hence the necessity of abundant plant-food during the early stages. No tendency was observed on the part of the absorbed nitrogen and potash to pass back into the soil. A yield of 900 lb. of dry grain involved a depletion in the soil of 29·33 lb. of nitrogen, 9·64 lb. of phosphoric acid, and 49·69 lb. of potash. An investigation of the feeding values of the parts of the plants at different stages, showed that the straw declined in value with the age of the plant; that leaves were more nutritious than stems of the same period, containing more oil and protein, slightly more carbohydrates, and less fibre. The food value of the leaves is greatest in the pre-flowering and the flowering stages. Dead-ripe plants are at least of equal nutritive value to the normally ripe samples.—E. H. T.

Stable manure ; Composition of army —. E. J. Russell. J. Board Agric., 1917. 23, 1053—1055.

ANALYTICAL data show that army stable manure compares very favourably with farmyard manure (Rothamsted). The former is very good both as regards condition and composition, being as rich in nitrogen, potash, and phosphoric acid, as the latter; it does not, however, equal cake-fed farmyard manure. It contains but very little litter; its moisture content is much lower, and its mineral content higher, than the farmyard product. Owing to the facts that the ammoniacal nitrogen content is low, and that the dumps are compacted by the running of carts over them, the loss on storage is relatively small. Army stable manure is a valuable source of potash,

one ton containing about 18 lb., equivalent to 144 lb. of kainite. At 1s. per load (1s. 1½d.—1s. 1d. per ton), it is extremely cheap; it is worth at least 5s. per ton on the farm.—E. H. T.

Potash [and cement] ; Manufacture of — from felspar. J. Board Agric., 1917. 23, 1087—1091.

A SUB-COMMITTEE of the Government Fertilisers Committee has tested Rhodin's process for converting felspar into a potash fertiliser (Eng. Pat. 18,338 of 1910; this J., 1911, 688), and utilising the residue for the manufacture of a white cement (Eng. Pat. 16,780 of 1899; this J., 1900, 633). Felspar from Loch Eriboll, Sutherlandshire, containing 8·6% of potash, yielded 60% of it in a soluble form; mineral from Derome, near Värberg, Sweden, containing 12·9%, gave 51% of the potash in soluble form; and Roche spar from Cornwall, with 10·8% potash, yielded 75% of it soluble in water. The white, or nearly white, hydraulic cement manufactured from the insoluble residue is suitable only for decorative purposes. As its yield is about 27 times that of the potash fertiliser and as the demand for it is limited, it would be necessary to sell it abroad, or to strengthen it and sell it at home. The Sub-Committee is satisfied with the process and recommends it for adoption on a large scale. It is calculated that 100 tons of Roche spar would yield 220 tons of white cement, and 8 tons of potash (K_2O), equivalent to 16 tons of 80% muriate.—E. H. T.

Fertilisers ; Plant-physiological study, preliminary to the chemical analysis of —. E. A. Mitscherlich. Landw. Jahrbücher, 1916, 49, 335—416. Z. angew. Chem., 1916, 29, Ref., 479—480.

THE sand-culture method which is regarded as the basis of manure analysis shows that when all the factors of growth, except one, are kept constant, the plant-yield (y) increases with this variable factor (x) in accordance with the law: $\log(A-y) = \log(A-a) - cx$. A comparison of the increase of yield obtained with different fertilisers containing similar plant nutriment gives an efficiency ratio for these fertilisers which, with similar manuring, is independent of all other factors of growth and of the species of plant. Excessive manuring causes plasmolytic abnormalities which render the law inapplicable. Since different plants take up different quantities of the various foodstuffs, it is thought that the value of the ratio is influenced by physical rather than chemical factors.—F. SOPN.

PATENTS.

Fertiliser composition, and process of making same. G. H. Earp-Thomas, Glen Ridge, Assignor to H. K. Hannah, Montclair, N.J. U.S. Pat. 1,212,196, Jan. 16, 1917. Date of appl., Nov. 10, 1914. Renewed Oct. 28, 1916.

THE fertiliser consists of a mixture of ground eel-grass, ground mineral phosphate, compounds of potassium and nitrogen, together with humus-forming material.—E. H. T.

Fish-scrap, kelp, etc. ; Apparatus for the reduction of —. G. H. Stillson, Port Townsend, Assignor to Pacific Products Co., Seattle, Wash. U.S. Pat. 1,212,416, Jan. 16, 1917. Date of appl., Dec. 21, 1915.

A CONVEYOR cylinder, containing a rotating conveyor screw, is surrounded by a jacketed chamber built in sections. A communicating shoot which can be closed automatically, and an air-duct, connect this cylinder with a drying cylinder furnished with a revolving paddle. From a hot-air chamber, fitted with steam coils, a blast of hot air is blown through an air-duct into and through the drying cylinder and the jacketed chamber. Separate sections of the latter are heated by the waste gases from a boiler furnace, by exhaust

steam from a steam pump and a steam engine, and by the waste steam from the coils in the hot air chamber. — E. H. T.

Fertiliser; Manufacture of — from Steffens waste water, etc. — E. Herzka, Arecibo, Porto Rico. U.S. Pat. 1,212,181, Jan. 16, 1917. Date of appl., Oct. 24, 1916.

STEFFENS waste water, osmosis water, or other waste liquor obtained in the extraction of sugar from beet molasses, is concentrated to 55 Brix., and treated with sulphuric acid in amount chemically equivalent to the total lime and alkali present. Calcium superphosphate, nitrogenous animal refuse, and sawdust are then added, and the mixture is dried. — E. H. T.

Fertilisers; Manufacture of — — D. Shields, Edgeworth, Pa. U.S. Pat. 1,212,573, Jan. 16, 1917. Date of appl., Nov. 23, 1916.

CARBONACEOUS matter, *e.g.*, that derived from comminuted coal, is mixed with finely divided clay, and treated with subterranean salt water at 212° F. (100° C.); or the carbonaceous substance is mixed with the salt water, heated to 212° F., and the clay then added. — E. H. T.

Fertilisers; (Continuous) process and apparatus for decomposing raw (phosphate) material for the manufacture of — — S. Barth, Düsseldorf, Ger. Pat. 291,575, Jan. 31, 1915.

THE mixture of raw material and acid, as it passes from the mixing vessel to the reaction chamber, is broken up by a current of compressed air, and the product is mechanically discharged from the chamber as a granular mass which is conveyed away for further treatment or for storage. — E. Sopn.

Fertiliser containing ammonium magnesium sulphate and ammonium chloride; Preparation of a — — H. Precht, Hanover. Ger. Pat. 291,857, Feb. 11, 1916.

AMMONIUM sulphate is allowed to react with magnesium chloride or material containing magnesium chloride, such as mother-liquors of the potash industry, and carnallite. The double salt obtained is non-hygroscopic and is much less soluble than ammonium sulphate. — E. Sopn.

XVII. SUGARS; STARCHES; GUMS.

Massecurite; Treatment of the — in the centrifugal (in Hawaii). — J. H. Pratt, Hawaiian Chemists' Assoc., Nov., 1916. Intern. Sugar J., 1917, 19, 89–90.

IN order to prevent the gradual destruction of the basket, when hastening drying by the aid of steam, it is suggested that the steam should be discharged between the curb wall and the basket, and caused to flow in the same direction as the revolving machine by a deflector fastened to the curb. When this procedure was adopted there was a saving of 10 per cent. in time, and the sugar showed an increased polarisation of 1°, while the purity of the molasses was practically unaffected. In carrying out the "hot molasses method," the machine is started empty, and when it has acquired sufficient speed to prevent swinging, the massecurite is run in slowly, hot molasses at 82° to 88° C. (180° to 190° F.) being introduced at the same time through a 3-in. pipe, three-quarters open or more. The outlet of this pipe is placed just above the drip-pan, almost touching and in front of the inflowing massecurite. Even when the molasses is not thinned by wash-waters, there may be a rise in the purity, but not enough to offset the great gain in the time of drying, which sometimes is

diminished by half, while the sugar may have a polarisation of 81°, as compared with 68° when hot molasses is not used. — J. P. O.

Sugar; Extraction of — from low-grade cane molasses by the Williams process. — J. N. S. Williams, Report to the Hawaiian Sugar Planters' Assoc., 1916. Intern. Sugar J., 1917, 19, 90–92. (See Eng. Pat. 16,799 of 1915; this J., 1916, 611.)

It is claimed by the author that if a final molasses be concentrated to a dry substance content of 99 Brix., practically the whole of its sucrose will crystallise, thus demonstrating, contrary to the theory of molasses formation held by Geerligns and others, that it is not the glucose, gums, or mineral matter which either singly or in combination prevent crystallisation, but solely the water present. In experiments made in Hawaii a quantity of "final molasses" was boiled to an almost complete absence of water, and run into small containers, in which sucrose separated in the form of a very fine grain. By using a centrifugal with a non-perforated bowl, operating at a very high speed of revolution, it was found that the very dense and practically solid mass could be separated into two parts, one containing a major portion of sucrose and a minor portion of impurities, and the other containing a minor portion of sucrose, but a major portion of glucose, gums, etc. It is claimed that over 45% of the sucrose present in the original "final molasses" (which had a purity of about 10%) was recovered in the form of a massecurite having a polarisation of 50° and a purity of 53°. In another experiment 644 lb. of dried molasses having a purity of 47° was diluted with 47 lb. of water, producing a massecurite, which was spun in a high-speed machine, when a massecurite weighing 365 lb. (53% of the original charge), and a polarisation of 57° and a purity of 60°, was obtained; while the molasses removed weighed 327 lb., and had a purity of 28.8°, and a polarisation of 25.6%. — J. P. O.

Risks in using commercial glucose in pharmaceutical preparations. — Cowie. See XX.

XVIII.—FERMENTATION INDUSTRIES.

Malt; Evidence of the existence in — of an enzyme hydrolysing the furfuroids of barley. — J. L. Baker and H. F. E. Hulton. Chem. Soc. Trans., 1917, 111, 121–130.

THE authors use the term "furfuroids" to denote substances which, like pentoses and pentosans, yield a considerable amount of furfural when distilled with hydrochloric acid under the usual conditions; for the determination of the furfural produced they employed Fehling's solution (see this J., 1916, 1127). The distribution of furfuroids in different parts of barley and malt corns is indicated by the following yields of furfural, referred to dry material in all cases:—entire barley corn, 5.9%; excised embryos before germination, 1.7%; young plumules germinated in the dark, 5.7%; rootlets (malt-culms), 9.1%; malt-husks (brewers' grains), 20.5%. During the conversion of barley into malt the amount of furfuroids present undergoes a small but distinct increase. Excised barley embryos, germinated on sand moistened with sucrose

solution, were found to increase in weight and furfuroid-content at the expense of the sugar. Under normal conditions of germination the furfuroids gained by the embryo are drawn from the endosperm, probably by the agency of an enzyme which renders them soluble. Experiments described indicate that such an enzyme occurs in extracts of green malt and is precipitable therefrom, like diastase, by alcohol. Digestion of green malt and barley *in vitro* showed that a portion of the insoluble furfuroids of barley is rendered soluble as the result of enzymic activity of the green malt. About 10% of the insoluble furfuroids of purified malt-husks was rendered soluble by the action of the precipitate produced by alcohol from an extract of green malt, at 30° C. An aqueous extract of green malt, allowed to act on brewers' grains, produced reducing sugars (pentose).—J. H. L.

Potato-starch as malt adjunct [in brewing]. V. Koudelka. *Allgem. Zeits. Bierbrau. u. Malzfabr.*, 1916, 44, 71. *Z. ges. Brauw.*, 1916, 39, 222.

IN Austria brewers are now permitted to replace 30% of their malt by sugar and to use potato-starch in addition. Very pure starch is necessary for this purpose. It must first be mashed-in with cold water to prevent the formation of lumps, and it may be saccharified either by itself in a subsidiary mash or after addition to the main mash; the former method is recommended for large breweries, the latter method requiring very efficient mash-tun rakes. According to Lintner the amounts of conversion products formed from 100 parts of potato-starch by the action of diastase at 50°, 55°, 60°, and 65° C. are 0.13, 5.03, 52.68, and 90.31 parts (dry substance) respectively. Since starch contributes no nitrogen to the wort, steps must be taken to utilise to the full the nitrogenous matters of the malt.—J. H. L.

Yeast maceration juice: Von Lebedeff's —. M. W. Beijerinck and J. J. van Nessel. *Folio Microbiologica, Holland. Beitr. ges. Microbiol.*, 1916, 4, No. 2. *Woch. Brau.*, 1916, 33, 176.

THE author modifies von Lebedeff's method of preparing yeast for maceration (this J., 1911, 1081) as follows:—Beer yeast which has not been pressed is allowed to ferment a 10% solution of sucrose. The yeast crop is pressed, passed through a hair sieve, and spread out on filter paper, in as fine a form as possible, to dry in a warm chamber. The dry material is again sifted, and only the floury portion is used, since this contains a larger proportion of ruptured cells and yields a much more active juice than the larger fragments. Auto-digestion liberates zymase only from previously ruptured cells, and the same is true of yeast catalase, which like zymase occurs as a suspension colloid in juice prepared by von Lebedeff's method. Both these enzymes are probably of greater molecular magnitude than diastase, tryptase, pepsin, and some classes of proteins.—J. H. L.

Titration [of brewing materials] in stages by means of two indicators. A. Reichard. *Z. ges. Brauw.*, 1916, 39, 313—315, 322—324, 329—331, 337—339, 345—347, 353—351.

IN the titration of barley and malt extracts, worts, and beers, with alkali, considerably lower results are obtained with litmus as indicator than with phenolphthalein. The development of acidity which accompanies the malting process cannot be directly determined by comparing the acidities of the barley and malt, as it is to some extent masked by a loss of acidity from the barley husk during steeping. The increase of acidity associated with the first stages of germination is due mainly

to the formation of very feebly acid substances which react acid towards phenolphthalein but not towards litmus. The acidity developed in wort during fermentation is due, on the other hand, mainly to substances which react acid towards litmus. The author considers that the stability of beer depends not so much upon the total acidity (determined with phenolphthalein), as upon a high acidity to litmus in proportion to the total acidity. Some experiments are described which show that in an electric field the aromatic substances of hops and malt migrate towards the anode and are therefore negatively charged. Under normal conditions they are probably adsorbed on positively charged colloidal particles in the beer.—J. H. L.

Amino-nitrogen in worts, extracts, etc.: Gasometric determination of —. R. Ensländer. *Z. ges. Brauw.*, 1916, 39, 265—267.

THE author has modified slightly the method described by Van Slyke (this J., 1911, 774). Octyl alcohol is used instead of amyl alcohol to overcome frothing; and the evolved gas mixture, before being transferred to the Hempel pipette for purification, is freed from most of its nitric oxide in the burette (P. *loc. cit.*) which is filled with concentrated ferrous sulphate solution instead of sulphuric acid. This avoids the frequent renewal of the alkaline permanganate solution in the Hempel pipette.—J. H. L.

Barley: Utilisation of the nutritive value of — in brewing. M. Busemann. *Z. ges. Brauw.*, 1916, 39, 331—332.

THE author adduces evidence to show that the nutritive value of barley is well utilised in brewing. According to Rubner, 70% of the nutritive value appears in the beer, and to this must be added the value of the spent grains and yeast as fodder. When barley is used directly for feeding pigs or other stock, only about 10% of the nutritive substances is eventually consumed by human beings, the remainder being destroyed within the animal.—J. H. L.

Adenine-uracil dinucleotide and the structure of yeast nucleic acid. Jones and Read. See XX.

Yeast nucleic acid: Mode of nucleotide linkage in —. Jones and Read. See XX.

PATENTS.

Yeast, mucorini, m-adds, bacilli, etc.: Pure-culture apparatus for —. J. H. P. Magné, Mexico. U.S. Pat. 1,212,656, Jan. 16, 1917. Date of appl., June 19, 1916.

THE apparatus comprises a small initial closed vat and a large secondary one, and means for transferring liquid from one to the other and for supplying them with steam and sterilised air under pressure. The mechanism for sterilising the air may include a sterilising or filtering medium so arranged as to be enveloped by steam in one of the vats (when these are steamed).—J. H. L.

Beverages: Process of preparing [alcoholic] —. G. Defren, Newton, Mass. U.S. Pat. 1,211,518, Feb. 6, 1917. Date of appl., June 29, 1911.

MATERIAL containing starch and protein is heated with acidulated water to produce a sufficient quantity of fermentable sugar. The conversion is then arrested, but the product is left somewhat acid to retain proteins in solution. After separation of undissolved matter, the liquid is boiled with hops and fermented. Before this boiling a portion of the liquid may be caramelised and again mixed with the bulk; and after the hop-boiling the product may be fined with casein.—J. H. L.

Beverages: Process of producing—. Extract having the flavour and aroma of malt and process of producing the same. M. and L. Wallerstein, New York, U.S. Pats. (A) 1,211,729 and (B) 1,211,730, Feb. 6, 1917. Date of appl. June 21, 1916.

(A) A SYNTHETIC extract containing the products formed by interaction between amino-compounds and sugars is dissolved in water, and the solution is boiled with hops and cooled. It may be filtered and carbonated, or fermented by yeast and then filtered and carbonated. (B) A synthetic extract having the flavour and aroma of malt is made from amino-compounds (proteolytic products) and sugars, e.g., by their interaction in a concentrated form at 90° C.—J. H. L.

Food product. U.S. Pat. 1,212,722. See XIXA.

Method of extracting and modifying proteins or albuminous matter [from yeast]. U.S. Pat. 1,213,515. See XIXA.

XIXA.—FOODS.

Milk powder: Analysis of—. Determination of moisture and fat. C. Porcher. Ann. Falsif., 1916, 9, 150—156.

THE quantity of moisture in milk powders is best determined by drying the sample over phosphorus pentoxide at 15° C. for 48 hours, or, if necessary, for 72 hours. Sulphuric acid is unsuitable as a drying agent owing to its marked vapour pressure at 15° C., and desiccation over calcium chloride is very slow. The ordinary method of drying in a steam-oven causes the milk powder to develop a brown colour and evidently alters the composition of some of the constituents; this discoloration is more pronounced in the case of milk powders prepared from milk which has been treated with sodium bicarbonate. The Röse-Gottlieb method is recommended for the determination of the fat; direct extraction of the powder with ether in a Soxhlet apparatus gives low results.—W. P. S.

Coconut oil [in butter and margarine]: The Shrewsbury and Knapp process for the determination of—. G. D. Elsdon and C. R. Bagshawe. Analyst, 1917, 42, 72—83. (See this J., 1910, 1128; 1912, 117.)

VARIOUS modifications in the working of this process were examined, the object being the prevention of error due to the different rates of separation of the insoluble acids from the alcoholic solution and also to ascertain the most suitable strength of alcohol to be used. The greatest difference between the values obtained for coconut oil and margarine, respectively, were obtained by using alcohol of sp. gr. 0.920 at 15.5° C. The details of the procedure recommended are as follows:—Five grams. of the fat is saponified by heating in a flask with 15 c.c. of glycerol-sodium hydroxide solution (a mixture of 700 c.c. of glycerol and 200 c.c. of a solution made by dissolving 1 lb. of sodium hydroxide in 1 litre of water), the soap is dissolved in 115 c.c. of boiling water, 10 c.c. of 10% (by vol.) sulphuric acid is added, the mixture is shaken, cooled, and the liquid filtered. The cake of fatty acids is shaken with 20 c.c. of boiling water, cooled, and the liquid filtered, the cake of fatty acids being broken up and rinsed on to the filter with 30 c.c. of cold water. The filter paper is opened and supported in the rim of the filter-stand and the flask is inverted over the filter paper, in which position both are allowed to drain and dry overnight. The flask is then heated in a water-oven for 5 minutes, while a current of air is blown into it, the filter paper is added, and the drying continued for a further 10

mins. One hundred c.c. of alcohol of sp. gr. 0.920 at 15.5° C. is then added, the flask is corked, its contents are heated until the fatty acids have dissolved completely, then cooled to 15.5° C., shaken, kept at this temperature for 30 mins., and the liquid filtered. Fifty c.c. of the filtrate is titrated with N/10 sodium hydroxide solution, using phenolphthalein as indicator. The value obtained for coconut oil, under these conditions, is 102, for butter 11, and for margarine 6.2. Tables are given showing the values obtained for various mixtures of coconut oil, butter, and margarine. —W. P. S.

Corn [maize] gluten: Relative value of certain proteins and protein concentrates as supplements to—. T. B. Osborne and L. B. Mendel. J. Biol. Chem., 1917, 29, 69—92.

THE products studied included casein, lactalbumin, edestin, cottonseed protein, cottonseed flour, soya bean flour, "milk-albumin," fish meal, maize oil cake, "vegetable albumin flour," brewers' grains, distillers' grains, pea meal, and earlham meal. The efficiency of these supplements to maize gluten presumably depends on their relative content of lysine and tryptophane, which substances are lacking in maize gluten. Lactalbumin proved to be the most efficient, and satisfactory growth was produced with smaller quantities of this protein than of any of the others; the least effective were brewers' grains, distillers' grains, and "vegetable albumin flour," probably because of their low lysine content. Small additions (one-eighth of the amount of maize gluten) of the more efficient proteins appeared actually to supplement the maize gluten, for equivalent amounts of these proteins alone, in a similar ration, were incapable of inducing a comparable degree of growth.—W. P. S.

Hydrocyanic acid [in plant tissues]: Determination of— and the probable form in which it occurs in *Sorghum vulgare*. J. J. Willaman. J. Biol. Chem., 1917, 29, 25—36.

METHODS in use for the determination of hydrocyanic acid in plant tissues are of doubtful accuracy owing to the difficulty of obtaining complete hydrolysis of the glucosides by means of acids, and because of the retention of the hydrocyanic acid by the tissues. Hydrolysis of the dhurrin in *Sorghum vulgare* is best attained by means of the glucosidase found in the same tissues (autolysis); it takes place rapidly at 45° C. Retention of hydrocyanic acid by the tissues during distillation cannot be prevented by the addition of tartaric acid nor can it be lessened appreciably by distilling under reduced pressure. Hydrocyanic acid occurs in *Sorghum vulgare* as a glucoside, dhurrin, and also in the form of a non-glucoside, the nature of which is as yet unknown; it is the latter portion of the cyanide of this plant which is probably responsible for the poisoning of cattle. The non-glucosidic cyanide can be distinguished from the glucosidic by macerating the leaves with 5% tartaric acid solution to prevent any enzyme action, and then distilling. —W. P. S.

Cyanogenetic compounds of Sorghum vulgare: Effect of anaesthetics and of frost on the—. J. J. Willaman. J. Biol. Chem., 1917, 29, 37—45.

THE leaves of *Sorghum vulgare* after exposure to the vapours of chloroform, ether, and alcohol, yield more hydrocyanic acid, both glucosidic and non-glucosidic, than do the normal leaves; the anaesthetics thus stimulate the hydrolytic and synthetic actions of the glucoside enzymes. Enzyme powder prepared from leaves which had been subjected to the action of chloroform was about twenty-five times as active towards amygdalin as was the powder prepared from

untreated leaves. Freezing also increases the quantity of hydrocyanic acid yielded by the leaves; this is due to the rupturing of the cells and to disturbed enzyme equilibrium.—W. P. S.

Cocoa; Alkalinity of —. Arpin. Ann. Falsif., 1917, 10, 10–11.

ACCORDING to French law, the alkalinity of the ash of pure cocoa should not exceed 2.75%, calculated as potassium carbonate and expressed in terms of the dry, fat-free substance; when this limit is exceeded, the cocoa must be sold as "alkalised" or "soluble cocoa," indicating that it has been treated with an alkali during manufacture. The author has examined certain samples lately which had an alkalinity corresponding with 3.1 to 3.5% of potassium carbonate and which the manufacturers guaranteed to be free from added alkali. Examination of cacao beans from various sources showed that the alkalinity sometimes exceeds the limit mentioned. *e.g.*, Madagascar beans had an alkalinity of 3.5%, Chuao beans, 3.59%. It is concluded, therefore, that slight excess of alkalinity in the three samples may have been due to natural causes.—W. P. S.

Coffee substitutes from malt, etc. L. Ronnet. Ann. Falsif., 1917, 10, 23–25.

To determine whether differences existed in the compositions of decoctions prepared from roasted barley, roasted green malt, roasted malt, etc., analyses were made of decoctions prepared under identical conditions from the various grains: 10 grms. of the sample was boiled for 5 mins. with 150 c.c. of water and, after standing for 18 hours, the solution was diluted to 250 c.c., and filtered. In all cases the total soluble substances amounted to about 38%, calculated on the dry substance; the reducing substances, expressed as maltose, varied from 5.3 to 8.5%, except in the case of malt which had been moistened and kept at 60 to 70° C. for three hours, the quantity of reducing substances then increasing to about 20% with a corresponding decrease in the amount of starch and dextrins. This reduction in the quantity of starch and dextrins was about 9%, *i.e.*, from about 29% to 20%.—W. P. S.

Study in the assimilation of nutrients by the rice plant. Sen. See XVI.

Utilisation of the nutrient value of barley in brewing. Busemann. See XVII.

PATENTS.

Egg-preserving compound. H. D. Bostock, Jacksonville, Fla. U.S. Pat. 1,212,445, Jan. 16, 1917. Date of appl., June 13, 1916.

THE compound consists of a solution of 1 lb. of *Desmodium tortuosum meibomia* in one gallon of water, in which the eggs are immersed.—J. H. J.

Curing meats; Art of —. G. F. Doran, Omaha, Nebr. U.S. Pat. 1,212,614, Jan. 16, 1917. Date of appl., Apr. 29, 1916.

THE meat is treated with a pickling liquor containing either sodium nitrite or a mixture of sodium chloride, an alkali nitrate, and an alkali nitrite.—J. H. J.

Food product. R. Wiles, Riverside, Ill. U.S. Pat. 1,212,722, Jan. 16, 1917. Date of appl., Dec. 26, 1914.

THE food consists of a powder composed of the solid constituents of fermented malt liquor, in the same relative proportions as in the liquor. The powder is soluble in water, and when the solution is carbonated, it has the original properties of the malt liquor without the alcohol content.—J. H. J.

Bread; Mineral water for use in the manufacture of leavened —. H. A. Kohman, Pittsburgh, C. Hoffman, New York, and T. M. Godfrey, Pittsburgh, Pa. U.S. Pat. 1,213,210, Jan. 23, 1917. Date of appl., June 8, 1916.

WATER containing ammonium chloride, calcium chloride, and potassium bromate is used as a yeast stimulant and dough ripener in making bread. (See also this J., 1916, 1030.)—W. P. S.

Dough; Composition for leavening —. A. M. Hamblet, Winchester, Mass. U.S. Pat. 1,213,357, Jan. 23, 1917. Date of appl., Dec. 10, 1914.

THE composition is a liquid containing lactic acid, lactic anhydride in amount not less than 15% of the lactic acid, and a solvent in amount not less than 20% of the total volume of the composition. The total acidity of the composition is greater than that of an N 4 acid solution.—J. H. J.

Bread; Process for the manufacture of whole-grain —. P. Gross, Charlottenburg, Assignor to Vollbrot Patent-Verwertungs Ges. m. b. H., Berlin. U.S. Pat. 1,213,627, Jan. 23, 1917. Date of appl., Dec. 5, 1916.

GRAIN is heated with water at about 60° C., the bran and suspended particles of starch are separated from the decorticated grain kernels, the latter are disintegrated while moist, and the product is worked into a dough for baking.—W. P. S.

Proteins or albuminous matter [from yeast]; Method of extracting and modifying —. C. C. Ringler and J. Beerhalter, Assignors to Pitzer Brewing Co., Duluth, Minn. U.S. Pat. 1,213,545, Jan. 23, 1917. Date of appl., Mar. 13, 1916.

BREWERS' yeast is freed from hop resins, heated under pressure with ammonia solution to dissolve the proteins, the excess of ammonia is then removed by evaporation, and the solution is separated from the sediment.—W. P. S.

Baking-powder. M. Vaygouny, Berkeley, Cal., Assignor to Royal Baking Powder Co. U.S. Pat. 1,214,726, Feb. 6, 1917. Date of appl., Feb. 1, 1912.

THE baking powder consists of a mixture of racemic acid, mesotartaric acid, and an alkali bicarbonate.—J. H. J.

Bread or the like; Manufacture and composition of —. E. S. Roworth, Assignor to G. Roworth and F. C. Lynn, Matlock. U.S. Pat. 1,215,995, Feb. 13, 1917. Date of appl., May 27, 1916.

SEE Eng. Pat. 100,295 of 1916; this J., 1917, 302.

Margarine; Manufacture of —. K. Erslev, Nijmegen, Netherlands. U.S. Pats. 1,216,671 and 1,216,675, Feb. 20, 1917. Date of appl., Nov. 13, 1916.

XIXB.—WATER PURIFICATION; SANITATION.

PATENTS.

Softening water; Process of —. Oelwerke Stern-Sonneborn A.-G., Hamburg, Germany. Eng. Pat. 103,698, Feb. 9, 1916. (Appl. No. 1934 of 1916.) Addition to Eng. Pat. 22,362 of 1911 (this J., 1915, 977).

THE water is boiled for 5 mins. before being treated with commercial sodium phosphate.—J. H. J.

Purifying liquids; Composition for—A. H. Krieger, Assignor to Kieselguhr Co. of America, Los Angeles, Cal. U.S. Pat. 1,212,618, Jan. 16, 1917. Date of appl., Sep. 27, 1915.

The composition consists of a finely divided mixture of kieselguhr and hydrous aluminium silicate or colloidal clay in about equal quantities.—J. H. J.

Liquids [drinking water]; Method of purifying—Elekro-Gemose A.-G. (Graf Schwerin Ges.), Berlin. Ger. Pat. 291,751, June 11, 1915.

The liquid is treated with amorphous silicic acid which has been given a sufficient electropositive or negative charge by the action of acidic or basic substances to enable it to adsorb the impurities present. For example, silicic acid which has been positively charged by treatment with hydrochloric acid is employed to adsorb electro-negative impurities from drinking water.—F. SODX.

Centrifugal machines and the like, Eng. Pat. 102,407. See I.

XX.—ORGANIC PRODUCTS; MEDICINAL SUBSTANCES; ESSENTIAL OILS.

Medicinal plants; Cultivation of—J. Board Agric., 1917, 23, 1103–1104.

Much has been done during the past two years to meet the demand for medicinal plants. According to a communication from the National Health Insurance Commission (England) to the Board of Agriculture, the quantities of belladonna, henbane, digitalis, and colchicum required for home consumption are approximately: belladonna, 50 tons of the dried leaves and 50 tons of the dried roots; henbane and digitalis, 20–25 tons of the dried leaves or each; colchicum, considerably less. The home demand for digitalis and colchicum could be met by collecting wild plants. The yields of belladonna and henbane could be improved in a similar way, but in these cases skilled cultivation is indispensable; the acreage under cultivation has considerably increased of late, and it is probable that the combined supply from both sources would now be sufficient to meet the home demand.—E. H. T.

Adenine-uracil dinucleotide and the structure of yeast nucleic acid, W. Jones and B. E. Read, J. Biol. Chem., 1917, 29, 111–122.

ADENINE-URACIL dinucleotide was prepared from yeast nucleic acid; on acid hydrolysis it yielded adenine and uracil but no adenosine or cytosine. When submitted to ammoniacal hydrolysis it gave adenosine and uridine but not guanosine or cytidine. It contained an equal number (one of each) of purine and pyrimidine groups and formed a tetrabasic salt. The latter fact indicates that the two mononucleotide groups are joined to one another through their carbohydrate groups. This mode of linkage must of course exist also in yeast nucleic acid so far as two of its nucleotide groups are concerned, and evidence is adduced that the same mode of linkage is maintained throughout the entire nucleic acid molecule (see following abstract).—W. P. S.

Yeast nucleic acid; Mode of nucleotide linkage in—W. Jones and B. E. Read, J. Biol. Chem., 1917, 29, 123–126.

YEAST nucleic acid is a tetranucleotide composed of groups of two purine nucleotides and two pyrimidine nucleotides; it has been shown (preceding abstract) that there is no direct phosphoric acid linkage in adenine-uracil dinucleotide and there is, therefore, no linkage at the corres-

ponding point in yeast nucleic acid. It must be concluded that the nucleotide groups of yeast nucleic acid are united to one another through their carbohydrate groups.—W. P. S.

Glucose in pharmaceutical preparations; Risks in using commercial—W. B. Cowie, Pharm. J., 1917, 98, 235–236.

THE suggestion to employ commercial glucose syrup as a substitute for sucrose in the preparation of pharmaceutical syrups is only feasible in the case of neutral syrups, as practically all commercial samples of glucose contain small quantities of sulphur dioxide. When used, for instance, for the preparation of the compound syrup of hypophosphites, containing free hypophosphorous acid, reduction of the sulphur dioxide gradually takes place with formation of free sulphur and hydrogen sulphide, accompanied by a change of colour and odour of the syrup. A useful test for the presence of sulphur compounds in sugar and glucose is as follows:—10 grms. of the substance is dissolved in water and made up to 50 c.c., 1 gm. of sodium hypophosphite and 10 c.c. of syrupy phosphoric acid (sp. gr. 1.5) are added, and the mixture set aside in a corked vessel in a warm place for a few hours, when hydrogen sulphide may be detected by its odour. Commercial glucose contains from 160 to 350 parts of SO_2 per million and even a sample which passes the B.P. test for sulphur dioxide will produce objectionable effects when used to the extent of 20% in the compound syrup of hypophosphites.—J. F. B.

NOTE.—Commercial glucose quite free from sulphur dioxide is already easily obtainable under the title of "neutral glucose."

Methyl compounds in ether; Note on the B.P. test for—D. B. Dott, Pharm. J., 1917, 98, 236.

SEVERAL difficulties have been noted in connection with the B.P. test for methyl compounds in ether by the fuchsin-sulphurous acid reaction. Many samples of fuchsin are not completely decolorised by sulphurous acid, and even when practically colourless the delicacy of the test is a matter of doubt, some samples even not reacting at all. A fair sample of fuchsin reagent will show a doubtful reaction with 0.1% of wood naphtha in pure ether and a distinct coloration with 0.2%. Even with a good sample of fuchsin the reagent may be spoiled if the solution be kept hot while the bisulphite and acid are added gradually. It is best to let the fuchsin solution cool to 60°C., then add the bisulphite and shake, next the acid, 2 c.c. at a time, shaking after each addition, cool, and dilute to 1 litre.—J. F. B.

PATENTS.

Cephaeline iso-amyl ether and salts thereof; Process for producing—J. W. Menden, Indianapolis, U.S.A. Eng. Pat. 103,881, Feb. 21, 1916. (Appl. No. 2599 of 1916.)

THE iso-amyl ether of cephaeline, of the probable formula, $\text{C}_{25}\text{H}_{37}\text{O}_3\text{N}_{20}\text{C}_6\text{H}_{11}$, is produced by treating cephaeline with an alkali metal and an iso-amyl halide. *Example*, 46.6 grms. of cephaeline, 4.6 grms. of sodium, and 17 grms. of iso-amyl bromide are heated together under a reflux condenser for 2 hours. The alcohol is distilled off, the

residue dissolved in dilute hydrochloric acid, made alkaline with ammonia, and extracted with ether. Unchanged cephaline is extracted from the ethereal solution with excess of dilute caustic soda solution, and the ether is evaporated off on the water bath. The product may be purified by dissolving it in an acid, crystallising the salt, dissolving it in water, adding ammonia, extracting with ether, evaporating off the ether, and drying *in vacuo*. Cephaline *iso*-amyl ether is a varnish-like substance, easily soluble in alcohol, ether, and chloroform. It dissolves in acids to form salts, the hydrobromide crystallising in white needles. The ether and its salts are valuable medicinal products.—F. Sp.

Cholic acid - formaldehyde condensation product. E. Rietz, Elberfeld, Germany, Assignor to Synthetic Patents Co., New York. U.S. Pat. 1,213,261, Jan. 23, 1917. Date of appl. Dec. 29, 1911.

A COMPOUND of therapeutic value is produced by the combination of cholic acid and formaldehyde. It is a whitish powder soluble in alkali, alcohol, and glacial acetic acid, and melts at about 110° C.—F. Sp.

Acetaldehyde; Method of making—H. Hibbert and H. A. Morton, Pittsburgh, Pa., Assignors to Union Carbide Co., New York. U.S. Pat. (A) 1,213,486, and (B) 1,213,487. Jan. 23, 1917. Date of appl., Nov. 5, 1915.

(A) ACETALDEHYDE is produced by passing acetylene into dilute sulphuric acid containing a salt of mercury and a salt of a relatively weak acid which is not reduced under the working conditions, e.g., a borate. The acetaldehyde may be distilled off simultaneously. (B) Acetaldehyde is produced by passing acetylene into a solution containing a salt of mercury and an acid salt of a strong acid, e.g., a bisulphate, but practically no hydrogen ions. The solution may also contain a salt of a relatively weak acid, and the acetaldehyde may be distilled off simultaneously.—F. Sp.

Fusel oil or similar products; Manufacture of—from *petroleum*. H. Hibbert, H. Essex, and B. T. Brooks, Assignors to Gulf Refining Co., Pittsburgh, Pa. U.S. Pat. 1,214,919, Feb. 6, 1917. Date of appl., Apr. 8, 1915.

A PETROLEUM distillate boiling from 25 to 75° C., containing pentanes and hexanes, is treated with chlorine to produce chiefly mono-chloro derivatives, which are heated with an acetate at 170–250° C. and a pressure of 300 lb. per sq. in., to form pentyl and hexyl alcohols. The olefines formed at the same time may be treated with dilute sulphuric acid and hydrolysed to produce a further amount of pentyl and hexyl alcohols.—F. Sp.

Arsenobenzene derivatives containing nitrogen; Preparation of—Farbw. vorm. Meister, Lucius, u. Brünig. Ger. Pat. 294,276, Sept. 5, 1915.

3,5-DINITRO-4-DIALKYLAMINO BENZENE-1-ARSINIC acids are treated with reducing agents. The preparation of tetramethylhexa-aminoarsenobenzene, tetraethylhexa-aminoarsenobenzene, and dipiperidotetra-aminoarsenobenzene hydrochlorides is described. The products have a higher therapeutic value and a more pronounced action on certain parasites than the corresponding dialkyl compounds.—F. SODX.

Thiourac compounds of arsenic acid, its homologues and derivatives; Preparation of—H. Thoms, Berlin-Steglitz, Ger. Pat. 294,632, July 23, 1911.

ARSANILIC acid or a homologue or derivative is treated with allyl mustard oil, using methyl alcohol as solvent. The products have the combined therapeutic action of allyl and arsenic com-

pounds, without exhibiting the poisonous character of the latter. The compound of allyl mustard oil and arsanilic acid melts at 185° C., with decomposition; it is almost insoluble in water and alcohol, and is sparingly soluble in methyl alcohol. The corresponding compound of methylarsanilic acid darkens and intumesces at 170° C. without melting.—F. SODX.

Hydrogenisation and dehydrogenisation of carbon compounds. C. Bosch, A. Mittasch, and C. Schneider, Assignors to Badische Anilin u. Soda Fabr., Ludwigshafen, Germany. U.S. Pat. 1,216,933, Feb. 20, 1917. Date of appl. June 1, 1914.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

PATENTS.

Photographic images; Colouring or dyeing—H. Miller, New York, Assignor to Brewster Film Corporation, Newark, N.J. U.S. Pat. 1,214,940. Feb. 6, 1917. Date of appl., Feb. 26, 1915.

THE silver image is converted into an adsorbent halide by treatment with a halogen and a halogen salt, and is then coloured with a suitable dye.—B. V. S.

Screen for moving and other projected pictures. E. G. Meadway, Assignor to The British Patent Surbrite Co., Ltd., London. U.S. Pat. 1,216,151. Feb. 13, 1917. Date of appl., Mar. 1, 1915.

A SUITABLE support is coated with a mixture of a bright metallic powder, such as nickel, and a solution of rubber and some other substance, such as naphthalene, which crystallises out on evaporation of the solvent. The naphthalene is used in such proportion that it forms a reflective coating covering practically the whole of the surface.—B. V. S.

Film or the like for colour photography. Producing coloured photographic pictures. C. Raleigh, Jersey City, N.J., and W. V. D. Kelley, Brooklyn, N.Y., Assignors to Prizma, Inc. U.S. Pat. 1,216,493 and 1,217,125, Feb. 20, 1917. Dates of appl., Apr. 13, 1916, and Oct. 7, 1911.

SEE Eng. Pat. 11,225 of 1915; this J., 1916, 1189.

XXII.—EXPLOSIVES; MATCHES.

PATENTS.

Smokeless powders; Process for making—D. S. Kondratieff, Wilmington, Del., Assignor to B. Edelbartz, New York. U.S. Pat. 1,212,770. Jan. 16, 1917. Date of appl., Nov. 16, 1916.

NITROCELLULOSE, after washing, is centrifuged, and without further drying is gelatinised by a mixture of alcohol and ether.—J. N. P.

Explosives: Manufacture of —. Explosive and method of producing same. H. Hibbert, Pittsburgh, Pa. U.S. Pat. (A) 1,213,367 and (B) 1,213,369, Jan. 23, 1917. Dates of appl., Feb. 23, 1915, and Jan. 10, 1916.

STABLE explosives of a relatively non-volatile nature and low freezing point are composed of:—(A) A mixture of nitrated ethylene, propylene, and butylene-glycols with other explosive compounds; (B) a nitrated polyglycol or mixture of polyglycols, or a mixture of nitrated polyglycols and nitrated glycols; nitrocellulose may be dissolved in the nitrated polyglycol. J. N. P.

Explosive powder. J. L. Donner, Oregon City, Oreg., Assignor to J. Brosnan, jun., Washington, D.C. U.S. Pat. (A) 1,211,765 and (B) 1,211,766, Feb. 6, 1917. Date of appl., June 13, 1916.

(A) A heated aqueous solution of sugar is mixed successively with manganese dioxide, crude oil, and potassium chlorate, and the mixture is dried. The crude oil forms an envelope around the individual particles of chlorate and the quantity is adjusted so as to permit a quick and ready drying of the mixture. (B). The powder is prepared as in (A) but without manganese dioxide. J. N. P.

Matches: Process for the manufacture of —. T. T. Best, St. Helens, Lancs. Eng. Pat. 101,015, Feb. 15, 1916. (Appl. No. 2235 of 1916.)

SODIUM chlorate freed from hygroscopic impurities is used in place of potassium chlorate for match compositions. The chlorate is made by treating a solution of sodium carbonate with chlorine and separating the sodium chloride by crystallisation from a solution containing 1100 grms. NaClO₃ per litre. The chlorate is used in powdered form or in solution. A suitable composition is gum arabic 4 parts, sodium chloride 12 parts, potassium chromate 1.3 parts, sulphur 1.5 parts, glass powder or quartz 6.9 parts. The sodium chlorate may be partly replaced by potassium chlorate up to 50%.—W. F. F.

XXIII.—ANALYSIS.

Mercury in organic compounds: Determination of —. J. E. Marsh and O. G. Lye. Analyst, 1917, 42, 81.

To prevent the formation of a fatty or crystalline distillate in the method of determining mercury by combustion with calcium oxide, calcium sulphate is added to the mixture of calcium oxide and the mercury compound; the quantity of calcium sulphate necessary is about twice the weight of the portion of mercury compound taken for the determination. The mercury vapour remaining in the combustion tube at the end of the operation is expelled by carbon monoxide evolved on heating calcium oxalate placed at the closed end of the tube.—W. P. S.

Water content of coal, with some ideas on the genesis and nature of coal. Mack and Hulett. See IX.

Apparatus for determination of benzol and toluol in coal gas. Copp. See IX.

PATENTS.

Condenser for laboratory purposes. H. P. Clarke, Turlton, Lancs. Eng. Pat. 103,892, Mar. 2, 1916. (Appl. No. 3131 of 1916.)

A TANK through which the condensing fluid circulates is provided with short tubes or nipples projecting downward from the bottom, and corresponding clips at the top to receive condensing tubes which pass through from top to bottom. The joint between the condensing tube and the nipple may be formed by a piece of rubber tubing enclosing both, or by a rubber plug carried by the tube and fitting into the outlet of the nipple. —W. F. F.

Gas analysis apparatus. Aktiebolaget Ingeniörsfirma F. Egnell, Stockholm. Eng. Pat. 100,066, Jan. 25, 1916. (Appl. No. 1205 of 1916.) Under Int. Conv., Feb. 6, 1915.

SEE FR. Pat. 180,661 of 1916; this J., 1917, 106.

Trade Report.

Prohibited exports.

An Order of Council, dated 30th March, orders that the following headings in the list of prohibited exports* should be deleted:—(c) Citric acid; (c) Lead, white; (a) Chestnut extract; (a) Oakwood extract; (a) Valex; (a) Valonia; (b) Other extracts and substances for use in tanning; (c) Lead, oxides of; (b) Lead (except pig lead), alloys of lead, solder containing lead, and manufactures of lead or its alloys, not otherwise prohibited; (a) Lead, pig; (b) Quercitron bark extract.

The following headings are added:—(c) Aloes; (b) Barium peroxide; (c) Cascara sagrada; (b) Citric acid; (b) Hydrogen peroxide; (c) Jalap; (a) Lead compounds, and mixtures containing lead compounds; (c) Rhubarb (medicinal); (c) Senega; (a) Lead, lead alloys, and manufactures of lead or of lead alloys; (a) Tanning extracts and substances for use in tanning.

* The prohibition of exports is as follows:—

Goods marked (a), to all destinations.

Goods marked (b), to all ports and destinations abroad other than ports and destinations in British Possessions and Protectorates.

Goods marked (c), to all destinations in foreign countries in Europe and on the Mediterranean and Black Seas, other than France and French Possessions, Russia, Italy and Italian Possessions, Spain and Portugal, and to all ports in any such foreign countries, and to all Russian Baltic ports.

P. F. Frankland.	R. S. Morrell.	

Hon. Local Secretary and Treasurer :

F. R. O'Shaughnessy, 42, Temple St., Birmingham.

The following take office after the Annual General Meeting
 Chairman : R. S. Morrell ; Vice-Chairmen : W. J. Rees and
 E. W. Smith ; Committee : F. C. A. H. Luntsberry, H. T. Pincock,
 T. F. E. Rhead, D. F. Twiss, L. P. Wilson.

Canadian Section.

Chairman : T. H. Wardleworth.

Vice-Chairmen :

S. B. Chadsey, N. N. Evans, W. L. Goodwin.

Committee :

L. T. Acton.	J. A. De Cew.	Robt. Jol.
J. W. Bain.	J. R. Donald.	Otto G. Palma.
J. S. Bates.	C. F. Heebner.	W. H. Thorn.
D. G. Buchanan.	Milton L. Hersey.	

Hon. Treasurer : E. G. R. Ardagh.

Hon. Local Secretary :

Alfred Burton, 2-16, Liberty Street, Toronto.

Hon. Resident Secretary for Montreal :

Joel B. Saxe.

Acting Resident Secretary for Montreal.

J. R. Donald, 318, LaGauchetiere Street West, Montreal.

Edinburgh Section.

Chairman: James Walker.
Vice-Chairman: D. B. Dott.

Committee:
J. G. Annan, J. Rutherford Hill, Wilfrid A. Sim.
J. F. Briggs, Jas. C. Irvine, Allan Smith.
J. D. Brunton, D. S. Jordan, S. Stewart.
L. Dobbin, A. P. Laurie, H. E. Watt.

Hon. Local Secretary:

A. Lauder, 13, George Square, Edinburgh.

The following take office after the Annual General Meeting:—
Chairman: D. B. Dott; *Vice-Chairman:* J. S. Ford; *Committee:* J. Hendrick, B. D. W. Luff, B. D. Porritt, James Walker.

Glasgow Section.

Chairman: James Macleod.
Vice-Chairman: Quintin Moore.

Committee:
E. G. Beckett, Jas. Faill, J. McLarkue
A. R. Berry, Robert Hamilton, W. G. McKellar.
Thomas Cullen, T. H. P. Heriot, G. T. Purvis.
R. M. Clark, S. H. B. Langlands, James Reid.
W. H. Coleman, James Lawrence, James Robertson.
Cecil H. Desch.

Hon. Secretary and Treasurer:

G. S. Cruikshanks, Royal Technical College, Glasgow.

The following take office after the Annual General Meeting:—
T. Ewan, T. Gray, James Hope, D. A. MacCallum

Liverpool Section.

Chairman: John Gray.
Vice-Chairman: E. C. C. Baly.

Committee:
A. Carey, E. L. Peck, W. P. Thompson.
P. de G. Coghill, H. E. Potts, G. Carruthers.
J. Findlater, J. T. Smith, Thomson.
J. Hazen, Frank Tate, Stuart J. Willour.
R. D. Mason.

Hon. Treasurer:

Edwin Thompson, 25, Sefton Drive, Liverpool.

Hon. Local Secretary:

Alfred Holt, The University, Liverpool.

The following take office after the Annual General Meeting:—
Chairman: A. T. Smith; *Vice-Chairman:* John Gray; *Committee:* E. C. C. Baly, W. M. W. Fell, E. G. Jones, W. Mansbridge, J. W. Towers.

London Section.

Chairman: A. R. Ling
Vice-Chairman: H. E. Armstrong.

Committee:
Julian L. Baker, J. W. Hinchley, W. J. Leonard.
W. A. Bone, W. R. Hodgkinson, J. W. McDonald.
A. W. Crossley, E. Grant Hooper, Stephen Mall.
E. V. Evans, H. A. D. Jowett, R. Seligman.
J. T. Hewitt, C. A. Keane.

Hon. Local Secretary and Treasurer:

T. D. Morson, 14, Elm Street, Gray's Inn Road, W.C.

Manchester Section.

Chairman: J. H. Hoscason.
Vice-Chairman: W. Thomson.

Committee:
J. Allpass, L. Blundell, A. Lapworth.
E. Arden, Bertram Hart, E. F. Morris.
E. F. Armstrong, J. Huchner, A. Worthington.
J. Baddiley, A. C. Dunningham.

Hon. Local Secretary:

L. E. Vlies, Belmont, Gowan Road, Alexandra Park, Manchester.

The following take office after the Annual General Meeting:—
Chairman: W. Thomson; *Vice-Chairman:* (not elected); *Committee:* W. Andrews, A. C. Dunningham, W. B. Hart, J. D. Paton, L. G. Radcliffe, S. Smith.

Newcastle Section.

Chairman: H. Peile.
Vice-Chairman: T. W. Lovibond

Committee:
P. P. Bedson, J. T. Dinn, G. P. Lishman.
C. Bodde, F. C. Garrett, J. H. Patterson.
S. H. Collins, T. Hardie, H. D. Smith.
W. Diamond.

Hon. Local Secretary:

E. F. Hooper, Pilgrim House, Newcastle-on-Tyne.

New England Section.

Chairman: Robert W. Neff.
Vice-Chairman: Prof. L. A. Olney.

Committee:
E. L. Atteaux, C. L. Gagnebin, Hervey J. Skinner.
Eugene Barry, A. H. Gill, F. H. Thorpe.
R. L. Chase, Chester A. Howe, W. S. Willans.
W. C. Durfee, W. D. Livermore, S. W. Wilder.
Walter E. Piper.

Hon. Treasurer:

Frank W. Atwood, 216, Milk Street, Boston, Mass., U.S.A.

Hon. Local Secretary:

A. A. Clafin, 176, Federal Street, Boston, Mass., U.S.A.

New York Section.

Chairman: Jerome Alexander.
Vice-Chairman: C. E. Sholes.

Committee:

J. B. Granger, A. B. Hector.

Hon. Local Secretary and Treasurer:

S. E. Sibley, c/o Messrs. Mauri Bros. & Thomson, Castlereagh Street, Sydney, N.S.W.

Yorkshire Section.

Chairman: J. W. Cobb.
Vice-Chairman: W. McD. Mackey.

Committee:
A. M. Aubin, J. Evans, C. H. Hardy.
James E. Bedford, C. P. Finn, F. W. Richardson.
B. A. Burrell, W. M. Gardner, J. T. Thompson.
S. H. Davies, A. G. Green, Geo. Ward.

Hon. Local Secretary and Treasurer:

T. Fairley, 17, East Parade, Leeds.

Official Notices.

ANNUAL GENERAL MEETING, 1917.

In accordance with the provisions of By-law 61, notice is hereby given that the Annual General Meeting will be held in The University Buildings, Edmund Street, Birmingham, at 10.30 a.m. on Wednesday, July 18th, 1917. A programme of the proceedings will be issued later.

In accordance with the provisions of By-law 21, those members whose names are printed in *italics* in the List of Council will retire from their respective offices at the forthcoming Annual Meeting.

Prof. Henry Louis has been nominated to the office of President under By-law 20; Dr. Charles Carpenter has been nominated Vice-President under By-law 20; Mr. John Gray, Mr. A. R. Ling, Prof. R. F. Ruttan, and Mr. J. T. Wood have been nominated Vice-Presidents under By-law 21.

Members are requested to nominate on or before May 23rd next, fit and proper persons to fill four vacancies among the ordinary Members of Council. Forms for this purpose can be obtained from the Secretary of the Society.

By-law 23:—An Ordinary Member of Council shall be nominated by ten or more members upon Form B in the Schedule, a copy of which form shall be furnished by the Secretary upon the written or verbal request of any member, but a member shall not be eligible to sign more than one such nomination form, and the member nominated shall sign the declaration set forth on the form. A nomination shall be declared invalid by the Council if:

a. The member thereon nominated is disqualified for election, or ineligible to be elected, as provided by the By-laws.

b. The nomination is not made on the authorised printed form or substantially not in the manner directed thereon.

c. The nomination form is signed by less than ten members not disqualified or not ineligible to nominate as provided by the By-laws.

d. The nomination form is not received before or upon the day appointed therefor.

e. The member nominated has not signed the declaration printed upon the form.

A member whose nomination aforesaid is declared to be invalid, shall receive notice thereof from the Secretary, and shall not be submitted for election.

J. P. LONGSTAFF,
Secretary.

REPORTS OF THE PROGRESS OF APPLIED CHEMISTRY.

The first volume of these reports is now ready. As the issue is strictly limited, those who desire to obtain copies are advised to apply for them without delay. The price is 3s. to members and 5/6 to non-members, including postage.

REFRACTORY MATERIALS RESEARCH.

In the last issue of this Journal, page 370, reference was made to the appointment of a Committee on Refractory Materials Research, which is collecting data as to (A) the extent of such research work now in progress; (B) the facilities for research existing in this country;

(c) the facilities for collecting published information on refractory materials and making it generally available. This Society is represented on the Committee by Prof. J. W. Cobb, of the University, Leeds, who will be glad to receive particulars of problems in regard to refractory materials, especially in relation to the chemical industries, which call for immediate attention.

OUTPUT OF HIGH BOILING TAR ACIDS.

The Army Council have issued an Order, under date 11th April, requiring the occupiers of the factories and/or workshops specified in the Schedule hereunto annexed to place at the disposal of the Army Council the whole output of: (1) The high boiling tar acids capable of being produced at the said factories from such blast furnace creosote oil as may be supplied to them by or on behalf of the Director of Army Contracts between 16th April, 1917, and 15th July, 1917, and (2) such spent oil as may remain over from the manufacture of such high boiling tar acids; and to deliver such high boiling tar acids and spent oil in such manner as may be directed by or on behalf of the Director of Army Contracts; and to furnish to the Director of Army Contracts such information as to the cost of, and profit on, the production of the high boiling tar acids as he may cause to be required and to verify the information aforesaid in such manner as he may direct.

Schedule. W. Baird & Co., Ltd., 168, George Street, Glasgow. British Phenoloids Co., Ltd., Gables Road, Irvine, Carnbroe Chemical Co., Ltd., 14, St. Vincent Place, Glasgow. David Colville & Sons, Ltd., Glengarnock Steel Works, Glengarnock. W. Cooper & Nephews, Kelvindale Works, Lochburn, Maryhill, Glasgow. Killgerm Co., Ltd., Cleckheaton, Yorks. Langloan Iron and Chemical Co., Ltd., Coatbridge. National Tar Products, Ltd., Barhead, Newton, Chambers & Co., Ltd., Thorncliffe, near Sheffield. Quibell Bros., Ltd., Newark. Robert Young & Co., Ltd., 38, Elliott Street, Glasgow.

INTERESTS OF BRITISH AND ENEMY SUBJECTS IN PATENTS, TRADE MARKS, AND DESIGNS.

According to an announcement issued by the Foreign Trade Department of the Foreign Office, under date 13th April, every person, or body of persons, incorporated or unincorporated, resident, carrying on business or being in the United Kingdom, is granted full licence and authority to apply on behalf of any person, or body of persons, whose name now is, or shall hereafter be, placed on the Statutory List of persons with whom trading is forbidden by any Proclamation issued under the Trading with the Enemy (Extension of Powers) Act, 1915, for the grant, or for the renewal of the grant, of any letters patent, or for the registration, or for the renewal of the registration, of any trade mark or design in the United Kingdom, or in any part of His Majesty's Dominions outside the United Kingdom, where such applications are allowed by the Government of that part of His Majesty's Dominions to be made on behalf of persons, or bodies of persons, whose names are on the Statutory List, and for that purpose to transact all necessary business with regard to the application, and to all matters arising thereout with the person, or body of persons, on whose behalf the application is made, and generally to do all things necessary for carrying the application into effect, and in particular to pay any fees payable in the United

Kingdom, or in any such part of His Majesty's Dominions outside the United Kingdom as aforesaid (provided that no fees be paid to any person, or persons resident or carrying on business outside the United Kingdom, unless such person or persons is or are permitted by the Government of that part of His Majesty's Dominions in which he or they is or are resident or carrying on business, to pay fees on behalf of persons or bodies of persons whose names are on the Statutory List), and to pay and retain any charges or expenses incurred in relation to the matter aforesaid.

DEALINGS IN LEAD. MINISTRY OF MUNITIONS ORDER.

The Minister of Munitions has issued an Order as follows, dated April 6, 1917:—

1. No person shall until further notice purchase, sell, offer to purchase or sell, or, except for the purpose of carrying out a contract in writing existing prior to April 6th for the sale or purchase of white lead, lead oxides, lead manufacture, lead alloys or lead compounds of any kind, or a contract in writing existing prior to the 2nd February, 1917, for the sale or purchase of any other kind of lead, enter into any transaction or negotiation in relation to the sale or purchase of lead situated outside the United Kingdom except under and in accordance with the terms of a licence issued under the authority of the Minister of Munitions.

2. No person shall until further notice offer to purchase, purchase or take delivery of any lead situated in the United Kingdom except under and in accordance with the terms of a licence issued under the authority of the Minister of Munitions, or offer to sell, sell, supply or deliver any such lead to any person other than the holder of such a licence and in accordance with the terms thereof; provided that no such licence shall be required in the case of any offer to sell or purchase, sale, purchase or delivery of such lead:—

(A) For the purpose of a contract or order for the time being in existence certified to be within Classes "A" or "B" in the Order of the Minister of Munitions as to priority (see this J., 1917, 356).

(B) For the purpose of necessary repairs or renewals requiring immediate execution and involving the use of not exceeding 1 cwt. of lead and not exceeding 28 lb. of white lead, lead oxide or lead compound.

3. No purchase or sale of lead situated in the United Kingdom, or offer to purchase or sell any such lead, whether such purchase, sale or offer is or is not under any licence issued under the authority of the Minister of Munitions, shall in the case of any class of lead specified in the schedule hereto be at a price exceeding the price set opposite the same in the said schedule.

4. No person shall until further notice use any lead for the purpose of any manufacture or work except:—

(A) For the purpose of a contract or order for the time being in existence certified to be within Classes "A" or "B" in the Order of the Minister of Munitions as to priority.

(B) For the purpose of necessary repairs or renewals involving the use of not exceeding 1 cwt. of lead and not exceeding 28 lb. of white lead, lead oxide or lead compound.

(C) For the purpose of type casting from metal already in the form of type on the 2nd February, 1917, or from lead purchased for that purpose prior to that date.

(D) Under and in accordance with the terms of a licence issued under the authority of the Minister of Munitions.

5. All persons shall within seven days from the

first day in each month send in to the Director of Materials (A.M.2. (E)), Hotel Victoria, Northumberland Avenue, London, W.C.2, monthly returns of:—

(A) All lead held by them in stock or otherwise under their control on the last day of the preceding month, the lead actually in stock to be shown separately.

(B) All lead purchased or sold by them for future delivery and not yet delivered on such last day.

(C) All lead delivered to them during the preceding month.

(D) All contracts or orders existing on the last day of, or entered into during, the preceding month requiring for their execution the use of lead for any purpose, specifying the amounts of lead required monthly for the purpose of such contracts or orders, and distinguishing between the amounts required for work certified to be within Classes "A" and "B" respectively in the said Order of the 8th March, 1917, and the amounts required for other purposes.

Notwithstanding the above, no return is required from any person whose total stock of lead in hand and on order for future delivery to him has not at any time during the preceding month exceeded 1 cwt.

6. For the purpose of this Order the expression lead shall mean pig lead, whether virgin or remelted, sheet lead, lead pipe, and old scrap lead, white lead, whether dry, in oil, or prepared for use, lead oxides, lead manufactures, lead alloys, and lead compounds of every kind, or any of them.

7. All applications for licences to purchase or use lead shall be made to the Director of Materials (A.M.2. (E.)), Hotel Victoria, Northumberland Avenue, London, W.C.2, and marked "Lead Licence."

8. The Order of the Minister of Munitions dated the 2nd February, 1917, relating to certain classes of lead is hereby cancelled, but such cancellation shall not affect the previous operation of that Order or the validity of any action taken thereunder, or the liability to any penalty or punishment in respect of any contravention or failure to comply with the same prior to its cancellation, or any proceeding or remedy in respect of such penalty or punishment.

Schedule of maximum prices.

Pig lead. Virgin pig lead, £29 per ton net ex ship, £30 per ton net ex store or ex refiners' works. Scrap lead or remelted scrap lead, £26 per ton net ex sellers' premises.

Manufactured lead. Sheet lead, £39 10s. per ton; lead pipe, £40 per ton, delivered United Kingdom, less 2½% monthly account; the usual trade extras and allowances to apply. The rate of exchange between chemical houses and manufacturers of chemical sheet lead, for the old lead in pig lead shape, to be £8 per ton net for sheet lead and £8 10s. per ton for lead pipe, the manufacturer paying cost of delivery of the old lead; the sheet lead or lead pipe to be delivered United Kingdom. The usual trade extras to apply.

Lead compounds. Dry white lead, £16 per ton, less 5% monthly account, delivered United Kingdom. The usual trade extras and allowances to apply.

White lead in oil, £53 per ton, less 5% monthly account for deliveries in packages of 5 cwt. and over; £55 per ton, less 5% monthly account, for lots of less than 5 cwt. White lead in packages less than 5 cwt. to be charged at the customary trade extra for packing.

These prices for white lead in oil are based on a price of £50 per ton as the spot price for raw linseed oil in barrels. If the average daily spot price of raw linseed oil during the preceding month rises or falls by multiples of £6 then the above maximum price of white lead in oil shall rise or fall

by 10s per ton for every £6 per ton rise or fall in the price of linseed oil.

Red lead and litharge. £42 per ton, less 2½% monthly account, in 5 cwt. casks delivered United Kingdom. The usual trade extras and allowances to apply.

Note.—Licences to purchase and take delivery of lead situated in the United Kingdom will usually be granted by the Minister of Munitions under the above Order for necessary repairs and renewals in the ordinary course of trade, and will also be granted for any other purposes which may be approved by the Minister of Munitions, including manufacture for the purposes of export trade.

Every applicant for a licence must state the amount of lead required by him per month and the use to which it will be put.

MANUFACTURERS' ADVISORY COMMITTEE.

A Manufacturers' Advisory Committee to the Ministry of Munitions has been formed. It consists of Mr. G. Mure-Ritchie and Mr. Douglas Vickers, who are connected with a number of mining, metallurgical, railway, and engineering enterprises; Mr. George Terrell, M.P. (nominated by the British Manufacturers' Association), representing the interests of the smaller manufacturers; Mr. R. G. Perry, of Messrs. Chance and Hunt, and Mr. H. G. McGowan, of Nobel's Explosives Co., representing the chemical and explosives industries; and Sir Frederick H. Smith, representing the textile industries.

MALT (RESTRICTION) No. 2 ORDER.

A further malt restriction Order, issued by the Food Controller under date 12th April, makes it illegal, except under licence, to manufacture any further malt, to sell or deliver any malt, or for anyone other than a brewer for sale to use malt for any purpose. The effect of this Order is to prevent home brewing, and it will apply also to the manufacture of any non-alcoholic liquors containing malt.

MANUFACTURE OF FLOUR AND BREAD ORDER.

By the Manufacture of Flour and Bread Order (No. 3), 1917, the Food Controller increases the percentage of flour from other cereals to be mixed with wheaten flour, from a maximum of 15% to a maximum of 25%, and from a minimum of 5% to a minimum of 10%.

FLOUR MILLS ORDER, 1917.

Acting on the powers conferred upon him by the Flour Mills Order, 1917, dated April 20th, the Food Controller takes over, as from April 30th, all flour mills in the United Kingdom which, on the date of the Order, used wheat in the making of flour, except those having an output capacity of less than five sacks of flour per hour.

The Food Controller has also issued an order forbidding the use, after April 28th, of any wheaten or rice flour, or of their products, except for human food; and any person who wastes, or permits to be wasted, any flour or article containing it will be guilty of an offence against the Defence of the Realm Regulations.

London Section.

Meeting held at Burlington House on Monday, April 2nd, 1917.

MR. A. E. LING IN THE CHAIR.

FURTHER NOTES ON THE ACTION OF ACETIC ACID ON ALUMINIUM.

BY RICHARD SELIGMAN, PH.D., AND P. WILLIAMS.

Introductory.

In an earlier paper (this Journal, 1916, 35, 88 *seq.*) the action of boiling concentrated acetic acid and some of its homologues upon aluminium was described, and reasons were given for the separate treatment of this section of the subject.

The present communication deals with the action of boiling acetic acid of lower concentrations, and also of acetic acid of all concentrations at ordinary temperatures. In addition the effect of the presence of small quantities of various substances in the acetic acid has been determined.

Action of boiling dilute acetic acid. The action of boiling acids of lower concentrations has been found to be analogous to that of the solutions containing between 100% and 50% acetic acid previously examined, and it has been found that the rate of dissolution of the aluminium rises continuously until the concentration of the acid falls to 1%. With acids of lower concentration than 1% it is not possible to obtain reliable figures owing to the fact that the metal becomes coated with a protective skin which interferes with the action of the acid. Even with solutions containing 5% acetic acid the numerical results become erratic owing to the same cause, but it is, nevertheless, possible to conclude definitely that where unprotected by a coating the aluminium dissolves at an ever-increasing rate.

The experiments made with boiling dilute acids had not proceeded far before it was found that the rate of dissolution was very much affected by the products of the interaction, and for this reason it became necessary to investigate the effect of fresh acid as well as that of acid already saturated with such products. It was found that this disturbance grew very rapidly with increasing dilution, so that in the case of acid of 1% concentration the rate of dissolution rose as the experiment proceeded to more than five times its initial value. It is not yet possible to assign a definite cause to this phenomenon and it is difficult to see which of the products of the interaction could account for so great an increase in the rate of dissolution. For a time the only possible explanation appeared to be that the acetate formed played some part, but it has since been found that acid which has become thus highly active with regard to aluminium can be distilled without change in its activity. Consequently, whatever it is that causes the rise in the rate of dissolution must be volatile, or else during the early course of the interaction some inhibiting substance or condition is eliminated.

This question is still under investigation, but it is obvious that a practical deduction can already be made from the facts observed. Where aluminium vessels are to be used in connection with dilute acids the greatest care must be taken in their design to avoid small recesses or pockets in which the circulation of the contents cannot take place freely, and in which, therefore, the products of the interaction can accumulate. Attention has been drawn to this fact in considering the effect of other acids on aluminium (this Journal, 1916,

35, 665 *seq.*), and the correctness of the view now expressed is fully borne out by experience in practice. The facts recorded here also explain why aluminium articles in contact with these acids invariably last much longer if subjected to frequent and rigorous cleansing operations than if left in contact with fouled contents.

During the experiments about to be described it has frequently been observed that at the very outset the rate of attack is rapid, but that the initial rate quickly falls and thereafter remains approximately constant until the accumulation of products of the interaction brings about the rise already referred to. As the main object of the experiments has been to reproduce practical conditions, the figures given in the tables for the initial rate of dissolution are those observed when the rate of attack had become constant, because in practice it is only necessary to consider repeated attack on the same metal by fresh acid and continuous attack by acid which is not frequently renewed and therefore becomes saturated with the products of the interaction. The case of fresh metal attacked by fresh acid need not be considered.

Solutions of acetic acid boiled in contact with aluminium become turbid after a period which is short or long according to the concentration of the acid, and the nature of the turbid solutions produced varies in different cases. Acids of concentration between 60% and 5% give rise to turbid solutions which clear on standing or on the addition of hydrochloric acid. The white precipitate which separates on standing dissolves readily in dilute hydrochloric acid. Little or no deposit is formed on the aluminium strip itself, and if any deposit be formed it is loosely attached and always readily removable. Such turbidity appears to be due to the separation of basic acetate or acetates of aluminium. In the case of acids of about 0.2% concentration the turbid solutions do not clear on standing, and the addition of dilute hydrochloric acid or caustic soda produces a flocculent precipitate which does not readily dissolve in boiling dilute hydrochloric acid. Such solutions give rise to a deposit which adheres firmly to the aluminium and is not removed readily either by chemical or mechanical means. It is considered that the turbidity in these cases may be due to the formation of a colloidal solution of aluminium hydroxide. Solutions containing between 5% and 0.2% of acetic acid give rise to turbid solutions of intermediate character. Thus, for instance, the solution produced by acid of 1% concentration falls into the second category with regard to the permanence of the turbidity, the formation of the precipitate by hydrochloric acid or caustic soda, and the insolubility of the precipitate, but the deposit is loose and does not adhere to the aluminium as in the case of more dilute solutions of acetic acid.

The amount of dissolved aluminium necessary to produce turbidity naturally varies with the concentration of the acid. It is found to increase as the concentration falls, and is at a maximum with acid of about 10% concentration.

In all cases where the action of boiling acetic acid of whatever concentration has been examined, the attack is uniform and no evidence of local action has been observed. The only exception is formed by anhydrous acetic acid as described in the previous communication (*loc. cit.*).

Cold acids. The rate of attack by cold acetic acid is in general small. As in the case of boiling acids, the rate of dissolution increases with increasing dilution of the acid, and the highest rate so far noted took place with a solution containing 0.02% acetic acid. The rate of dissolution is frequently high at first, but rapidly falls off and then remains approximately constant over prolonged periods. This phenomenon has not been

explained so far but does not appear to be of practical importance.

The attack is in most cases uniform, but between concentrations of 70% and 95% local action has frequently been observed, and where such local action takes place the rate of dissolution is also greater than would be expected from comparison with the figures given by acids of lower and higher concentrations. Local action has also been observed where the metal has been allowed to remain for prolonged periods in undisturbed contact with thin films of the dilute acid, which had thereby been subjected to intensive aeration. Indeed, the main factor determining local action appears to be the presence of oxygen, although there is evidence that some other factor plays a part. In the previous communication, cited above, the following statement was made: "It was considered at the outset of the experiments made to determine the conditions governing the rate of attack that the presence or absence of air might be the main factor, but this assumption was found to be erroneous although there was some evidence that in the absence of oxygen dissolution is more uniform than when oxygen is present."

In dealing with cold acetic acid it has been possible to show conclusively the effect of oxygen in promoting local action. Acids which normally cause local action of a serious kind can be made to act perfectly uniformly if the oxygen be entirely removed or if it be replaced by some inert gas. No doubt this accounts also for the fact that acids which in the cold or even at temperatures slightly below boiling point cause local action, nevertheless act perfectly uniformly at boiling temperatures when the oxygen is rapidly removed in the course of ebullition.

In the case of cold acids it has been found, moreover, that the actual rate of dissolution is increased by the presence of oxygen, and may be reduced to less than half its original magnitude if the oxygen be replaced by hydrogen.

Here again it may be well to point the practical moral of the observations made. Vessels used to contain solutions of these acids should not be allowed to remain wet for prolonged periods after being emptied and before cleaning. In such cases the metal is exposed to the action of thin films of acid subjected to intense aeration and, as practical experience has amply demonstrated, local attack frequently ensues. The metal should be purged as soon as possible of any remaining acid and, where practicable, left dry.

One of the original objects of this research was to find an explanation of the fact that in stills used for the distillation of acetic acid the still proper was often found to have a prolonged life whereas the condensers, notably in their lower part, were frequently subjected to rapid deterioration and to local perforation. It would appear that the effect of oxygen in promoting and localising such attack affords a sufficient explanation of this phenomenon, because it is precisely at the point where this attack has been observed in condensers that oxygen would have access to surfaces bathed in hot acids.

The question arises whether difficulties due to this cause could not be completely obviated by the introduction of some neutral gas at this point, or by preventing altogether access of oxygen to the condenser?

The effect of various foreign substances upon the rate at which aluminium dissolves in acetic acid has been referred to by many authors, but revision seemed desirable. It has been found that with dilute acids of about 10% concentration the addition of up to 1% of sodium chloride, potassium bromide, potassium iodide, or potassium nitrate has practically no effect in the case of boiling acid, whereas an equivalent amount of sodium sulphate raises the rate of dissolution appreciably. In cold

10% acetic acid, however, 1% of sodium chloride is sufficient to raise the rate of dissolution tenfold, whereas potassium bromide effects a much smaller increase in the rate of attack, and potassium iodide and potassium nitrate none at all. 0.5% of sulphuric acid in the form of sodium sulphate raises the rate of dissolution fourfold in the case of dilute acid at normal temperature.

Dealing with strong acids of about 80% concentration in the cold, 1% of sodium chloride was found to raise the rate of dissolution from 3.6 to 270 mgrms. of aluminium dissolved per hundred sq. cms. per 24 hours. The same amounts of potassium bromide and potassium iodide increase the rate of dissolution approximately tenfold, but 0.5% of sulphuric acid in the form of sodium sulphate cannot be said to have any effect on the rate of attack by 80% acid in the cold, and potassium nitrate reduces the rate of dissolution to one-fourth of its previous value. The most serious effect of the addition of the substances experimented with was noted in the case of 80% acid at boiling point. Here the rate of dissolution is raised by 1% of sodium chloride from 290 to 16,000. By 1% of potassium bromide the rate is only increased from 290 to 485, whilst potassium iodide and potassium nitrate may be said to have no effect; 0.5% of sulphuric acid in the form of sodium sulphate somewhat increases the rate of dissolution.

It will be seen throughout these experiments that the effect of the addition of chlorides to acetic acid is far greater than that of the addition of bromides or iodides. It was to be assumed that this was due to the fact that aqueous hydrochloric acid alone attacks aluminium much more readily than aqueous hydrobromic acid, and this was found to be the case, the rate of attack by half normal hydrochloric acid being at least tenfold that of the equivalent hydrobromic acid solution. It also appeared that the presence of potassium iodide had very little effect upon the rate of attack by hot acetic acid, but had considerable influence in the cold. This was found to be due to the fact that if acetic acid containing potassium iodide be allowed to stand, free iodine is rapidly produced, and in solutions containing free iodine the attack upon aluminium is considerable. If the free iodine be removed from cold acetic acid solutions in which it has been formed, the rate of attack falls to that of the acid alone.

The form of attack by acids to which the salts named had been added was such that acids which without addition attack aluminium in a uniform manner were not affected by the addition of these salts, except that where the rate of attack was raised considerably, etching of the surface could be observed.

Where, however, the acids alone caused local action, such local action was generally promoted by the presence of halogens, but retarded by the presence of small quantities of sulphuric acid and absolutely inhibited by as little as 0.1% nitric acid. It is hoped that there may be cases where this fact can be taken advantage of in practice.

Experimental.

The general arrangements adopted in the experiments about to be described followed closely the lines laid down in the previous communication (*loc. cit.*). The metal used was in the form of thin rolled strips 70 × 25 × 0.5 mm. thick. The composition of the metal was Si 0.45%, Fe 0.45%, Cu 0.00, Al (by diff.) 99.1%. Unless otherwise stated the metal was annealed before the experiments for 3 hours at 450°C. The surface of the aluminium was cleaned, first with caustic soda and then with dilute nitric acid immediately before each determination of the rate of dissolution.

As in the previous communication so here all numerical results are given as milligrammes of

aluminium dissolved per 100 sq. cm. per 24 hours and denoted thus (S.R.).

Series A. The experiments of this series were made with a view to determine the effect of boiling acids of lower concentration upon aluminium and thus to complete Table II. of the previous communication.

In view of the part played by the products of the interaction the bulk of acid used is naturally of importance. Throughout these experiments, except in the case of those conducted in sealed tubes, the quantity of acid used was either 1000 c.c. or 70 c.c. In the former case the experiments were conducted in a conical Jena flask fitted with a reflux condenser. In the latter a boiling tube served to contain the acid. In order to prevent evaporation the boiling tube was lightly stoppered by means of a narrower glass tube through which cold water was passed. The strips of metal were, in both cases, carried in a light frame made of glass.

Various samples of acid were used without marked differences in the rates of dissolution being observed except where the concentration was 5%, in which case the formation of a crust of acetate probably affected the figures.

The numerical results obtained are shown in Table I. With a view to facilitating comparison the figures given in Table II. of the previous communication are repeated here in brackets. In addition to the initial rates of dissolution, the rates when the acid had become saturated with the products of the interaction have been tabulated as well as the amount of aluminium dissolved when the solutions were first seen to be turbid.

TABLE I.

Concentration of acid.	Initial rate of dissolution.	Final rate of dissolution.	Grams. of Al dissolved per 100 c.c. which produce turbidity.
99.9%		S.R. = (7)	
98		(35)	
90		(165)	
80		(295)	
70		(330)	
60	S.R. = 390	(405) 410	0.11
50		(415) 420	
40	445	492	0.157
20	450	533	0.19
10	275	582	0.24
5	350	610	0.20
1	230	1200	0.058
0.2	60	770	

In the case of the 1% and 0.2% acids the results fluctuated considerably, due it is assumed to the formation of a protective crust. Therefore the figures given for the final rate of dissolution are the highest noted. In the case of the 0.2% acid no reliance is to be placed upon the figures. After a few hours solution ceased altogether, the coating formed entirely shielding the metal from contact with the acid.

An anomaly will be noted in the case of the 10% acid, the initial rate of dissolution found being lower than was to be expected. The experiment was, however, repeated several times with similar results, and it appears, therefore, that the figure given is substantially correct.

From this table the increase in the rate of dissolution as the experiments proceeded is clearly apparent, as well as the growth of this factor as dilution increased. In order to demonstrate the course of this change as well as the initial falling off in the rate of dissolution referred to above, one of several experiments with acid of 1% concentration is given in full, the numerical results obtained being shown in Table II. In this case the acid used was a sample purified by distillation over potassium permanganate, the strength, as determined by titration, being 1.07%, and the bulk 1000 c.c.

After the experiment had proceeded for four hours the saturation of the solution was expedited in the case under review by boiling for 1½ hours with some pure aluminium foil, the surface of which is, of course, very large.

TABLE II.

Time in hours from start.	Total weight of aluminium dissolved, grms.	S.R.	Remarks.
1	0.0066	440	Slight deposit on the aluminium
2	0.0094	187	
3	0.0138	295	
4	0.0173	240	
Acid boiled for	1½ hours with	aluminium foil.	Solution turbid.
1	0.5453	1179	
2	0.5628	615	
3	0.5720	659	
4	0.6023	700	
5	0.6192	1130	

The acid being now at its maximum activity was distilled. The distillate was found by titration to contain 1.08% acetic acid, and its concentration was, therefore, practically unchanged. On continuing the experiment the following results were obtained.

Time in hours from start.	Total weight of aluminium dissolved.	S.R.
1	0.0165	1100
2	0.0306	940
3	0.0453	980
4	0.0599	975
5	0.0737	925

With such dilute acids the results are irregular owing to the metal becoming coated, but it is nevertheless clear that the rate of dissolution rose from about 200 to over 1100. It is further clear that acid which attacks aluminium at the higher rate may be distilled without losing its enhanced power of dissolving aluminium. It may be added that the replacement of one sample of aluminium by another of the same composition did not materially affect the rate of dissolution by the same acid.

Series B. The experiments of this series were made to determine the action of cold acetic acid of varying concentration upon aluminium. The numerical results obtained are given in Table III.

TABLE III.

Concentration of acid.	Rate of dissolution.
99.2	0.00

0.1	2.8 (2.2)
0.02	(3.2)
0.004	(1.00)
0.000 (distilled water)	(0.00)

The acid used in the experiments detailed was prepared from a sample of glacial acetic acid purchased. The experiments with acids of from 99.2 to 0.1% concentration were conducted in stoppered bottles of 165 c.c. capacity about three parts full, maintained at a temperature of 20° C., in the thermostat described in a communication to this Society (this J., 1916, 35, 667.)

The experiments with lower concentrations could not be carried out in the thermostat because 1000 c.c. of solution was used in order that the acid might not become unduly neutralised during the course of the experiments. Consequently the temperature was not maintained above about 10–15° C., and the figures which are shown in brackets in Table III. are, therefore, somewhat low but strictly comparable among themselves. The period of exposure was from 5 to 9 weeks, weighings being made weekly.

It will be seen that from 85% concentration down to 25% the rate of dissolution was in this case practically constant, whilst in other experiments made under identical conditions but with different samples of acid the limits of constant rate of dissolution were raised or lowered somewhat. Except in the case of acids of between 70% and 95% concentration the attack, under the conditions of the experiment, was invariably uniform, but between 70% and 95% local action, varying in intensity with different samples of acid, was noted. When the action was markedly local the rate of dissolution was largely increased. Thus, for instance, one sample of acid which at a concentration of 80% caused serious local action dissolved aluminium at the rate of 1.8 mgrms. per 100 sq. cm. per 24 hours, which is three times as fast as the same sample of acid at 70% and 90% concentrations, in which cases the local action was much less pronounced.

Series C. The experiments of this series were designed to elucidate the conditions determining whether the action of acetic acid was general or local. Whilst it cannot be said that all the conditions have so far been determined it now appears certain that in the absence of oxygen no local attack takes place, whatever the other conditions may be.

From the previous paragraphs it will be seen that solutions of equal concentration prepared from various samples of acid differ as to the form of attack, so that although it has not yet been possible to determine what the impurities are, it must be concluded that foreign bodies present in some acids are responsible for local action.

The following experiments appear to be almost conclusive on this point. (1) A sample of commercial acid which was freed from copper and then redistilled was found to attack aluminium locally when at a concentration of 80% in the presence of air. A further quantity of this acid was purified by distillation over potassium permanganate, and then found to attack aluminium very much more uniformly than before treatment.

(2) A different sample of acid was found to cause local action at the outset of the experiment, but after a time no fresh evidence of local action was observed. Moreover after seven weeks contact with strips of aluminium, the latter were removed and replaced by fresh strips. In spite of frequent aeration no local action took place upon these fresh strips during five weeks, and it may, therefore, be concluded that whatever had caused the local action in the first case had been eliminated.

The effect of oxygen. (3) The acid used in Experiment (1) was found to attack aluminium locally, not only in the cold but even more markedly at temperatures slightly below the boiling point of the acid. However, when the acid was raised to the boiling point, whereby the air was eliminated, no further local action could be detected. On passing a current of oxygen through the boiling acid a

small amount of local action took place although as was to be expected, not to so marked an extent as with the acid below its boiling point.

(1) It was possible that during boiling some volatile constituent other than oxygen had been removed from the acid, and therefore further experiments were made to settle this point. Three tubes containing strips of aluminium and a quantity of the acid used in experiment (3) were freed from air by being boiled out and sealed. One of these tubes was opened in an atmosphere of oxygen and one in carbon dioxide, and both then resealed. In the tube containing oxygen local attack commenced within 24 hours and proceeded vigorously. Neither the sample of aluminium *in vacuo* nor that in an atmosphere of carbon dioxide showed any sign of local action during the 3 months for which the experiment was continued. Two further tubes prepared and sealed in the same manner, the one containing oxygen, the other free from oxygen, were heated to 100 C. in a water bath. The sample of aluminium in the tube containing oxygen showed marked local action within 30 minutes, the other remained free from any sign of local attack for over six hours. Oxygen was then admitted to this tube, which was resealed and heated again. Local action was observed within 30 minutes.

(5) A further experiment on this subject may be cited, because it shows the effect of oxygen, not only upon the form but also upon the rate of attack.

Samples of aluminium were sealed in four tubes containing respectively (a) 99% acetic acid *in vacuo*, (b) 99% acid and oxygen, (c) 90% acid *in vacuo*, (d) 90% acid and oxygen, the acid being derived from a different source from that used in the experiments so far described.

The tubes were maintained at room temperature for 130 days. After four days distinct evidence of local action was observed in tube *d*, but to the end of the experiment there was no sign of any but general dissolution in the other three cases.

The rates of dissolution were found to be (a) 0.02, (b) 0.04, (c) 0.08, (d) 0.48.

No weight can be attached to the very small figures obtained with acid of 99% concentration, but the effect of oxygen in promoting the attack and in localising it seems irrefutable in the case of acid of 90% concentration.

(6) Finally an experiment was made with very dilute acid in atmospheres of air, oxygen, and hydrogen respectively. The weighed samples were enclosed in glass bottles fitted with rubber stoppers which were furnished with inlet and outlet tubes by means of which the various gases could be admitted, and the bottles then sealed. The dissolved oxygen was removed by boiling before the introduction of the aluminium, and the acid was then allowed to cool in a current of hydrogen, air, or oxygen as the case might be. The bottles were sealed and allowed to stand at room temperature for 91 days, during which time three weighings were carried out. As in most similar cases the rates of dissolution were high at first but soon fell off, only to rise again towards the end of the experiment. Over a period of 63 days the numerical results obtained were: in air S. R. = 1.1, in oxygen 1.0, and in hydrogen 0.26. As in all cases under similar conditions, the attack was uniform.

Series D. The experiments of this series were designed to show the effect of the presence of small quantities of various inorganic acids upon the rate of dissolution of aluminium in acetic acid of varying concentration, both at 20° C. and at boiling temperature. The concentrations selected for the acetic acid were 80% and 10%, and the inorganic acids were added in the form of their salts, this being the most convenient method in view of the very small weights involved. Experiments

were made with hydrochloric, hydrobromic, hydriodic, sulphuric, and nitric acids. The experiments were carried out at various times over a prolonged period, and it was, therefore, not possible to use the same sample of acid for all the determinations. Consequently the rate of dissolution in the acetic acid without addition is given in each case so that a sufficiently accurate comparison of the effect of the addition of various acids may be arrived at.

The main results are shown in tabular form.

TABLE IV.
10% acetic acid boiling.

	Substances added.				
	NaCl	KBr	KI	SO ₄ (as Na ₂ SO ₄)	NO ₃ (as KNO ₃)
Acetic acid without addition	S.R.	S.R.	S.R.	S.R.	S.R.
" " with 0.1%	480	480	480	490	490
" " with 0.5%	500	—	—	690	485
" " with 1.0%	540	480	470	780	510

In all cases the attack was perfectly uniform. Only in the case of sulphuric acid can any appreciable effect upon the rate of dissolution be noted.

TABLE V.
10% acetic acid at 20° C.

	Substances added.				
	NaCl	KBr	KI	SO ₄ (as Na ₂ SO ₄)	NO ₃ (as KNO ₃)
Acetic acid without addition	S.R.	S.R.	S.R.	S.R.	S.R.
" " with 0.01%	0.65	0.9	0.9	0.7	0.7
" " with 0.1%	3.2	1.0	0.85	—	—
" " with 0.5%	4.2	1.5	0.80	2.5	0.8
" " with 1.0%	5.8	2.5	0.80	—	—

In all cases the attack was uniform, but the addition of sodium chloride and also of 0.1% and 1% of KBr gave rise to an etched appearance of the metal.

The solutions containing potassium iodide were faintly coloured by iodine. It will be seen that neither potassium iodide nor potassium nitrate affects the rate of dissolution, but that the latter is very much increased by the addition of sodium chloride and sulphate and potassium bromide.

TABLE VI.
80% acetic acid at 20° C.

	Substances added.				
	NaCl	KBr	KI	SO ₄ (as Na ₂ SO ₄)	NO ₃ (as KNO ₃)
Acetic acid without addition	S.R.	S.R.	S.R.	S.R.	S.R.
" " with 0.01%	3.6	1.2	1.2	2.0	2.0
" " with 0.1%	25	0.6	0.75	—	—
" " with 0.5%	65	1.8	1.5	2.0	0.4
" " with 1.0%	270	10.5	9.5	1.2	0.45

The sample of acid used when free from all added substances gave rise to local action in the course of a few days. The addition of sodium chloride promoted this form of attack in a very marked manner, 1% of this substance giving rise to rapid local disintegration of the metal. In the case of the other two halides no definite effect

upon the form of attack could be established, except that the acid containing 1% of potassium iodide appeared to promote local action to some extent and to a great extent if any free iodine were present. The addition of 0.1% of SO_3 in the form of sodium sulphate retarded the appearance of local action for several months, whilst with acid to which 0.5% of this substance had been added no local action was discernible at the end of four months. No local action could be seen on strips of aluminium exposed for 8 months to acid containing 0.1% of NO_3 in the form of potassium nitrate.

TABLE VII.
80% acetic acid boiling.

	Substances added.				
	NaCl	KBr	KI	SO_3 (as Na_2SO_4)	NO_3 (as KNO_3)
Acetic acid without addition	S.R.	S.R.	S.R.	S.R.	S.R.
" " with 0.01%	290	290	290	290	290
" " with 0.1%	340	—	—	—	—
" " with 0.5%	4400	270	—	336	280
" " with 1.0%	—	—	—	380	260
" " with 1.0%	16,000	485	217	—	—

It was noted that high rates of dissolution were only obtained with acids containing 0.1% and 0.01% of sodium chloride if the metal were boiled in acid containing these admixtures from the start. When the metal was boiled for 1 hour in acetic acid free from sodium chloride subsequent addition of up to 0.1% of this substance had no effect upon the rate of dissolution.

The addition of 1% of potassium iodide at first gave rise to erratic rates of dissolution, which were found to be due to the fact that after standing for a short time these solutions become coloured owing to the formation of free iodine. In the presence of free iodine aluminium was found to be attacked very rapidly, the interaction being accompanied by decolorisation of the solution.

The observation that small quantities of nitrates prevented local action and in some cases actually reduced the general rate of dissolution of aluminium in acetic acid suggested that nitrates might also neutralise the injurious effects of the presence of chlorides, and it was found that this may under some conditions be the case.

Experiment 8.

80% acetic acid at room temperature.

0.1% NaCl added. S.R. = 56.

0.1% NaCl + 0.5% HNO_3 in the form of KNO_3 added. S.R. = 9.0

Experiment 9.

80% acid at 90°–100° C.

0.1% NaCl added. S.R. = 2400.

0.1% NaCl + 0.5% HNO_3 in the form of KNO_3 added. S.R. = 187

Series E. In view of the marked difference shown by the results tabulated above between the effect of the addition of chlorides and bromides to acetic acid, it was naturally assumed that similar differences would obtain between the action of hydrochloric and hydrobromic acids without acetic acid, and as no data were available on this subject the two acids were compared with regard to the rate at which they dissolve aluminium.

At boiling point. Concentration of the acids N/2.

S.R. in HCl = 24,000.

S.R. in HBr = 2,500.

At 20° C. Concentration of the acids 0.686 N.

S.R. in HCl = 50.

S.R. in HBr = 14.5.

DISCUSSION.

The CHAIRMAN having complimented the authors on their valuable work,

Dr. C. A. KEANE pointed out that the character of the reactions due to concentrated and dilute acetic acid respectively must be essentially different and that it might be advantageous to differentiate them in discussing the chemical changes involved. In respect to the action of concentrated acetic acid, had they examined the acetic acid for any reduction products that might be formed? The generation of hydrogen might lead to the formation of acetaldehyde which by local re-oxidation might be concerned with the effects produced upon the aluminium, and it would accordingly be of interest to know whether the presence of acetaldehyde had actually been detected; the aluminium itself might act catalytically in this connection. In the case of dilute acetic acid such an effect was improbable, and in the corrosion by sea-water and tap-water other reactions must be concerned.

Mr. E. J. BOAKE thought, from the samples handed round, and from his experience of the practical employment of aluminium vessels, that the local corrosion of aluminium was due to impurities in the metal. He instanced a case coming under his own observation, where the mercury from a broken thermometer had been spilt in the still; very shortly afterwards the still bottom was found to be perforated, and upon examination there appeared relatively large cavities—many of them almost through the substance of the metal. He further suggested that it would be highly desirable if experiments could be conducted on aluminium of known purity, or failing this that the amount or nature of the impurities should be known, and results noted.

Mr. C. E. BAUS inquired whether the authors had made any experiments with aluminium of varying purity, and if so, was the corrosion increased by some impurities and decreased by others? The film of oxide formed by nitrates present in the acetic acid seemed to exert a retarding action. Had the authors ascertained whether treating an aluminium still with acetic acid containing nitrates prolonged the life of the vessel?

Mr. W. C. REYNOLDS asked whether the presence of traces of ammonium had any effect on the action of acetic acid on aluminium. He pointed out that it was a very common impurity in commercial acetic acid.

Mr. NICHOL said he thought from the appearance of the samples shown that the commercial metal had been used in the experiments, and that possibly chemically pure aluminium might yield different results. He suggested that the more rapid action of acids on aluminium, as the time of immersion increased, might possibly be due to the readiness with which gas might be evolved from a surface already acted upon?

Mr. E. T. BREWIS said that he had known cases of pitting of aluminium and could testify to the necessity of drying vessels after they had been used. Had the authors made any experiments as to the action of a fairly pure water, highly aerated, for example a condenser water which had been passed through cooling towers and become highly aerated?

Mr. FRYER asked whether the figures given for dilute acetic acid might safely be taken as applicable to butyric, propionic and the lower fatty acids generally?

Mr. W. C. HANCOCK considered that although the experiments described seemed to show that oxygen was the cause of the pitting, he agreed with a previous speaker that the action was more likely due to some impurity in the metal. If the corrosion was due to oxygen, how was it that the action was not more uniform over the whole surface? It was difficult to imagine that there were "pockets" of oxygen which localised the pits. He asked the authors if they had made any experiments with

the aluminium partly exposed to the air and partly immersed in the acid.

Mr. BREWIS inquired whether the authors had noticed any difference in the behaviour of aluminium treated in various ways, *e.g.*, cast, hammered, or rolled aluminium, and whether these various metallurgical treatments caused any variations in the resistance to corrosions.

Dr. SELIGMAN, in reply, said that with reference to the discussion which had arisen as to whether these experiments should have been conducted with chemically pure aluminium or aluminium of the purity in use in commerce, he had no doubt that experiments should if possible be carried out with both materials. It was true that experiments carried out with pure material would not be of much direct guidance when considering practical conditions, but on the other hand from experiments with material free from all impurities information would be gained which would be extremely valuable in estimating the effect of impurity, but unfortunately chemically pure aluminium was an unknown commodity. The purest sample of aluminium he had ever had through his hands contained 99.8% of aluminium, and a good many of the experiments which the authors had made with these acids had been done with material of this purity. The present series of experiments had, however, been done with a different metal, and the question of the bearing of the purity of the metal had never been overlooked. The authors were also alive to the possibility of the effects of certain additions to the aluminium not only in accelerating but in some cases in retarding corrosion, and information was gradually being accumulated on this subject. As an example he drew attention to the effect of as little as 0.5% of copper in stopping absolutely the action of mercury upon aluminium, to which Mr. Boake had referred. There were other cases in which the addition of small quantities of other metals had a beneficial effect upon aluminium, and it might ultimately be possible to make use of these facts. He could not agree with Mr. Boake's explanation of the fact that mercury attacked aluminium locally. Mr. Boake appeared to attribute this to the presence at the points attacked of small quantities of impurities, whereas the fact was that wherever aluminium became amalgamated attack developed, but amalgamation only took place under very definite physical conditions which did not prevail over the whole surface of the metal.

He quite agreed with various speakers that the appearance of a sample of aluminium which had been subjected to local attack at once suggested the presence at such points of impurities, and for a long time he had held the view that impurities in the metal were responsible for such occurrences. Gradually, however, he had forsaken this view, especially since almost every investigation made had shown that such impurities as were present in the aluminium were quite uniformly distributed throughout the metal. On the other hand he was now convinced that physical differences in the metal might under certain conditions account for the fact that the attack took place at one point in preference to another. Aluminium became amorphous under the effect of work, and amorphous aluminium was electro-positive to crystalline metal, and therefore it might occur that two adjacent points differed in polarity, and one of them would tend to corrode more rapidly than another. This also answered the question raised by Mr. Brewis as to whether different forms of aluminium showed differences with regard to corrosion. As to the other question raised by Mr. Brewis, the authors had not found that distilled water, even when aerated, caused any other than a general solution of aluminium, but they had not devoted special attention to excessive aeration of such water.

In reply to Mr. Barrs, he said that the effect of washing aluminium with dilute nitric acid prior to an attack by acetic acid had been examined. They had not been aware that, as Mr. Reynolds pointed out, acetic acid contained small quantities of ammonium acetate, and had, therefore, not so far investigated the effect of ammonia upon the rate of attack.

He could not agree with Mr. Nichol's suggestion that the increase in the rate of dissolution was due to the fact that as the surface of the metal became attacked the escape of gas from the surface was facilitated, because the authors had found that once an acid had increased in activity a fresh sample of aluminium immersed therein dissolved at the higher rate.

Mr. Hancock appeared to think that the authors attributed the localising effect of oxygen to the presence of "pockets" of oxygen in the acid, so that action only took place at the points where such pockets of oxygen occurred. The authors had no such idea. They merely stated that in the presence of oxygen the metal was attacked at certain points, but they were still far from being able to say in all cases why the metal broke down at those points and not at others. He wished to repeat that whilst many materials did not attack aluminium locally in the presence of oxygen, no materials which had so far been examined did attack it locally in the absence of oxygen. If aluminium was only partially immersed in acetic acid corrosion took place quickest at the water line, as Mr. Hancock anticipated.

In reply to Mr. Fryer's question, he said that they had examined the effect of a series of other acids and hoped to be able to bring the results forward later. Such figures as they had obtained indicated effects of the same order as those given for acetic acid.

The authors were very interested in Dr. Keane's suggestion that the formation of acetaldehyde might account for the accelerating effect of the products of the interaction upon the interaction. Acetaldehyde was undoubtedly formed during the dissolution of aluminium in acetic acid, but the authors' difficulty had been to explain how a product of the reduction of acetic acid could promote the attack. Dr. Keane's suggestion, as he understood it, was that they would have to look to the re-oxidation of the aldehyde for an explanation of the phenomenon. He could, of course, not say whether there was any substantiation for this view, but the matter would be investigated at once.

Manchester Section.

Meeting held at the Grand Hotel, on Friday, January 12th, 1917.

MR. J. H. ROSEASON IN THE CHAIR.

ESTIMATION OF PHOSPHORIC ACID AND PHOSPHATES BY ALKALIMETRIC METHODS.

BY JOHN H. SMITH, PH.D., F.R.C., A.R.C.S.I.

It is well known that the point of neutrality obtained by titrating phosphoric acid with an alkali differs according to the indicator taken, sodium dihydrogen phosphate, *e.g.*, being indicated as neutral when methyl orange is employed and disodium hydrogen phosphate when phenolphthalein is used. This difference in indication

suggested some useful applications for the special work I was engaged upon, but the results did not possess the accuracy aimed at; and the various and serious irregularities which may be introduced explain why such a method had not been suggested seriously for the estimation of phosphoric acids and phosphates in compounds, but has been confined to the estimation of the strength of solutions of pure phosphoric acid using phenolphthalein as indicator.

Foreseeing the possibility of eliminating the irregularities to a large extent, the author was led to investigate their cause more thoroughly in the hope that some reliable method might result for the analysis of mixtures of phosphates, and applicable to a large number of cases which would occur in ordinary practice, particularly that of the alkaline phosphates.

It was necessary first to find the exact point of neutrality with different indicators, to ascertain whether the end points are sufficiently definite and correspond sufficiently closely to the accepted ones. This necessitated the employment of pure phosphoric acid of known strength and a reliable standard solution of alkali. Caustic soda was selected as the alkali to be employed, but as this is difficult to obtain free from carbonate, a factor was introduced leading to the vitiation of the results. As an illustration of the amount of error which may be introduced from this source, 100 c.c. of strictly normal hydrochloric acid, accurately standardised against pure sodium carbonate dried at 250° C., and requiring 100 c.c. of the standard caustic soda solution in question to neutralise with methyl orange, required 100.6 c.c. with methyl red and 101.3 c.c. with phenolphthalein as indicator. Identical numbers were obtained with 100 c.c. of normal sulphuric acid. This would correspond to about 2.7% of the sodium being present in the form of carbonate.

Although phenolphthalein can hardly be recommended as an indicator for the estimation of carbonates in bulk, the results obtained in the cold, with such small quantities as would occur in the case of their presence as impurities, are satisfactory. For example, 100 c.c. of a *N*/20 solution of pure sodium carbonate required at normal temperature for neutralisation 99.85 c.c. of *N*/20 hydrochloric acid with methyl orange, 93.15 c.c. with methyl red, and 49.25 c.c. with phenolphthalein, but 49.60 c.c. with phenolphthalein when a few grammes of pure sodium chloride had been added to the solution. The end point with phenolphthalein corresponds approximately with the formation of sodium bicarbonate, and is fairly definite, in fact quite satisfactory, after the addition of sodium chloride.

The regularising action of sodium chloride and glycerin in titrations with phenolphthalein has been observed and their addition recommended by other workers. In the case of phosphoric acid and its salts the addition of sodium chloride is also extremely useful and generally preferable to glycerin.

In experiments of this delicate nature it is essential to be convinced with regard to the purity of all the reagents employed, and even the distilled water must be tested by blank experiment. One sample, although quite neutral to phenolphthalein, showed an alkalinity of 6.25 c.c. *N*/10 to methyl orange and 5.0 c.c. *N*/10 to methyl red per litre of water. This seemed to point to the presence of bicarbonates, but the alkalinity was considerably greater than that of the tap water in use.

It seemed interesting to determine what influence small amounts of ammonia and ammonium salts might have upon the results. 100 c.c. of a dilute solution of ammonia required: 100 c.c. of *N*/20 hydrochloric acid with methyl red, 102.8 c.c. with methyl orange, and 91.1 c.c. with phenolphthalein,

but 95.5 c.c. with phenolphthalein after the addition of sodium chloride. In this case again the addition of the salt renders the end point much more definite and brings it nearer to the theoretical 100 c.c. point of methyl red accepted as standard for ammonia.

With sodium carbonate and with ammonia the end points when using methyl orange and methyl red are quite definite and not influenced by addition of chloride.

Returning to the impurity contained in the standard sodium hydroxide solution, it might reasonably be inferred that this could be compensated for by making corresponding corrections in the calculations. This, however, is tedious, and not altogether satisfactory; hence the caustic soda was purified by addition of barium hydroxide. As it was essential that no barium salt should be left in the final solution on account of the precipitation of barium phosphate which would inevitably occur and vitiate the results in the analyses in view, it was necessary to add the barium hydroxide in just sufficient quantity to precipitate the whole of the carbonate present in the caustic solution. Even then a small quantity of the barium carbonate remained dissolved in the caustic soda, and although the barium could be removed by the addition of a sulphate the small proportion of carbonate could not be further eliminated. By this means, however, it was possible to reduce the amount of carbonate from about 2% as found in the best samples of caustic soda in lumps, as sold for analysis, to 0.2%. As only half of the carbonate is indicated by phenolphthalein this means an error of 0.1% when using this indicator, which is almost negligible.

As the barium hydroxide contains a large percentage of carbonate it is necessary to estimate its amount, which may be done volumetrically, using phenolphthalein and methyl orange as indicators; the barium carbonate remaining in the solution and the trace of excess hydroxide which it is advisable to add are precipitated by sulphuric acid after neutralising the solution, and the barium sulphate estimated gravimetrically. An amount of crystallised sodium sulphate equivalent to the barium left in the solution is then added to it. The solution should not be filtered from its precipitates of barium carbonate and sulphate respectively, but allowed to stand over night in closed bottles and decanted carefully. The sodium hydroxide solutions once standardised must naturally be protected from the action of atmospheric carbon dioxide by every possible means.

Titration of phosphoric acid.

A satisfactory sample of phosphoric acid was obtained and proved to be practically pure by ordinary qualitative tests. Ignited in a platinum crucible it gave a mere trace of residue. The specific gravity of the acid was 1.7421 at 17.5° C., which is equivalent to 88.3% H_3PO_4 according to Hager's table of specific gravity. From gravimetric analysis by the magnesia method a mean percentage of 88.605 H_3PO_4 was obtained, and as this is probably the more reliable result 88.6% was accepted as the correct strength.

The hygroscopic nature of phosphoric acid is well known, but the acid does not lose all its combined water when dried at 100° C.; even at 110° C. it was found that 3.25% H_2O remained combined, corresponding approximately to the formula $6\text{H}_3\text{PO}_4 \cdot \text{H}_2\text{O}$.

An amount of the phosphoric acid corresponding to 9.802 grms. of H_3PO_4 (0.1 mol.) required for neutralisation the following amounts of pure *N*/1 sodium hydroxide solution: 101.8 c.c. with methyl orange, 105.4 c.c. with methyl red, and

202.7 c.c. with phenolphthalein. The generally accepted points of neutrality with methyl orange and phenolphthalein are thus shown to be only approximately correct. The end points are, however, quite regular and fairly definite. This has been proved by a large number of comparative tests, so that it would be possible to make estimations of phosphoric acid and phosphates by multiplying the results obtained by the corresponding factors, viz.: 0.9823, 0.9488, and 0.9867 respectively, but the corrections make the work tedious and I have devised a method which makes it possible to dispense with such calculations.

While examining the effect of temperature of solution upon the end point I found that phosphoric acid is particularly sensitive to change of temperature as the following figures illustrate: 100 c.c. of a solution of phosphoric acid containing 32.68 grms. of H_3PO_4 per litre, required with methyl orange as indicator:—32.5 c.c. $N/1$ sodium hydroxide at 70°C ., 33.4 c.c. at 50°C ., 34.0 c.c. at 20°C ., and 34.2 c.c. at 5°C ., while with phenolphthalein the following amounts were required:—66.0 c.c. at 70°C ., 66.9 c.c. at 50°C ., 67.4 c.c. at 20°C ., and 67.6 c.c. at 5°C .. In the first case the theoretical point for NaH_2PO_4 is 33.33, and the second case 66.66 c.c. Curves plotted with these points taken to represent 100% in each case cross the 100% line about 55°C ., so that a mean temperature of 55°C ., may be taken as the best for conducting titrations of phosphoric acids and phosphates, without any necessity of making corrections in the results; this temperature has been adhered to in all further experiments.

Similar comparative experiments with other acids showed that temperature is without effect upon titrations with hydrochloric acid either with methyl orange or phenolphthalein. The same is the case for sulphuric acid, but only for phenolphthalein; with methyl orange accurate results are only obtained at very low temperatures; at high temperatures considerable deviations occur giving errors of more than 1%.

For acidimetric work hydrochloric acid possesses the great advantage over sulphuric acid that it is not affected by temperature, and this acid was usually employed in the subsequent titration of alkaline phosphates. As carbonates are constantly found in combination with the phosphates it was necessary to know how the presence of these affected the results, and a series of experiments on the titration of carbonates was made at various temperatures. Even with methyl orange the deviations are quite appreciable and point to a high temperature being preferable for the titration, unless the solution be boiled on approaching the end point. The results of the experiments indicated that the temperature chosen for titration, 55°C ., is suitable for all the acids with the exception, perhaps, of sulphuric acid with methyl orange.

Although I have shown in a second paper that there is reason to doubt the usually accepted constitution of some of the ordinary alkali phosphates under normal conditions, for convenience of calculation the results will be expressed in terms of NaH_2PO_4 , Na_2HPO_4 , and Na_3PO_4 . There are three definite points in the titrations which enable us to make analyses of a mixture of any three of these compounds, including the possible presence of free Na_2O .

Method of analysis.

As the phosphates generally crystallise with a large proportion of water it is preferable to weigh out 5 to 6 grammes of the substance to be analysed, to ensure greater accuracy.

After dissolving in a minimum quantity of

distilled water, two drops of phenolphthalein solution are added; if the solution is not coloured pink the absence of Na_3PO_4 and Na_2CO_3 may be assumed. The solution is then heated to 55°C . and kept at this temperature during the whole of the titrations, being particularly careful to have the temperature correct when each end point is nearly reached. In the case under consideration the solution is first titrated with $N/1$ sodium hydroxide until a pink coloration is noticeable. It requires a certain amount of practice to determine the end points, and particularly this first one, with certainty, but once this practice has been attained there is no further difficulty, especially in presence of sodium chloride. One must not expect the same strong pink colour which is found when working with alkali and strong mineral acids; it is more of the nature of the pink coloration obtained with a drop of acid in excess when employing methyl orange as indicator.

This first end point will be called A and the number of c.c. of $N/1$ alkali required to reach this point is (a). The solution is now titrated back with $N/1$ hydrochloric acid with addition of a few drops of methyl orange solution, until the second end point (B) is reached, when the solution changes to a faint pink colour again. The number of c.c. of $N/1$ acid required between the A and B points will be denoted by (b). Now if we know that the solution contains only $\text{Na}_2\text{HPO}_4 + \text{NaH}_2\text{PO}_4$, or $\text{NaH}_2\text{PO}_4 + \text{H}_3\text{PO}_4$, or only one of these compounds, we have sufficient data, because if a is greater than b, $a-b$ represents the amount of H_3PO_4 and b the NaH_2PO_4 , whereas if b is greater than a, $b-a = \text{Na}_2\text{HPO}_4$, and $a = \text{NaH}_2\text{PO}_4$. If $a=b$ then each is equal to the NaH_2PO_4 present and if $a=2b$ only H_3PO_4 is present.

In order to make the method uniform I prefer to proceed further in every analysis and obtain a third end point, C, in the following manner. An amount of normal hydrochloric acid (b') approximately equal to b is added to the solution, which is then boiled vigorously for a quarter of an hour at least. By this boiling any metaphosphoric acid or metaphosphate is converted into the ortho form, while in the case of alkaline salts containing carbonates these will be destroyed and carbon dioxide evolved. After boiling, the solution is cooled again to 55°C . and titrated back with $N/1$ sodium hydroxide first to the B point again in which b'' c.c. of alkali is used and finally to the third end point C, where the phenolphthalein pink coloration is again reached and where the consumption of normal alkali is denoted by (c). In titrating back after boiling, the b' amount of alkali required to reach the methyl orange point where the pink coloration just disappears should always be exactly the same amount as the b' excess of acid added for boiling (except in the case of polyphosphates being present as referred to in my second paper), and in practice this is found to be the case, the difference seldom exceeding 0.05 c.c.; b'' may be less than b' by this quantity owing to a trace of the hydrochloric acid having evaporated, but if care is taken not to concentrate the solution too much no more serious error is likely to occur. In any case, however, it is preferable to consider the point reached after the addition of the b'' quantity of alkali as the identical point with B, so that b' and b'' are not used in the calculations but simply employed as a comparative check upon each other. If now the C point coincides with the A point, i.e., if $c=b$, the possibility of the presence of metaphosphoric acid and its salts, as well as of carbonates, in the original substance is excluded; if c is greater than b the presence of the former is indicated, while carbonates, which so frequently occur with the tribasic alkali phosphates, cause c to be less than b.

It is most convenient in working with normal solutions to consider each c.c. employed as equal to one molecule of NaH_2PO_4 , Na_2HPO_4 , Na_3PO_4 , H_3PO_4 , etc., in their transformation from one stage to another, i.e., in changing between the A and B points, the absolute weights being easily found by multiplying by $\frac{1000}{\text{m.w.}}$ of the respective molecular weights. Similarly the amounts of Na_2CO_3 and Na_2O present in the respective compounds are found by multiplying by $\frac{1000}{\text{m.w.}}$ of their respective molecular weights.

With the aid of the three fixed points A, B, and C, and the amounts of acid or alkali required to reach them, a, b, and c, it is possible to calculate the percentages of practically all the phosphoric acids and their salts which may exist together in a compound, including the carbonates and the free alkali which may be present with them, as shown in the accompanying chart.

In the titration of acid salts where a is greater than b, then $\text{H}_3\text{PO}_4 = a - b$, $\text{NaH}_2\text{PO}_4 = 2b - a$, and $\text{NaPO}_3 = c - b$ (generally nil).

If a were greater than 2b, then $a - 2b$ would be the measure of the metaphosphoric acid or of the foreign acid present.

When a is less than b, then $\text{NaH}_2\text{PO}_4 = a$, $\text{Na}_2\text{HPO}_4 = b - a$, and $\text{NaPO}_3 = c - b$ (usually nil).

With alkaline salts, C coincides with A, i.e., when no carbonate is present, and a is less than b, then $\text{Na}_3\text{PO}_4 = a$ and $\text{Na}_2\text{HPO}_4 = b - a$. Where c is less than b, i.e., where carbonate is present, and a is less than b, then $\text{Na}_3\text{PO}_4 = a + c - b$, $\text{Na}_2\text{HPO}_4 = b - a$, and $\text{Na}_2\text{CO}_3 = b - c$. Where no carbonate is present, and a is greater than b, then $\text{Na}_3\text{PO}_4 = b$ and $\text{Na}_2\text{O} = \frac{1}{2}(a - b)$. Where carbonate is present, and a is greater than b, then $\text{Na}_2\text{CO}_3 = b - c$, $\text{Na}_3\text{PO}_4 = c$, and $\text{Na}_2\text{O} = \frac{1}{2}(a - b)$.

These formulae have been proved to be correct by hundreds of experiments, and by mixtures of standard solutions of phosphoric acid and alkali in nearly every proportion. Comparative tests are concordant within the usual limits of experimental errors; in fact if every precaution is taken, results within 0.5% of accuracy are obtained which can hardly be excelled by other methods of phosphoric acid determination.

It is well, of course, to verify the results in some cases with qualitative tests, particularly in the case of the presence of the meta acid or its salts, and also of the pyro acid and its salts. When the pyro acid is present, point A is obscured and lies much nearer to B, but the correct A point is point C obtained after boiling with excess of acid.

When metaphosphate has been proved to be present it is advisable to repeat the titrations, employing normal sulphuric acid instead of hydrochloric acid, and evaporating to dryness after boiling, when the

last one or two per cent. of the acid is converted into the ortho form which is liable to escape conversion on merely boiling; otherwise, however, it is always preferable to adhere to hydrochloric acid.

On boiling pure acid phosphates in glass beakers or porcelain dishes a portion of alkali is almost invariably dissolved, but there is no difficulty in detecting this as *b''* in this case is less than *b'*. Under the conditions existing when the titrated solutions are boiled, this effect seems, however, hardly appreciable, which may be due to the considerable amount of sodium chloride present in the solution.

I have not been able to confirm the statement in the text books that sodium pyrophosphate is neutral to phenolphthalein, *i.e.*, to such an extent as to make the *c-b* amount quite reliable. In a test with fused sodium pyrophosphate it required 11.8% of the sodium hydroxide necessary to convert it into Na_2HPO_4 , but this may have been due to the partial conversion of the salt into NaH_2PO_4 on dissolving in water.

This method was applied to the examination of some commercial samples of phosphates. A specimen of ordinary sodium phosphate, $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$, was found to contain 38.92% Na_2HPO_4 , 2.41% Na_3PO_4 , and 59.57% H_2O ; theory requires 39.64% Na_2HPO_4 .

A sample of trisodium phosphate, dried at 110°C , contained $\text{Na}_3\text{PO}_4 + \text{H}_2\text{O}$, 26.70%, Na_2HPO_4 , 19.56%, and Na_2CO_3 , 23.95%. On examining the undried salt carefully it was found that the bulk of the crystals had become dried up so that decomposition of the salt from atmospheric influence seemed probable. A few fresh crystals still remained, however, and these contained Na_3PO_4 , 11.90%, Na_2O , 2.01%, Na_2CO_3 , 0.66%, H_2O , 55.43% ($\text{Na}_3\text{PO}_4 + 12\text{H}_2\text{O}$ requires Na_3PO_4 , 43.13%, H_2O , 56.87%). The original salt had probably a similar composition to these selected crystals and had been decomposed by atmospheric carbon dioxide. In my paper on the constitution of the alkali phosphates I shall show that Na_3PO_4 only crystallises with an excess of alkali, so that the above proportion of Na_2O is not to be looked upon as an impurity, and that it is a very unstable compound.

A specimen of sodium pyrophosphate contained $\text{Na}_2\text{P}_2\text{O}_7$, 92.62%, Na_2O , 6.50%, H_2O , 6.12%. In titrating both the pyrophosphate and the ordinary phosphate a small precipitate was found after boiling with the acid and subsequently neutralising with sodium hydroxide.

A compound was examined which was labelled "glacial" phosphoric acid. It was rather soft and lumpy, and seemed to have been dried at a high temperature and afterwards to have absorbed moisture from the atmosphere. It had a strong acid reaction and gave a strong sodium flame reaction. Analysis showed it to contain NaH_2PO_4 , 60.35%, H_3PO_4 , 35.30%, water (by diff.) 4.35%. It is remarkable that this substance with no trace of metaphosphoric acid should have come to be sold as "glacial" phosphoric acid. I presume, however, that it had been produced by heating ortho acid at an insufficiently high temperature, the sodium present being accounted for by the action of the acid on the vessels.

ON A NEW ACID SODIUM PHOSPHATE AND ITS ACTION UPON GLASS, PORCELAIN, SILICA, PLATINUM, AND NICKEL VESSELS.

BY JOHN H. SMITH, PH.D., F.I.C., A.R.C.S.I.

In the course of the experiments described in the foregoing paper relating to the estimation of phosphoric acids and phosphates, I discovered that phosphoric acid is capable of combining with

sodium oxide in a much higher proportion than is represented by sodium dihydrogen phosphate or the metaphosphate.

The composition of the three known forms of ignited sodium phosphates and of the new salt may be represented thus:—

The new salt is easily prepared in an impure state by evaporating mixtures of caustic soda or sodium carbonate and phosphoric acid with a sufficient proportion of the latter and igniting the residue. Any excess of acid is volatilised during the ignition, so that this proportion of acid is evidently the highest with which Na_2O is capable of combining and resisting the high temperature employed. The ignition was finished in a muffle furnace at a bright red heat.

The salt is a fused glassy mass which dissolves slowly in cold, but more readily in warm water, and is nearly neutral to both methyl orange and phenolphthalein.

That the fused residue is a distinct chemical compound is shown by the fact that the substance is stable at a bright red heat, thus excluding the presence of either free orthophosphoric acid or the meta acid, while its neutrality to methyl orange precludes the possibility of its having the composition of $2\text{NaPO}_3 + \text{HPO}_3$ even after solution in cold water. In an actual test it was found that only 8% of the amount of free acid shown in the above formula was indicated by methyl orange.

There is evidence, however, that the new acid salt on prolonged boiling with water is converted into sodium metaphosphate and free orthophosphoric acid, not the meta acid. The sodium metaphosphate does not seem to become converted into sodium dihydrogen phosphate by further boiling with water under these conditions, but if it is boiled with excess of mineral acid, only the ortho acid is found in the solution and no meta acid. To ensure complete conversion it is necessary to evaporate the solution to dryness, and of course sulphuric acid must be employed for quantitative work.

I have never found either sodium metaphosphate or the new salt, which I shall call sodium polyphosphate, to be quite neutral to phenolphthalein, but this is no doubt due to the impossibility of dissolving them even in cold water without a partial change. The figures varied from 12% to 15% of the acidity represented by the salts after conversion into the ortho form, and in the case of $\text{Na}_4\text{P}_2\text{O}_7$ this would not even suffice to bring the excess of P_2O_5 over the meta form up to that condition. It would require one molecule of Na_2O to bring the formula to 6NaPO_3 and another $3\text{Na}_2\text{O}$ to bring this again to $6\text{Na}_2\text{HPO}_4$ after converting to the ortho state, *i.e.*, 25% of the total alkali required is necessary to neutralise the excess of acid.

A remarkable property of sodium polyphosphate is its exceedingly energetic corrosive action upon glass, porcelain, and even platinum and silica vessels. The action was naturally most energetic at the high temperature of fusion, the glaze of porcelain dishes being eaten into, and leaving generally after dissolving out the salt a deposit of granular silica. Silica vessels were also sensibly attacked and silica entered into the composition of the resulting salt. A platinum dish was strongly attacked and became brittle wherever it had been in contact with the fused salt, being torn right across afterwards as easily as a piece of paper. A nickel vessel was attacked until the residue consisted entirely of sodium and nickel pyrophosphates. The corrosive action of the metaphosphate is appreciable, but nothing like that of the polyphosphate. This suggests

a use for the salts in the preparation of phosphates which cannot be obtained under usual low temperature conditions.

This corrosive action rendered it almost impossible to obtain the salt in a pure condition and to determine its exact composition.

By taking a mean of all the experiments a fair approximation to the real composition could be obtained, and I think I am justified in giving the salt the formula I have quoted until some more satisfactory method for obtaining and analysing the pure substance is found.

No reliable quantitative results could be obtained from the experiment in the platinum dish as there was a loss of substance from the holes which were formed in the bottom of the dish by the fused salt. It was exceedingly difficult to get the last traces of salt separated from the platinum; only after separate treatment with boiling hydrochloric and nitric acids and ammonia was this approximately possible, the excess weight of the platinum dish being reduced in this way from 0.075 gram. to 0.010 gram. After the platinum dish had been ignited again in the muffle furnace for one hour at a bright red heat, the metal had regained its original properties but had lost not only the 0.010 gram. excess weight but 0.030 gram. of its own weight.

Several experiments were made in porcelain dishes, which were strongly attacked, the alkali being extracted from the fusible glaze and silica remaining on the bottom of the dish. Concordant results could not be expected under such circumstances, since the action must depend to a large extent upon the conditions of the reaction, and again it is not only the polyphosphate which acts upon the porcelain but the excess of acid, as was proved by an independent experiment.

A pure sample of phosphoric acid which left a mere trace of residue when ignited at a low temperature in a platinum vessel, left 3.15% residue in a porcelain dish, i.e., this proportion of acid had been fixed by alkali abstracted from the dish. As this reaction would be taking place simultaneously with the volatilisation of the excess of acid, it is not necessary to assume that the polyphosphate enters into the reaction until all excess of free acid has been volatilised. In one experiment 6.9 c.c. of *N*/1 caustic soda, together with some water, was added to 1.5 grms. of pure phosphoric acid of 88.6% strength in a porcelain dish and the solution evaporated to dryness. Dried in an air bath at 110° C. the weight of the residue was 1.59 grms.; ignited over a weak Bunsen flame until no more fumes were given off the residue weighed 1.19 grms., while after one hour's fusion in a muffle furnace at a bright red heat the weight of residue was 1.11 grms. After dissolving the salt in hot water the dish had lost 0.015 gram.

If the porcelain glaze was a pure feldspathic one the 0.045 gram. abstracted from the dish would be K_2O . Potassium was present in the solution but its amount was not determined. In the calculations I have considered the 0.015 gram. both as (a) Na_2O and (b) K_2O .

The salt would have the following percentage composition after ignition in the muffle furnace:—

	a.	b.	$Na_4P_6O_{17}$	$NaPO_3$	$Na_2O + 2P_2O_5$	$4Na_2O + 7P_2O_5$
P_2O_5	77.57	78.73	77.45	69.61	82.08	80.0
Na_2O	22.43	21.27*	22.55	30.39	17.92	20.0

* Calculated from K_2O .

The (a) composition is thus exceedingly close to that of the calculated percentage composition of $Na_4P_6O_{17}$ or $2Na_2O \cdot 3P_2O_5$.

The (b) calculation gives 1.3% P_2O_5 in excess which would only be a comparatively small deviation. In any case it seems certain that the proportion of P_2O_5 given in the formula $Na_4P_6O_{17}$ is the least that can be assumed. The next formula of a simple nature which we could consider would be that of $Na_2O + 2P_2O_5$, containing 100% more P_2O_5 than the metaphosphate of sodium. But its percentage of P_2O_5 (82%) is much too high again. If we take the composition of the salt just after ignition over a weak Bunsen flame we find that about 80% P_2O_5 is then present, and this is the highest proportion which could be assigned to the salt. This proportion would correspond to the formula $4Na_2O + 7P_2O_5$. There may be a salt with a higher proportion of P_2O_5 stable at intermediate temperatures but probably not at bright red heat.

A confirmation of the formula $Na_4P_6O_{17}$ was obtained from an experiment in a fused silica dish. Normal caustic soda solution and water were added to 88.0% phosphoric acid and the solution evaporated to dryness in a silica dish, dried first at 110° C., then at 210° C. on the sand bath, and finally ignited for 35 minutes in a muffle furnace at a bright red heat. The portions of the residue soluble in cold water, boiling water, and sulphuric acid, and the insoluble portion were examined by the method described in the preceding paper, and the silica estimated gravimetrically.

With the exception of the acid extract, which had a greater proportion of phosphoric anhydride than necessary to combine with the silica present, all the results approached remarkably closely to the theoretical formula, $2Na_4P_6O_{17} + SiO_2 \cdot P_2O_5$. Whether this is a chemical compound and explains the difficult solubility, or is simply a mixture has not been investigated.

The silica was afterwards examined for associated P_2O_5 but with a negative result.

As far as the sodium salt is concerned I think the results prove satisfactorily that $Na_4P_6O_{17}$ is the formula of the salt formed, the excess of P_2O_5 found being only about 2%.

The action of the salt on nickel is the same as the action when phosphoric acid is boiled down in a nickel vessel, and the residue ignited, only it is much more energetic. In one case where 3 grms. of phosphoric acid was boiled down and the residue ignited, the loss of weight of the dish was 0.068 gram., whereas with 0.7 gram. of $Na_4P_6O_{17}$ after ignition 0.33 gram. of the weight of the nickel dish had been lost, the nickel having been quantitatively converted into pyrophosphate, while at the same time the salt had been reduced to the form of sodium pyrophosphate.

Sodium polyphosphate probably could be employed with advantage in many cases where exceedingly energetic chemical reactions are necessary, e.g., for the disintegration of complex minerals, silicates, etc.

ON THE CONSTITUTION OF THE ALKALI PHOSPHATES, AND SOME NEW DOUBLE PHOSPHATES.

BY JOHN H. SMITH, PH.D., F.I.C., A.R.C.S.I.

While applying the titrimetric method I have advocated for the estimation of phosphoric acids and phosphates (see p. 415) to the analysis of various commercial samples of phosphates, I was struck by the deviations which occurred in their composition as compared with the generally accepted formulae of the salts in question, such deviations being generally in a well-defined direction.

To take the most conspicuous case of the ordinary disodium hydrogen phosphate, it has long been known and remarked upon that this

salt, which theoretically should be neutral to phenolphthalein, is invariably alkaline. It seemed hardly likely that this result could be due in every case to the presence of free alkali or alkali carbonate as an impurity, and as my new method seemed particularly well adapted to elucidate the question, this salt was studied in the first instance.

Disodium hydrogen phosphate.

A particularly pure sample of phosphoric acid was secured which, ignited in a platinum crucible, left the merest trace of residue. The specific gravity was 1.7424 at 17.5° C., corresponding with 88.3% H_3PO_4 in Hager's table. Gravimetric estimation by the magnesia method gave a mean strength of 88.605%, so that 88.6% was accepted as the correct strength. Pure caustic soda in normal solution was employed as alkali.

A standard solution of the phosphoric acid was prepared containing 32.68 grms. of H_3PO_4 per litre; 100 c.c. of this solution is equal to 33.33 c.c., 66.66 c.c., and 100 c.c. of the pure normal alkali solution for the preparation of the theoretical salts NaH_2PO_4 , Na_2HPO_4 , and Na_3PO_4 respectively. From 50 to 100 c.c. of the H_3PO_4 was employed in order to obtain accurate results.

It might be assumed naturally that on adding the solutions in the exact proportions to form Na_2HPO_4 and evaporating there would be no difficulty in obtaining the pure crystallised salt. This was found, however, not to be the case. In the first instance an attempt was made keeping the H_3PO_4 in 2% excess. It was possible to evaporate this solution to 50% content of the dry salt without crystallisation occurring, or at any of the various intermediate concentrations at which attempts were made to crystallise. The solution was then diluted, and the 2% missing alkali added to it. The solution would not crystallise, however, until 0.05 gm. of commercial Na_2HPO_4 crystals, equal to about $\frac{1}{2}\%$ of the total salt, had been added. The crystals were rinsed with water and after dissolving in water were titrated by the method referred to. Neglecting the water of crystallisation they possessed the relative composition:—

93.93 mols. $\text{Na}_2\text{HPO}_4 + 6.07$ mols. Na_3PO_4 .
The mother liquor was also titrated and the missing H_3PO_4 was found quantitatively in it as NaH_2PO_4 .

As the commercial phosphate is made from sodium carbonate instead of caustic soda, a comparative experiment was made by using exactly equivalent quantities of acid and carbonate. The solution crystallised with difficulty and the crystals possessed the relative composition:

100 mols. $\text{Na}_2\text{HPO}_4 + 2.76$ mols. Na_2CO_3 .
The missing acid was again found quantitatively in the mother liquor.

As no carbonate was found in the commercial phosphate another experiment was made and the crystals dried at 110°C. The salt was then found to be quite free from carbonate, and of the composition, 94.48 mols. $\text{Na}_2\text{HPO}_4 + 5.52$ mols. Na_3PO_4 . Commercial phosphate had the composition, 94.6 mols. $\text{Na}_2\text{HPO}_4 + 5.4$ mols. Na_3PO_4 , neglecting the slight foreign impurities it contained.

If these results are reduced to a simpler denomination we obtain one molecule of Na_3PO_4 combined with 15.4 to 17.5 of Na_2HPO_4 . In order to obtain a greater degree of accuracy to find if there is any real difference between the results obtained by employing sodium carbonate instead of the caustic solution another experiment was made with sodium hydroxide solution, adding it to the phosphoric acid in the exact proportion to form $\text{Na}_3\text{PO}_4 + 16\text{Na}_2\text{HPO}_4$. The crystals possessed the composition 1:16.6 while the mother liquor contained the equivalent larger proportion of H_3PO_4 or NaH_2PO_4 . This shows that the results with caustic alkali and carbonate are identical

and that we may accept the proportion of the two salts in the purest form of disodium hydrogen phosphate to be: $17\text{Na}_2\text{HPO}_4 + \text{Na}_3\text{PO}_4$. This seems at least to be the nearest approach to the theoretical formula Na_2HPO_4 which it is possible to obtain under usual conditions.

From the manufacturer's point of view two points are brought out:—

(1) Sodium carbonate may replace caustic soda for the preparation of the salt.

(2) The carbonate should be added in the exact excess represented by the formula, viz., 2.8% reckoned on the pure chemical.

Crystals may be obtained containing a higher proportion of Na_3PO_4 . There seem to be quite a number of these double salts of $\text{Na}_2\text{HPO}_4 + \text{Na}_3\text{PO}_4$ which form well defined crystals. On employing 6% excess of alkali, crystals were obtained having the composition:— $8\text{Na}_2\text{HPO}_4 + \text{Na}_3\text{PO}_4$. The crystals were in lanceolate or lamellar forms and generally arranged themselves in radiating groups producing a feathery appearance. The laminae were thin and belonged apparently to the mono or triclinic systems.

Other double phosphates were also obtained in definite crystals and possessing the following approximate composition:—

$6\text{Na}_2\text{HPO}_4 + \text{Na}_3\text{PO}_4$, in fine rhombic tables with angles of 66°.

$3\text{Na}_2\text{HPO}_4 + \text{Na}_3\text{PO}_4$, in rhombic pyramids with basal planes in parallel grouping forming radiating spires—vitreous lustre.

$3\text{Na}_2\text{HPO}_4 + 2\text{Na}_3\text{PO}_4$, crystallising in very fine needles.

Both the crystals and mother liquors were titrated in order to check the analysis, but the crystals were not always recrystallised and purified.

The water of crystallisation, which was always very considerable, was not estimated.

Sodium pyrophosphate.

It would be expected that this salt would have exactly the same relative composition as the disodium hydrogen phosphate as far as the $\text{Na}_4\text{P}_2\text{O}_7$ and Na_3PO_4 are concerned, and this would no doubt be the case if the pyro salt were prepared by ignition of the disodium hydrogen phosphate and there were no action on the vessels at the high temperature of ignition.

I have not been able to go into this question fully from an examination of self-prepared samples, but I have found commercial samples with less excess alkali than that represented by the formula I have given. It does not follow because the disodium hydrogen phosphate invariably requires the excess of alkali to crystallise which I have stated, that the pyro salt has the same relative composition. It is quite probable that the excess of alkali on ignition is converted into the active form of Na_2O which would be free to act on the vessels employed.

From the manufacturer's standpoint it seems to me it would be much preferable to manufacture the salt not from the crystals, but using exact equivalents of the acid and carbonate, evaporating to dryness and igniting. In this way the theoretical salt $\text{Na}_4\text{P}_2\text{O}_7$ should be obtainable. If it were found necessary to crystallise the Na_2HPO_4 first to eliminate impurities, then an amount of acid equivalent to the excess of alkali could be added before the ignition.

Sodium dihydrogen phosphate.

Phosphoric acid and sodium hydroxide solutions were added in the exact proportions to form this salt, the solution evaporated to a small bulk and crystallised. The crystals were then dissolved and titrated and found to correspond exceedingly well with the theoretical salt NaH_2PO_4 , while the water of crystallisation, which was only roughly

estimated, was slightly in excess of the formula $\text{NaH}_2\text{PO}_4 + \text{H}_2\text{O}$. The salt was practically neutral to methyl orange, if anything slightly acid. The crystals were very clear, needle shaped, and many were joined at right angles, forming crosses with arms.

The mother liquor had abstracted a considerable amount of alkali from the beaker after standing a week.

Sodium metaphosphate.

This was formed by adding the acid and alkali in the exact proportion for NaH_2PO_4 , evaporating to dryness and igniting in a muffle furnace. The residue weighed 0.3% more than that represented by NaPO_3 , but as this is within the limits of the errors of experiment it may be neglected. It is difficult to find direct evidence of the constitution of this salt, but as NaH_2PO_4 is unquestionably a uniform substance there is no reason to doubt that the metaphosphate has the formula NaPO_3 or one of the multiples of this formula found in the text books.

Sodium polyphosphate.

This new acid phosphate which I have described fully in a separate paper (see ante, p. 419) contains 50% more acid than the meta salt, and although it could not be obtained in a pure state on account of its strong corrosive action, by fair deduction its simplest molecular constitution may be written as $\text{Na}_4\text{P}_4\text{O}_{17}$ or $2\text{Na}_2\text{O} \cdot 3\text{P}_2\text{O}_5$. The salt was a fused glassy mass, slightly soluble in cold, more readily in hot water, almost neutral to methyl orange and only slightly acid to phenolphthalein. After prolonged boiling with water it decomposes into orthophosphoric acid and sodium metaphosphate so that attempts to crystallise a corresponding hydrated salt proved fruitless.

Trisodium phosphate.

To find the constitution of this salt was exceedingly difficult, first on account of its extreme solubility and secondly on account of the rapid rate at which it took up carbon dioxide from the atmosphere. Commencing with a 2% excess of phosphoric acid over the theoretical quantities, it was found impossible to obtain crystallisation until a point was reached where on cooling the mass suddenly solidified into a block of solid, feathery crystals. A few drops of water sufficed to dissolve the crystals on heating and these would not crystallise again. As the water content was bordering upon that of the crystals of Na_3PO_4 themselves it can be concluded that this slight acid addition renders the crystals soluble in their own water of crystallisation at a slightly elevated temperature, as compared with the solubility of Na_3PO_4 crystals in the proportion of 28.3 to 100 water at 15° C.

An experiment with the theoretical proportions of acid and caustic alkali proved more successful, although it was here also necessary to evaporate to a high degree of concentration before crystals could be obtained. A crop of crystals was obtained containing about one quarter of the total phosphoric acid and these had the approximate composition: $-2\text{Na}_3\text{PO}_4 + \text{Na}_2\text{HPO}_4$. The mother liquor which on slightly further concentrating crystallised to a solid mass in feathery crystals, possessed the composition: $-18\text{Na}_3\text{PO}_4 + \text{Na}_2\text{O}$.

Here again it seems, just as in the case of the ordinary phosphate, that the orthophosphate cannot be obtained in crystalline form from its components, or else it does not exist under normal conditions. The excess of alkali necessary for crystallisation, as indicating the nearest approach to purity obtainable, is double in the case of the Na_3PO_4 salt than of the Na_2HPO_4 salt for equivalent molecules, but in the proportion of 4 : 3 when

the total alkali in the composition of the salts is considered.

In order to obtain a mere exact proportion, if possible, an experiment was made using 4% excess caustic soda over the theoretical proportion. The crystals, which represented then about 75% of the total phosphoric acid, had now the composition, $17\frac{1}{2}\text{Na}_3\text{PO}_4 + \text{Na}_2\text{O}$, while the mother liquor had the approximate proportion (not formula) $4\text{Na}_3\text{PO}_4 + \text{Na}_2\text{HPO}_4 + \text{Na}_2\text{CO}_3$. The crystals were in long fine needles.

Whether the proportion of $17\frac{1}{2} : 1$ or $18 : 1$ is taken as being the correct one is not a matter of great importance. I am inclined to think the simpler formula $18\text{Na}_3\text{PO}_4 + \text{Na}_2\text{O}$ is more likely to be the correct one. The sodium carbonate found in the mother liquor was repeatedly observed in later experiments, particularly where the proportion of alkali was further increased. It was due of course to the action of atmospheric carbon dioxide. This action is exceedingly energetic, in fact the Na_3PO_4 and the excess Na_2O seem both to be attacked and quite to the same degree as free hydroxide. In crystallising there was always a tendency for the first crop of crystals to contain no carbonate, this remaining in the mother liquor and crystallising with the remaining phosphate later. The amount of carbonate included in the crystals varies exceedingly and no definite ratios could be detected. The following typical examples will illustrate this apparent irregularity:—

A large number of crystallisations were made but no useful purpose will be served in bringing the results forward until some system has been found to exist. No crystals were found with $\text{Na}_3\text{PO}_4 + \text{Na}_2\text{CO}_3$ as sole ingredients, although a near approach was found in

which, neglecting the Na_2O , becomes

A remarkable fact regarding some of the crystals was the impossibility of recrystallising them without alteration. They seem to form and crystallise under the "equilibrium," so to speak, of the mother liquor surrounding them. When freed from these surroundings, dissolved in water, and the solution again crystallised, they split up into two new forms which balance again, one crystallising and the other remaining in the mother liquor. This also accounted for the fact that the crystals could not always be obtained by mixing their components in solution and crystallising.

Towards strong (95%) alcohol the crystals were mostly stable but with dilute alcohol they were generally decomposed, especially on heating, when part of the crystals dissolved and another part melted, forming an oily layer at the bottom of the test tube. This oily portion always contained carbonate but varied much in composition, e.g.:—

When carbonate is present an almost endless number of combinations seem possible, the carbonate evidently entering into the molecular constitution of the salt, even in large proportion.

In order to find whether it would be possible from the manufacturer's point of view to obtain under definite conditions a certain yield of Na_3PO_4 from the use of phosphoric acid and sodium carbonate only, the following experiments were made.

Phosphoric acid and sodium carbonate solutions

were employed in the proportion of 50% excess of the latter over the amount necessary to form Na_2HPO_4 theoretically.

(1) The carbonate was added all at once, 32.4% of the acid had been converted into Na_3PO_4 while 23% of the carbonate remained with a portion of the Na_3PO_4 , the remaining Na_3PO_4 crystallising out with the whole of the Na_2HPO_4 approximately in the proportion of $3\text{Na}_2\text{HPO}_4 + \text{Na}_3\text{PO}_4$.

(2) The carbonate was added first in the proportion to form Na_2HPO_4 and the other 50% later, after all evolution of carbon dioxide had ceased, the solution being kept at the boil. In this case only 10.2% of the acid had become converted into Na_3PO_4 while 30.4% of undecomposed carbonate remained in the mother liquor with a part of the Na_2HPO_4 ; this time the remaining Na_2HPO_4 crystallised out with the Na_3PO_4 in the approximate proportion of $6\text{Na}_2\text{HPO}_4 + \text{Na}_3\text{PO}_4$.

(3) 4% more sodium carbonate was added than in the two former cases, and the phosphoric acid was added to the carbonate solution at the boil, very slowly, almost drop by drop. It was hoped that a higher yield of Na_3PO_4 might be obtained but the reverse was the case. Not only was no Na_3PO_4 formed but both NaH_2PO_4 and NaHCO_3 were present, the former both in the crystals and the mother liquor, the latter only in the mother liquor. It seems then that by the slow addition of the acid, stable compounds are already formed before the acid addition is completed, so that the last quantities can only be effective in the formation of sodium bicarbonate and dihydrogen sodium phosphate. This is again evidence that the sodium carbonate enters into the chemical composition of the compound. I shall show later that there is strong evidence that Na_3PO_4 combines very energetically with Na_2CO_3 up to a proportion of one molecule of the former to 2 of the latter. Now if we assume that such a compound is first formed it is evident that the later portions of acid would be employed in decomposing this body first, probably by bringing the Na_3PO_4 to Na_2HPO_4 , and further, this again to NaH_2PO_4 , while the carbonate would be simultaneously attacked. The mother liquor had the approximate composition $\text{NaHCO}_3 + 3\text{NaH}_2\text{PO}_4 + 7\text{Na}_2\text{CO}_3$.

The crystals (containing the bulk of the original acid) had the approximate composition $\text{NaH}_2\text{PO}_4 + 4\text{Na}_2\text{CO}_3 + 8\text{Na}_2\text{HPO}_4$ which after recrystallisation was altered approximately to $\text{NaH}_2\text{PO}_4 + 3\text{Na}_2\text{CO}_3 + 8\text{Na}_2\text{HPO}_4$.

The sodium carbonate (including bicarbonate) remaining was equivalent to 42.3% of the original amount.

(4) The same proportion (104%) of caustic soda solution was used, the solution being added all at once as in experiment 1. The salt, however, was evaporated to dryness and dried at 110°C . re-dissolved and then allowed to crystallise. Instead of the high temperature and greater concentration assisting the further action of the Na_2HPO_4 in decomposing the carbonate the reverse was the case. 20.4% of the phosphoric acid had been converted into Na_3PO_4 while 31.5% of the carbonate remained behind. The whole of the Na_3PO_4 had crystallised out in the same form as in experiment 1, viz.:— $3\text{Na}_2\text{HPO}_4 + \text{Na}_3\text{PO}_4$, while in the mother liquor both Na_2HPO_4 and NaH_2PO_4 were found with the whole of the carbonate in the approximate proportion of:— $3\text{NaH}_2\text{PO}_4 + 4\text{Na}_2\text{HPO}_4 + 17\text{Na}_2\text{CO}_3$.

We see from these experiments that the conditions of experiment 1 are by far the best, and that the yield of Na_3PO_4 which was obtained, 32.4%, is probably nearly the maximum which it is possible to attain. This corresponds closely

to the formula:— $\text{Na}_3\text{PO}_4 + 2\text{Na}_2\text{HPO}_4$, neglecting the carbonate, and this is possibly the highest form of alkaline phosphate which can be considered as a really stable compound: a greater proportion of Na_3PO_4 being easily attacked and decomposed by atmospheric carbon dioxide, as we know the Na_3PO_4 is attacked with re-formation of Na_2HPO_4 . I have not yet found definite crystals with this proportion of Na_2HPO_4 and Na_3PO_4 , the nearest approach I have found being $3\text{Na}_2\text{HPO}_4 + \text{Na}_3\text{PO}_4$ in well defined crystals, already referred to.

Trisodium phosphate is not a satisfactory product for the manufacturer as it is so exceedingly unstable, but the best method seems to be to use sodium carbonate for the first stage and caustic soda for the second stage, employing the exact proportions I have already indicated, viz.:—

As this proportion of caustic soda (commercial) would contain probably one molecule of Na_2CO_3 we should expect this in the commercial Na_3PO_4 and this I have found to be the case, the carefully selected crystals from one sample having the approximate composition $\text{Na}_3\text{PO}_4 + 5\text{Na}_2\text{O} + \text{Na}_2\text{CO}_3$ and water of crystallisation. This is more than double the excess of alkali it need have had, but we must not assume that the whole of the salt originally consisted of exactly the same crystals when the salt was freshly manufactured. These selected crystals might only have represented a fraction of the original substance. We have in any case a check upon the state of the original substance in an analysis from the bulk of the salt in its present condition, and by tracing this back *quantitatively* we can determine the average composition the salt must have had when freshly manufactured, neglecting the water of crystallisation.

The carbonate found now in the bulk must have been originally Na_2O , with the exception of the 1.48% now in the selected crystals. The Na_2HPO_4 now found in the bulk must have been in the form of Na_3PO_4 as the Na_2O then existing was in excess of that necessary to effect this transformation.

The following table shows the present and the original composition of the salt, working back in this way, neglecting water of crystallisation:—

Commercial salt.				
	Purest attainable $18\text{Na}_3\text{PO}_4 + \text{Na}_2\text{O}$.	Selected crystals.	From bulk.	Original state.
Na_3PO_4	97.9	94.01	26.01	95.88
Na_2O	2.1	4.51	—	2.64
Na_2CO_3	—	1.48	23.92	1.48
Na_2HPO_4	—	—	50.07	—

The quantity of alkali in the original state was thus still more than that necessary to obtain the purest form of salt, at the same time 2% less than that in the selected crystals. The Na_2O would naturally only suffice for a limited quantity of crystals in the form of those selected, and I am inclined to think that one of the other forms of crystals I have referred to, possibly the $2\text{Na}_3\text{PO}_4 + \text{Na}_2\text{HPO}_4$, had separated before the "selected" ones and that the salt had originally contained a heterogeneous mass of crystals. It was hardly possible to find this out from a careful examination of the salt in its present state as it was in such a crumbly condition.

Whether the manufacturer has well-founded reasons for supplying the salt in this form or

whether it is from ignorance on his part I cannot tell, but the customer should have a salt at any rate the nearest approach to the theoretical which can be produced and not something differing to such a degree. It is regrettable that the salt even in its nearest approach to purity is so impermanent.

It seems that $\text{Na}_3\text{P}_2\text{O}_7$ is capable of combining with still higher proportions of caustic alkali although the union is a much weaker one and the compounds are easily broken up by the action of atmospheric carbon dioxide. $\text{Na}_2\text{O} + 6\text{Na}_3\text{P}_2\text{O}_7$ was obtained in the crystalline form, but the Na_2O was rapidly replaced by carbonate.

Proportions of alkali up to that represented by $\text{Na}_3\text{P}_2\text{O}_7 + 2\text{NaOH}$ seemed to be held in a state of semi-combination; although they could not be obtained as definite crystallisation products, the excess of sodium hydroxide which clung to the actual crystals ($6\text{Na}_3\text{P}_2\text{O}_7 + \text{Na}_2\text{O}$) was not abstracted by 95% alcohol. On drying on a porous tile, however, this excess was eliminated.

The sodium carbonate which is soon formed in all cases where $\text{Na}_3\text{P}_2\text{O}_7$ with Na_2O exist, does not seem to be simply a by-product, but is a very active agent and an intimate constituent of the resulting body. $\text{Na}_3\text{P}_2\text{O}_7$ or its nearest approach is exceedingly soluble, much more so than Na_2CO_3 , but mixtures of these, at any rate up to those having a greater molecular proportion of the Na_2CO_3 , are still more soluble than $\text{Na}_3\text{P}_2\text{O}_7$.

$\text{Na}_3\text{P}_2\text{O}_7 + 2\text{Na}_2\text{CO}_3$ with a trace of Na_2O has been obtained crystallised in clusters of fine, hair-like crystals of silky lustre in radiating tufts. If the Na_2CO_3 did not enter into chemical combination it would have settled out and crystallised long before the concentration at which these mixtures crystallise.

Without entering into theoretical speculations, it may be suggested that there is a possibility that phosphorus becomes actively pentavalent in such conditions of extreme alkalinity, *e.g.*, as might be represented by the formula:—

The presence or absence of carbonate in the solution seems to determine, in many cases at least, the nature of the crystallisation which occurs, *e.g.*, the salt $3\text{Na}_2\text{HPO}_4 + \text{Na}_3\text{P}_2\text{O}_7$, which had been obtained in fine rhombic pyramids from sodium carbonate solution, did not crystallise from the same constituents in aqueous solution, but the ordinary salt, $17\text{Na}_2\text{HPO}_4 + \text{Na}_3\text{P}_2\text{O}_7$.

The work described in this and the two foregoing papers was done in the photographic laboratories of the Manchester School of Technology. I have to thank Professor Knecht and Mr. Peachey for valuable suggestions, and Mr. Rhead for assistance in describing the crystals.

DISCUSSION.

MR. J. H. ROSEASON thought Dr. Smith was to be congratulated on applying a purely chemico-physical method so as to place it on a practical footing in the laboratory for analytical work. There was always difficulty, more or less, in examining alkali phosphates volumetrically and one was forced in determining the phosphoric acid to do so gravimetrically. Had Dr. Smith applied his process to the ammonium phosphates, and if not, what modification of his process would he suggest? Was the process applicable to the examination of arsenates? An interesting application of the paper on polyphosphates would be the decomposition of mineral phosphates for commercial purposes.

MR. L. G. RADCLIFFE said that he had had occasion to prepare ethylene on quite a large scale for laboratory purposes, making many kilos. of

ethylene dibromide. The first method used was to run alcohol on to hot syrupy phosphoric acid. Glass vessels had proved unsatisfactory as they were rapidly corroded. Subsequently a thick porcelain chlorine still had been used and worked well for some three weeks at eight or ten hours a day continuously, when it had become worn out owing to the action of the phosphoric acid, and probably the formation of the salt $\text{Na}_4\text{P}_2\text{O}_7$ which Dr. Smith mentioned had such a drastic effect.

MR. L. E. VILES inquired whether gravimetric estimations had been made of the sodium and phosphorus in the polyphosphates to support the evidence he had obtained by volumetric methods of the existence of the new phosphate.

MR. J. BARNES inquired whether the corrosive action was noticeable in the case of gold. Was it possible to obtain further information by precipitating with silver nitrate and titrating any acid set free?

MR. F. W. ATTACK noticed that the author had mentioned heating sodium bicarbonate to 250°C . before using it for standardising purposes. A paper in the *Zeitsch. f. Phys. Chem.* (1908), by Johnson, had shown that if the temperature was taken much higher than 200°C . for any considerable period appreciable amounts of carbon dioxide were lost. Had Dr. Smith any experience in regard to this point?

DR. SMITH, in reply, stated he had not made any tests either with ammonium phosphates or arsenates, but thought such analyses were quite possible. He was not quite certain with regard to the methyl orange, but probably the process could be employed by using methyl red, and ascertaining the point at which 100% of phosphate was indicated. As far as phenolphthalein was concerned the point with ammonia was sufficiently exact to make the process workable. The new salt might be employed with advantage for the disintegration of mineral phosphates. He had not made any gravimetric estimations of the $\text{Na}_4\text{P}_2\text{O}_7$ as he was working with chemically pure alkali and phosphoric acid. He had no experience of the action of phosphoric acid on gold. He had not tried to precipitate the new salt by means of silver nitrate. The form of $2\text{Na}_2\text{HPO}_4 + \text{Na}_3\text{P}_2\text{O}_7$ seemed to be the largest proportion of $\text{Na}_3\text{P}_2\text{O}_7$ in a salt which would not be liable to the action of the carbonic acid of the atmosphere. He understood from the text books that a temperature of 250°C . was quite admissible for heating sodium bicarbonate, although of course a strong ignition over a Bunsen flame was not admissible.

Meeting held at Grand Hotel on Friday, February 2nd, 1917.

MR. J. H. ROSEASON IN THE CHAIR.

CATALYTIC ACCELERATION OF THE VULCANISING PROCESS.

BY S. J. PEACHEY, M.Sc.TECH.

The history of the rubber industry dates back to the year 1825, when Charles Macintosh established in Manchester the first factory for the manufacture of waterproof garments. The successful development of the industry dates, however, from the year 1839, when, as the result of a laborious investigation, Goodyear discovered the process of vulcanisation. Goodyear's process consisted in intimately mixing the rubber with a suitable proportion of sulphur and subjecting the mass to a temperature of $135^\circ\text{--}140^\circ\text{C}$. for a period of time varying with the amount of sulphur employed. Shortly

afterwards Hancock introduced a modification of the process, in which the formed articles of rubber were immersed in a bath of molten sulphur and kept at a temperature of about 135° C. until the raw rubber had become modified in properties to the desired extent. In 1846 Parkes introduced what is known as the cold-cure process whereby a superficial vulcanisation may be effected by immersing the rubber in a weak solution of sulphur chloride in carbon bisulphide.

Of the three processes the original one is by far the most widely employed in the industry, Hancock's method being applied to the manufacture of a few specialities only, and Parkes' cold cure being mainly used in the proofing of fabrics.

The changes in the nature of the rubber which are brought about by vulcanisation according to Goodyear's process may be summarised as follows :

(1) The strength, the durability, and the elasticity (or more correctly the distensibility) of the rubber are increased,

(2) The sensitiveness of the rubber to changes of temperature is diminished,

(3) The rubber loses its adhesiveness,

(4) The rubber becomes insoluble in the ordinary solvents for raw rubber and therefore resistant to the action of these,

(5) Rubber which has been softened and denatured by mechanical working recovers its valuable characteristics completely on vulcanisation, a property which enables the manufacturer to soften the raw material by mastication in order to work in the sulphur and any desired filling agents, to mould the mixing while in the plastic condition, and subsequently to produce the finished article by merely heating the mould to the vulcanising temperature for the requisite time.

The main drawback to Goodyear's process is the rather lengthy period of heating required to effect complete vulcanisation. This depends upon the amount of sulphur present and for average mixings may vary from about one to three hours, or, in the case of vulcanites, may be six hours or more. In the case of soft rubbers the speed of vulcanisation may be increased by the use of larger amounts of sulphur, but there are other considerations which make it desirable to keep the sulphur content within certain limits.

It has been known to manufacturers for a long time past that certain metallic oxides, when added to a mixing in moderate quantities, possess the property of accelerating vulcanisation, such substances being commonly termed sulphur-carriers. The best known of these are the oxides of lead, magnesium, and calcium; the addition of any of these substances to a mixing in appreciable quantities (say 5%, and upward, or somewhat less in the case of lime) will reduce quite considerably the time needed for complete vulcanisation.

The use of these mineral accelerators is, however, restricted to the manufacture of medium and low-grade goods owing to the fact that they produce other effects which are undesirable. Litharge, for example, can be employed in black or in dark-coloured mixings only, because it yields a certain amount of lead sulphide during vulcanisation; moreover its high density tends seriously to affect the specific gravity of the finished rubber. Lime, if used in any but very small quantities, tends to produce hardness especially on storing the rubber, and magnesia suffers from the same drawback, though to a less degree.

The idea that accelerators might be discovered amongst organic substances appears to have originated in the old observation that the presence of a little aniline in a rubber mixing facilitates to a slight extent the subsequent vulcanisation.

It was not until 1912, however, that a really powerful organic accelerator was found, the discovery being due to Messrs. Bayer und Co. of Elberfeld, who patented the use of piperidine for the purpose

(Ger. Pat. 265,221, 1912). They showed that the addition of as little as 0.5% of piperidine to a mixing consisting of 100 parts of rubber and 10 parts of sulphur brought about a very substantial reduction in the time needed for vulcanisation. A little later the same firm prepared a solid derivative of piperidine which possessed similar properties, and this substance appeared on the English market a few months prior to the commencement of the war. More recently Messrs. Bayer & Co. have taken out a patent in which they claim accelerating properties for all organic bases possessing a dissociation constant greater than 1×10^{-8} (Ger. Pat. 280,198, 1914). This unusually wide patent would include amongst other substances the primary, secondary, and tertiary aliphatic amines, the benzylamines, benzenediazonium hydroxide and the bromobenzenediazonium hydroxides, and a number of the well-known alkaloids. The dissociation constants of a few of the compounds referred to are given below.

Substance.	Dissociation constant.	Temp.
		° C.
Methylamine	5.0×10^{-4}	25
Ethylamine	5.6×10^{-4}	25
Propylamine	4.7×10^{-4}	25
Dimethylamine	7.4×10^{-4}	25
Diethylamine	1.3×10^{-3}	25
Dipropylamine	1.0×10^{-3}	25
Trimethylamine	7.4×10^{-5}	25
Triethylamine	6.4×10^{-4}	25
Tripropylamine	5.5×10^{-4}	25
Ethylene diamine	8.5×10^{-5}	25
Benzylamine	2.4×10^{-6}	25
Diethylbenzylamine	3.6×10^{-8}	25
Benzenediazonium hydroxide	1.23×10^{-8}	0
Bromobenzenediazonium hydroxide	1.5×10^{-4}	0
Brucine	7.2×10^{-4}	15
Strychnine	1.4×10^{-7}	15
Quinine	2.2×10^{-7}	15
Quinidine	2.4×10^{-7}	15
Cinchonine	1.6×10^{-7}	15
Cinchonidine	3.7×10^{-7}	15
Cocaine	4.0×10^{-7}	25
Emetine	2.0×10^{-8}	15
Cofline	1.3×10^{-8}	25
Piperidine	1.6×10^{-8}	25

The majority of these compounds, however, are far too costly to be available to the industry as activators.

For comparison the dissociation constants of some of the weaker bases are given below.

Substance.	Dissociation constant.	Temp.
		° C.
Urea	6.7×10^{-14}	16—31
Creatine	1.9×10^{-11}	40
Semicarbazide	2.7×10^{-11}	40
Aniline	3.2×10^{-10}	15
Methylaniline	7.4×10^{-9}	60
Dimethylaniline	2.4×10^{-10}	18
<i>o</i> -Phenylenediamine	3.3×10^{-10}	25
<i>α</i> -Naphthylamine	9.9×10^{-11}	11
<i>β</i> -Naphthylamine	5.0×10^{-10}	11
Quinoline	1.6×10^{-9}	15
Pyridine	2.3×10^{-9}	25

During the early part of 1914 the author was engaged in the problem of accelerating vulcanisation and in the course of numerous experiments with various types of organic compounds discovered that the nitroso-derivatives of certain bases such as dimethylaniline, methylaniline, and diphenylamine are capable of acting as powerful accelerators of the vulcanising process (Eng. Pat. 4263, 1914). A mixing consisting of 100 parts of rubber and 10 parts of sulphur which normally requires to be heated to 140° C. (40 lb. steam pressure) for one hour if a soft cure is desired, or for a longer period in the case of a harder cure, may be completely vulcanised

in from 20 to 25 minutes by incorporating 0.3 to 0.5% of *p*-nitrosodimethylaniline with the mixing, prior to heating. Similarly a vulcanite mixing consisting of 100 parts rubber and 10 parts sulphur, which normally requires to be heated for 6 hours at 140° C. may be completely cured in about 2 hours by the addition of 0.75% of the nitroso-base.

These examples illustrate the effect of the nitroso-base on pure mixings of rubber and sulphur, but the result is almost equally good with any high or medium grade quality of mixing. Thus, for example, the well-known SA mixing, which in addition to rubber and sulphur contains a moderate proportion of zinc oxide, normally requires to be heated for 3 hours to 140° C. for complete vulcanisation; by incorporating 0.5% of nitroso-base with the mixing perfect vulcanisation may be brought about by heating for 1 hour at the same temperature.

In fact, generally speaking, the addition of 0.3 to 0.5% of nitroso-base to any mixing of good quality is sufficient to reduce the time of vulcanisation to from one-quarter to one-third of that normally required. The value to the manufacturer of an accelerator such as this is fairly obvious, for at a comparatively small cost he should be able at least to treble the output of his existing vulcanising plant. The nitroso-base is now being employed successfully by a considerable number of important rubber firms under the trade name of "Accelerene."

p-Nitrosodimethylaniline is a green crystalline powder of melting point 85° C. It is usually marketed in a moist condition (about 30% water), this adding considerably to its stability and rendering it safer to store in bulk. Before use it may conveniently be dried by exposure to warm air or preferably in a vacuum dryer. It should be incorporated with the rubber towards the end of the mixing operation, as there is otherwise some danger of a partial vulcanisation taking place on the rolls, especially if these are fairly hot. The material shows some tendency to cake on the back roll of the mixer, but this is readily avoided by wrapping the weighed quantity of the accelerator in a portion of the sheeted rubber and then working this in with the remainder. Alternatively the roughly dried nitroso-base may, prior to use, be mixed with about 20% by weight of kieselguhr, which effectively overcomes the tendency to adhere to the rolls and in the small quantities employed is quite unobjectionable as an addition to the mixing.

The time required for curing the mixing may be roughly calculated on the assumption that the use of 0.5% (on the weight of the mixing) of nitroso-base reduces the time of cure to one-third of the normal. In the case of red mixings containing antimony sulphide as the vulcanising agent and no added sulphur the accelerator fails to develop its full effect. In such cases it becomes necessary to introduce a certain quantity of sulphur and to employ the sulphide mainly as a pigment. The presence of litharge in any quantity tends to diminish the effectiveness of the organic accelerator. On the other hand the presence of a small quantity of magnesia augments very considerably the accelerating power of the nitroso-base, and by using the two substances in suitable proportions it is possible to prepare high-class mixings which will vulcanise perfectly in about one-eighth of the normal time, that is to say, in ten minutes or thereabouts. This combination of accelerators is especially useful in connection with mixings for quick repair work.

It is to be noted that the maximum accelerating power of *p*-nitrosodimethylaniline is only fully manifested when new rubber is used; with reclaimed rubber or rubber waste the results obtained are not very satisfactory.

One of the most valuable applications of the new accelerator is in the manufacture of vulcanite. As

previously stated, a pure vulcanite mixing consisting of 100 parts of rubber and 40 parts sulphur, which normally requires about six hours' heating, may by the addition of 0.6 to 0.75% of nitroso-base be perfectly cured in two hours. Similar results are obtainable with any vulcanite mixing of good quality. Another point of interest to manufacturers may be briefly referred to, viz., the prevention of "blooming," or "sulphuring-up." The amount of sulphur employed in a mixing is invariably greater than that required to combine with the rubber and to produce the desired degree of vulcanisation. The result is that manufactured rubbers nearly always contain a considerable percentage of free sulphur; this appears to be present in the freshly vulcanised rubber in the form of minute globules, that is to say, in the superfluid condition, but on standing for a time the globules gradually crystallise in the form of small needles which penetrate the surface of the rubber and produce the effect known as sulphuring-up. By reducing the amount of sulphur in the mixing to something approaching the theoretical amount required for vulcanisation, adding a small proportion of nitroso-base (about 0.75%) and then heating for the normal period required for vulcanisation, it is possible to obtain a well-cured rubber containing practically no free sulphur and one which will remain quite free from bloom even on prolonged keeping. In such case there is naturally little or no reduction in the time of vulcanisation owing to the diminished proportion of sulphur present, the power of the catalyst being expended in bringing about practically complete combination between the molecules of the rubber and the sulphur.

The chemistry of the vulcanisation process is even at the present time not fully understood, and it may therefore appear rather premature to attempt any explanation of the action of accelerators and so-called sulphur carriers.

The majority of rubber chemists agree, however, that the vulcanisation of rubber must be regarded mainly as a chemical effect, whatever physical changes may simultaneously be concerned in the process. Thus it is fairly generally accepted that vulcanisation by Goodyear's process involves the following changes:—

- (1) Depolymerisation by heat of the complex rubber molecule.
- (2) Adsorption of sulphur by the rubber colloid.
- (3) Combination of the depolymerised rubber with sulphur.
- (4) Repolymerisation to complex molecules as a result of (3).

The final product, that is the vulcanised rubber, is regarded as being a solid (or semi-solid) solution of the compound of rubber and sulphur in unchanged rubber.

In seeking to explain the action of accelerators and of sulphur carriers one must therefore treat the process of vulcanisation as a chemical reaction and study the factors which are known to be operative in promoting chemical change.

Seidl (Gummi-Zeitung, 1911, 10, 748), Esch, and others attribute the accelerating effect of litharge and magnesia to the generation of heat in the interior of the mixing consequent upon reaction taking place between these oxides and a portion of the sulphur present in the following sense:—

in which M represents an atom of lead, magnesium, or calcium; or alternatively upon reaction occurring between the oxide and small quantities of hydrogen sulphide produced by the decomposition of the resins, which are invariably present, by a portion of the sulphur. In support of this theory Seidl quotes a series of experiments in which he claims to have detected and measured this thermal effect. Satisfactory methods for

making such determinations are exceedingly difficult to devise and to carry out on account of the low conductivity for heat of rubber. The author has made a considerable number of such experiments (the details of which will be published later) and has so far failed entirely to confirm Seidl's observations. In regard to the reaction between sulphur and the oxides of lead and magnesium which is stated by Esch to take place during vulcanisation, it may be remarked that the author has prepared a number of mixings containing different proportions of magnesia (5 to 50%) and normal amounts of sulphur and has vulcanised these in the usual manner. The vulcanised rubbers were subsequently finely ground and extracted for ten hours with boiling water. An examination of the extract for the presence of magnesium sulphate gave negative results in every case, from which it may be concluded that in the case of magnesia at any rate the theory supported by Esch cannot hold good. In the case of litharge there is no question that a certain amount of lead sulphide is formed, but whether this takes place in accordance with the equation given is open to doubt.

The heats of formation of the substances involved in this equation are as follows:—

and the reaction should be exothermic to the extent of 63.4 calories.

In the case of a mixing containing 5% of litharge this would correspond with the development of an amount of heat sufficient to raise the internal temperature of the rubber very considerably, but the author has not succeeded in detecting any such rise.

The newly discovered organic accelerators differ from the so-called sulphur carriers in that an exceedingly small quantity of material is effective in bringing about a very powerful acceleration. The obvious conclusion to be drawn from this fact is that their action is of a catalytic nature, that is to say, that these substances act by their mere presence and do not themselves undergo any permanent chemical change during the process. The main characteristics of catalytic action are that the catalyst is usually present in relatively small concentration and that it does not start a reaction, but only accelerates a change which can proceed by itself (though perhaps extremely slowly). Taking *p*-nitrosodimethylaniline as an example, a quantity of the accelerator having one two-hundredth of the mass of the reacting substances is sufficient to treble the speed of the reaction. The internal heat theory cannot possibly apply here, and indeed the only reasonable supposition is that the nitroso-base acts purely as a catalyst.

In this connection it should be stated that whilst the nitroso-derivatives of such bases as methylaniline, ethylaniline, diphenylamine, and others are powerful accelerators, the isomeric nitrosoamines produce no similar effect. The difference between the isomerides is one of constitution only. It would therefore appear that the accelerating effect of these nitroso-bases is in some manner bound up with the presence of a nitroso-group directly linked up with the nucleus.

It is important to note that the catalytic action of *p*-nitrosodimethylaniline appears to differ entirely in mechanism from that of piperidine and of the other bases covered by Bayer's patents. The latter appear to act by virtue of their powerful basic character, for the patentees specify as accelerators only those bases having a dissociation constant lying above 1×10^{-8} . *p*-Nitrosodimethylaniline is a very feeble base with a dissociation constant of 1.9×10^{-10} , a figure lying far

below that quoted in Bayer's patent. Further it has been found that certain nitroso-compounds which are quite destitute of basic properties, for example, nitrosophenol and nitrosonaphthol, possess marked accelerating power. The accelerators discovered by the author constitute in fact a new class and appear to owe their accelerating power entirely to the presence of the nitroso group. Experiments are now in progress to determine whether these compounds can function as catalysts in other reactions which involve the addition of sulphur to an unsaturated molecule.

The discovery of the accelerating effect produced by the nitroso-derivatives of aromatic bases rendered it important to study other classes of organic compounds in order to ascertain whether the property is peculiar to this type of compound or is shared by other types. Owing to the difficulty in arriving at any theoretical explanation of the mechanism of the supposedly catalytic action of the nitroso-compounds it was not possible to obtain any guidance as to which of the very numerous classes of organic compounds were likely to produce a similar effect. It was soon found, however, that members of another group of compounds were capable of bringing about a similar, although considerably less powerful, accelerating effect on vulcanisation. The group referred to comprises the condensation compounds formed by the interaction of aldehydes and amines, for example, benzyldene-ethylamine, benzyldene-aniline, and hydrobenzamide (Eng. Pat. 7370, 1914). These substances, even when used in small quantities, produce a well-marked effect in accelerating the combination of rubber and sulphur but they are considerably less effective than the nitroso compounds.

An interesting observation made in the course of these vulcanisation experiments is worth placing on record. It was found that certain organic compounds possess the property of retarding vulcanisation, that is to say, they appear to act as anti-catalysts. Phenylhydrazine is an example of such a compound. In spite of its well-marked basic properties, the presence of even a small quantity in a rubber mixing, is sufficient to hinder quite appreciably the process of vulcanisation. Other substances behave similarly, notably glucose and methylene blue. It is conceivable that these anticatalysts may find useful applications in certain branches of rubber manufacture when their behaviour has been studied more fully.

DISCUSSION.

Mr. H. L. TERRY understood that the discovery of catalytic acceleration resulted from research work in connection with synthetic rubber which would not vulcanise properly, owing doubtless to the absence of certain nitrogenous matters. There appeared to be about 35 different substances that had already been used with success as accelerators. The author had referred to the importance of the process in connection with the mixing known as 8A. The difficulty had always been to effect the vulcanisation within the amount of sulphur allowed by the Government, and from this point of view the shortening of the vulcanisation process was of advantage so far as the subsequent quality of the goods produced was concerned. It would be interesting to learn whether the use of piperidine, etc., was recognised by the experts at Woolwich. The author had raised a point with regard to the formation of inorganic sulphates during vulcanisation. He (Mr. Terry) had also found that magnesium sulphate was not formed, but calcium sulphate was easily produced during the period of vulcanisation. This fact had at times led to recrimination in the trade owing to the presence of gypsum being proved when the manufacturer said he had not used any. There had been a rather sweeping statement made with regard to reclaimed rubber and low-grade

mixings. He could quite understand that the sulphur was fully combined as far as the reclaimed rubber was concerned and that the "accelerene" and the piperidine only affected the unvulcanised rubber. At the same time if free sulphur were added it might be possible to reduce the quantity of that free sulphur by using piperidine. When reference was made to reclaimed rubber something should be said as to its quality. There was a great difference between high-grade alkali reclaimed and low-grade oil reclaimed rubber.

Mr. W. THOMSON inquired whether vulcanisation involved solely the combination of the rubber with the sulphur? Was it not possible that whilst some combination between the sulphur and rubber took place a certain amount of the rubber underwent polymerisation and that the rôle which the sulphur played was not entirely a direct combination. It was hardly conceivable that 1.5% nitroso-base would cause a piece of rubber to become perfectly black which otherwise would be white, unless there was a change in the molecules of the rubber of the nature of polymerisation. It would be interesting to learn whether nitroso bases had any oxidising effect on the rubber or an effect which did not involve the use of sulphur. Had the author tried vulcanising rubber with the nitroso base without sulphur? By placing in the steam bath a piece of copper upon a piece of sheet indiarubber for about 24 hours the rubber became hard under the copper through the sheet, proving that there was catalytic action between the copper and the rubber. If cloth containing even a trace of copper were coated with rubber, the rubber would speedily perish. So-called vulcanisation might possibly prove to be to some extent an oxidising action. A curious oxidising effect he had observed was that by passing ozone over a piece of stretched rubber thread, the stretched thread was destroyed within a few minutes whilst the unstretched part was apparently uninjured.

Mr. W. C. SMITH said that credit ought to be given to Ostronski who had endeavoured to vulcanise rubber without the aid of sulphur. A very serious problem in connection with the use of accelerene was the fact that it induced dermatitis, and that people who perspired freely should not be allowed to handle it. Did the use of an accelerator tend to overcome variability in the vulcanisation of plantation rubbers? What effect had the accelerene with regard to the porosity of the rubber and particularly so with regard to ebonite? What stability had the vulcanised article when accelerene had been used? He did not consider there was any danger of the material sticking to the back roller so long as the nitroso product was what it was claimed to be. Regarding the necessity for complying with the Government specification, the point was whether there was anything left after vulcanisation from the 0.5% which would injure the rubber or which could be found by chemical analysis. Personally he did not think there was. With regard to Mr. Thomson's comment, *re* the action of ozone upon rubber, he pointed out that the effect of ozone upon rubber was exactly the same as that which was noticed when high pressure cables broke down.

Mr. CHEETHAM inquired whether the first Bayer patent was English or German, whether publication preceded the second and whether the second really covered matter claimed by the first.

Mr. D. CARDWELL inquired whether it had been possible to determine any relationship between the catalytic effect of the bases mentioned and the readiness with which they themselves combined with sulphur. Aniline combined with sulphur to form thioaniline with elimination of hydrogen sulphide and most probably other bases acted in a similar manner. In what way did nitrosodimethylaniline react with sulphur? The fact that no catalytic effect had been observed when antimony

sulphide was used instead of sulphur, supported the view that the interaction of the catalyst with free sulphur played some part in bringing about the desired result. Could Mr. Peachey state whether any experiments had been made as to the effect of vulcanising agents on the unpolymerised hydrocarbons of which rubber consisted? Whether, in fact, polymerisation and vulcanisation had been carried out at the same time.

Mr. A. PORRER had found that indigo in the proportion of 0.25% gave quite a good blue colour to a vulcanised rubber. Contrary to expectation, Thioindigo Red or Scarlet in the same proportion gave at the most a pale strawberry colour. It would be interesting to know whether these dye-stuffs possessed any accelerating action in the vulcanising process. The compound of piperidylurea marketed by Bayer in 1913 was in the form of a fine yellow powder, something like sulphur, and it acted quite well both with raw rubber and with high-grade reclaimed rubber. It was interesting to learn that aniline had a slight effect in accelerating the vulcanisation process. This was rather surprising, because there was at least one process in use in which aniline, in conjunction with strong caustic soda, was claimed as a reclaiming agent, the patentees claiming that not only free sulphur but combined sulphur could be removed. He thought he was right in saying that it was upon the work of Stevens in connection with proteins that the use of accelerators was based. Stevens had found that rubber recovered from benzene solution gave quite different results on vulcanisation from the natural raw rubber, owing to the presence of the natural proteins in the latter. Certain American workers had carried the work still further by using other albuminoid bodies. Had Mr. Peachey tried the effect of accelerene on such a recovered rubber, and if so what was the quantity required to yield the same effect as the natural proteins?

Mr. F. J. THOMP drew attention to the fact that no satisfactory method had as yet been found for determining the true dissociation constants of bases. The constants usually given were too small, a consideration which might explain the anomalous behaviour of such a weak base as *p*-nitrosodimethylaniline in aiding vulcanisation.

Mr. PEACHEY in reply, said he had not made much progress as regards the possibility of detecting the nitroso-base in the vulcanised rubber, but he had found that the acetone extract of such a rubber was always so highly coloured that, in the absence of anything else which would yield a dark colour, he thought that alone would suggest the use of the accelerator. He intended to make further tests. His opinion was that a portion at least of the nitroso-base remained as such in the vulcanised rubber. Possibly it had been noticed by those who had already used the nitroso-base that the vulcanised articles tended to stain paper with which they came in contact. He considered that at least half of the substances alluded to by Mr. Terry had practically no accelerating effect. As regards reclaimed rubber he had only experimented on medium qualities. He could quite imagine that the new accelerator would produce a moderate effect with a high class reclaimed rubber. He thought it was now practically accepted that the process of vulcanisation was of a chemical nature and involved a certain degree of combination between the rubber and the sulphur. *p*-Nitrosodimethylaniline possessed high tinctorial power which tended appreciably to darken the vulcanised rubber. The rather strong green colour of the mixing, however, faded to a light drab on vulcanisation, provided only a small quantity of the accelerator was used. He would not like to state definitely as yet that it would be practicable to use the accelerator for very light-coloured goods.

If rubber were heated with nitroso-base a tarry

mass was formed; there was no evidence of vulcanisation. He thought it was now well established that the presence of copper accelerated oxidation. There was of course a very close parallel between the addition of sulphur to rubber and the addition of oxygen. Copper apparently acted as a catalyst, and activated oxidation. Ostromyslenski's work was intended to show that vulcanisation could be effected by means of such substances as nitrobenzene and a number of other comparatively simple organic compounds in the absence of sulphur. He felt considerable difficulty in accepting all that was stated in the abstract of the paper which had appeared. He was convinced that when Ostromyslenski spoke of rubber being vulcanised by nitrobenzene he did not attach quite the same meaning to the term as other chemists. With regard to the prejudicial effect of *p*-nitrosodimethylaniline upon the health of workers using it, he thought it was largely a question of the impurities originally present in the nitroso-base and that the pure material was not so objectionable as the crude. Whether the evil resulted from the presence of a little unaltered dimethylaniline in the base was a question worth investigating. He was not in a position as yet to answer the question with regard to the variability of different plantation rubbers. He had not carried out as many experiments with the steam cure as with the press cure, but so far the results had been equally good in both cases. Although the samples shown that evening were thin, some of them were remarkably solid, and showed no sign of porosity.

He was of the opinion that equally good results could be obtained with thicker rubber. Regarding the stability of vulcanised rubber he could speak with some confidence as he possessed samples which had been kept for two years or more. Except the case of a few which were not more than 0.1 mm. thick there had been no deterioration. The strength tests carried out with material vulcanised in conjunction with the accelerator gave better results than those obtained with material normally vulcanised as nearly as possible in the correct time to give the same cure. There appeared to be a uniform slight increase in strength as the result of using the accelerator, but too much confidence must not as yet be placed in these experiments as they would have to be repeated on a very large number of samples. Bayer's first patent (1912) covered the use of piperidine. The second patent covered the use of non-volatile aliphatic amines or non-volatile derivatives of volatile aliphatic amines, and a third covered the use of a solid derivative of piperidine, namely, piperidylurea or the carbon bisulphide addition compound. The fourth patent covered all bases having certain dissociation constants, and in regard to this he could not yet express an opinion as to validity. It appeared to him to be of an unusually wide character in that it covered substances known and unknown. He had experimented with all the nitroso compounds including nitrosodimethylanilines, but the effect of the latter was not so marked as that of *p*-nitrosodimethylaniline. He had already referred to the remarkable fact that nitrosophenol and nitrosonaphthol also had a marked accelerating effect notwithstanding the absence of basic properties. Mr. Tromp had questioned the accuracy of the dissociation constants as published in the literature, and had suggested the possibility of *p*-nitrosodimethylaniline falling under Bayer's patent. He did not think there was any fear of this. It was quite evident that the nitroso group was responsible for the accelerating power of the substance. Nitrosophenol exerted a marked accelerating action, although acidic substances generally either had no action or were actually retarding agents. The effect of the nitroso group appeared to outweigh the acidic property in the case of nitrosophenol.

A point had been raised as to whether a compound was first formed between the nitroso-base and sulphur, but as to this he had as yet no really reliable information to impart. Another question related to mixings containing antimony sulphide failing to respond to the action of the accelerator. This was especially curious because antimony sulphide invariably contained free sulphur. He had made no experiments with depolymerisation products or lower polymerisation products. He had not examined the effect of indigo on a mixing but he was aware there was a considerable bleaching effect in the case of ultramarine. Thioindigo red had been put on the market in Germany in the form of a lake for the special purpose of colouring rubber and he was rather surprised to learn that it gave only a strawberry colour. He had understood it to be a dyestuff that was fairly stable to sulphur at vulcanising temperature, but he could not say whether it produced any acceleration. The only observation he had made in connection with dyestuffs was that methylene blue had a distinct retarding action. At present he had no information to offer with respect to the effect of nitroso-base on de-resinated rubber except that as the result of his own experiments he did not agree with the conclusions published by Weber regarding the impossibility of vulcanising de-resinated rubber.

MR. HENRY PEILE IN THE CHAIR.

THE INFLUENCE OF ARSENIC IN BRASS.

BY OLIVER SMALLEY.

The influence of arsenic in copper has received much attention from various sources, and, where once it was regarded with great suspicion and looked upon as an undesirable impurity, it is now actually employed to increase the tenacity and hardness, yet displaying little effect on the ductility. It is valuable in neutralising the deleterious influence of bismuth, antimony, oxygen, etc., and it is used, in small amounts, for making copper more resistant to the action of reducing gases when hot. But this latter use is based on a more or less doubtful hypothesis, for the question of "gassing" is one that is based solely on the oxygen content.

As regards copper castings it is certainly beneficial in conferring soundness, even though inferior to silicon, manganese, or boron, so that arsenic is of real value in copper.

This information, though in itself definite, does not remove the feeling of scepticism that exists as to the value of arsenic in brass; and published information to date does no more than suggest that arsenic might be either beneficial or detrimental, depending upon the conditions under consideration. It is therefore with a view to the determination of the actual value, or otherwise, of arsenic in brass that this work has been undertaken.

Furthermore, it is common knowledge that there is a considerable exhaustion in the world's stocks of copper, as may be noted in the present prohibitive price and in the difficulty in obtaining current supplies. It is essential, then, that we utilise whatever copper we do possess or can obtain to the best possible advantage whatever its quality.

At the present moment a considerable amount of arsenical copper is obtainable in the form of scrap.

shell driving bands, turnings, swarf, etc. The arsenic content of these driving bands is between 0.25 and 0.45%, this being the range permitted in specifications. To use this copper for the manufacture of brass would give an arsenic content not generally met with, so that an early suggestion was to attempt the removal of arsenic by melting the copper in conjunction with suitable fluxing. This, of course, necessitated the erection of a new plant and an immediate expenditure such as could not be entertained. The first valuable outlet found was its use in the manufacture of tin bronzes where the arsenic introduced by the copper was found to be beneficial in the production of sound casts and in the obtaining of a slightly increased elastic limit.

The next outlet tried was in the making of Class "C" extruded bar, $2\frac{1}{8}$ in. diameter. An 80 lb. cast was made of the intended composition—Cu, 58.00%; Zn, 40.25%; Pb, 1.75%. The copper used in its manufacture was two-thirds electrolytic and one-third balled arsenical swarf. The tensile tests expected from such an extruded bar, together with those obtained, were as follows:—

	Yield point Tons sq. in.	Maximum stress. Tons sq. in.	Elongation % on 2".
Expected	10.0	22.0	28.0
Obtained	10.4	22.7	11.0

These clearly demonstrated the deleterious influence of small percentages of arsenic on extruded brass.

It may be said that the work so far carried out shows that small quantities of arsenic are beneficial to copper-tin alloys but detrimental to hot-working copper-zinc alloys.

From our present knowledge of the microstruc-

ture of the copper-zinc series of alloys we are able to divide commercial brass into three groups, each having its own specific value.

Group 1 possesses a simple microstructure consisting of allotrimorphic crystals of an isomorphous mixture of copper and zinc, and the brasses coming into this group are known as α -phase brasses. They may contain as much as 37% zinc, though 30% zinc is the true limit in which perfect mixed crystals exist at all temperatures in the solid state, and such material can only be worked cold. Brasses coming within this range are well known for their combined strength, ductility, and malleability, and so provide us with a simple, but valuable, range of alloys.

Groups 2 and 3. Between 30—37% zinc we have a series of alloys which are polymorphic and can be worked both hot and cold—their hot-working properties increasing with an increasing zinc content. Above 37% zinc we have a new constituent appearing at ordinary temperatures which is generally termed the β -constituent. It is stronger and harder than the α -constituent, but it is less ductile, and the percentage of β -constituent, which increases directly as the zinc content, determines the physical properties of the brass, everything else being equal.

The ease with which such an alloy lends itself to hot work classifies it purely as a hot-working alloy, for owing to the difference in the physical properties of the two micro-constituents present in such brasses, one soft and the other hard, this does not readily permit the application of cold work.

Thus we have two types of brass, each having its own sphere of usefulness, possibilities and necessary treatment; and attention is limited in this paper to the determination of the influence of arsenic on the two alloys most representative of their groups, namely, the 70/30 mixture and the 59/41 mixture.

Manufacture.

In all, nine alloys were made, five of the 70/30 mixture and four of the 59/41 mixture, the arsenic content varying from nil to 1.0% as shown in the following tables, where both intended and actual compositions obtained are given:—

Series No. 1.

Mark.	Intended composition.			Actual composition.			
	Copper.	Zinc.	Arsenic.	Copper.	Zinc.	Arsenic.	Iron.
	%	%	%	%	%	%	%
A.C. 8	70.0	30.0	Nil	70.10	29.90	Nil	Trace.
A.C. 7	70.0	29.92	0.08	70.45	29.55	0.09	0.10
A.C. 4*	70.0	30.0	?	69.57	30.00	0.18	0.25
A.C. 5	70.0	29.5	0.50	70.10	29.41	0.40	Trace.
A.C. 6	69.5	29.5	1.00	69.16	29.87	0.97	Trace.

* Copper driving bands.

Series No. 2.

Mark.	Intended composition.			Actual composition.			
	Copper.	Zinc.	Arsenic.	Copper.	Zinc.	Arsenic.	Iron.
	%	%	%	%	%	%	%
A.C. 0	59.0	41.0	Nil.	58.96	41.04	Nil.	Nil.
A.C. 1*	59.0	41.0	?	58.58	41.08	0.14	0.20
A.C. 2	59.0	40.5	0.50	58.91	40.54	0.48	0.07
A.C. 3	58.5	40.5	1.00	58.77	40.28	0.95	Trace.

* Copper driving bands.

In order that complete physical and chemical investigations might be completed and that the tests obtained should bear direct application to works' practice, in the "as cast," "worked," or "heat-treated" conditions, the whole series of alloys were made entirely under works' conditions.

Melting was done in an ordinary forced blast

Melting was done in an ordinary forced blast

coke furnace, 25 lb. ingots being made. The Series 1 set of alloys were cast into slabs 1.95 in. thick by 4 in. broad, and those of Series 2 were cast into ingots 3 in. square.

No perceptible objections or peculiarities arose through the presence of the arsenic. The alloys A.C.8 and A.C.0 were made from high grade electrolytic copper and "Crescent" brand spelter; each of these alloys represented a standard to the series, for comparative purposes only. The same brand of spelter was used for all the alloys: whilst

as the casting temperatures were all carefully controlled.

Mechanical treatment.

The upper half of each ingot was used for the necessary physical tests in the cast state. In Series 1 the lower half was treated exactly as an ordinary 18 pdr. cartridge case slab before attempting to cup for drawing purposes, such treatment being as follows:—cold roll in three passes to 0.55 in.; anneal at 600° C., reduce in two passes to 0.451 in.; and re-anneal.

In Series 2, the lower half of each ingot was forged hot from 3 in. sq. to 1½ in. sq., allowed to cool, re-heated and hot rolled to 1½ in. thick in three successive passes. Forging was commenced at 650° C., and finished at 590° C. Rolling was carried out at 630° C.

Physical tests.

Static tests were taken from each alloy in the cast condition. Alloys of Series 1 were tested after the third pass, first anneal, second finishing pass,

the only difference between alloy A.C.1, Series 1, and alloy A.C.1, Series 2, and the standard alloys A.C.8 and A.C.0, is that in the former mentioned pair of alloys scrap shell driving bands containing 0.28% arsenic were used in the place of electrolytic copper.

Alloy A.C.7, Series 1, was made from 50% scrap shell driving bands and 50% electrolytic copper by adding the requisite copper content; while the rest of the alloys were made from electrolytic copper, the desired arsenic content being obtained by suitable additions of a 5% arsenic-copper alloy.

On breaking a small fragment from the croppings of each alloy a strongly marked arborescent pattern was displayed by all the arsenical brasses, but with alloys A.C.8 and A.C.1, which are free from arsenic, this was not shown; thus indicating that the initial casting temperature of the arsenical alloys was too high. But this was not the case,

Arsenic—As forged.

and final anneal. Alloys of Series 2 were only tested after hot rolling to 1½ in. thick slabs.

As far as possible all test-pieces were cut from a similar position in each slab, all operations being performed under like conditions.

The Brinell hardness test was made with a 10 mm. diameter ball under a load of 1000 kilogrammes for 30 seconds.

Dynamic stress tests. For this purpose an alternating impact testing machine was used, the test-piece being 4 in. × ½ in. × ½ in. with a ⅛ in. radius groove milled in the centre of one face at right angles to the principle axis. A steel tup having a total weight of 10 lb. is allowed to fall untrammelled from a height of 18½ inches on the test-piece, the first blow being given on the face opposite the groove, and for every succeeding blow the test-piece is rotated through an angle of 180°. The

blows are given at a regular rate of 25 per minute and the number of blows received by the test-piece before fracture is taken as the alternating impact number.

Where considered necessary an Izod test was made. This figure is stated in foot-pounds absorbed in fracture.

The influence of arsenic on the mechanical properties of 59/41 brass.

The results of the tests made on this series of alloys are tabulated on Test Sheet No. 3, and shown graphically by Curves Nos. 1, 2, 3, and 4.

Arsenic—As forged.

Composition: % arsenic.

CURVE 4.

From these it may be seen at a glance that in every instance, with reference to the ductility, there is a serious drop in both the cast and hot-worked conditions as the arsenic content rises. In the cast state the presence of 0.14% arsenic reduces the elongation some 27% without appreciably affecting the yield point or ultimate stress; whilst the shock-resisting properties are seriously impaired, the impact test number, for instance, being only one quarter that obtained from the standard non-arsenical sample. As the arsenic content increases a further lowering of the shock-resisting properties is effected; whilst both the yield point and ultimate stress are somewhat reduced, this being marked in alloy A.C. 2, which contains 0.5% arsenic.

In the 1% arsenic alloy we have a material that is hopelessly brittle and in which the shock-resisting properties are practically reduced to zero, though the ductility, as measured by the elongation percentage from the tensile test, does not reveal this so clearly. In fact, it is here shown that the value of the elongation percentage, adopted as a measure of the ductility and a safeguard against brittleness, is of very little practical value unless accompanied by some suitable form of dynamic stress test.

The effect of hot-work. The effect of hot-working the non-arsenical brass, included in this series, is shown to have been distinctly beneficial to the physical properties in general; and, as anticipated, both the ductility and impact number are raised, while the tenacity is unaffected. But with the arsenical series there is the reverse effect. Here, the yield point and ultimate stress are increased, but only so slightly that they in no way compensate for the low ductility produced.

The elongation percentage of alloy A.C.2 does not seem to support this last remark; yet the decided fall in the impact number makes it an outstanding example of the conclusion just previously stated of the ambiguity of the elongation percentage as a reliable measure of ductility.

Fractures. A most noticeable feature of the

presence of arsenic in the cast series is the complete removal of the fine yellow-coloured granular fracture that always accompanies Muntz metal free from arsenic, it being replaced by a coarsely laminated crystalline fracture of a dull mossy brown appearance—the coarseness of the crystals and depth of colour increasing with a rising arsenic content until at 1% arsenic it takes an almost bluish hue.

The fractures of the forged specimens bear a close relationship to the "cast" with regard to colour, but all traces of the coarse laminated crystals are removed, the fracture taking in every instance the form of an exceedingly shallow cup and cone (See Notes, Test Sheet No. 3).

The elongation, not being confined to the vicinity of fracture, gives a reduction of area percentage the same at any position along the length of the parallel of the test piece, and this peculiarity seems common to all arsenical brasses.

In both the cast and forged specimens the presence of incipient signs of fracture throughout the 2 in. parallel of the test piece is apparent in this series, the cracks becoming more pronounced as the arsenic content increases.

Microstructure.

The microscope affords us a ready means with which to study the embrittling effect of the arsenic in the cast or hot-worked specimens.

In 1910 Bengough and Hill published an interesting research on the influence of arsenic in copper and the probable constitution of the copper-arsenic thermal equilibrium diagram, in which they showed the formation of two compounds, namely, Cu_3As and Cu_5As_2 , in confirmation of Friedrich's report of 1905. They also showed that the solubility of these two intermetallic compounds in the main copper-rich α -phase metal was dependant upon the rate at which the alloy was cooled, etc.

This latter feature, whilst not so important in this series of alloys, plays a great part in the 70/30 series and will be referred to later.

Photomicrographs No. 1 and 2, which represent the standard alloy in the "ascast" and "worked" conditions, do not call for special comment, their structural formation being that expected and are here reproduced for the purposes of comparison.

The presence of 0.14% arsenic is revealed microscopically in the formation of numerous minute granules of arsenide distributed mainly amongst the β -constituent and not easily shown photographically.

As the arsenic content increases the presence of these granules becomes more pronounced and can readily be shown at lower magnifications (see photomicrographs Nos. 3 and 4). Here, with such lowering of the magnification, the photographic rendering does not do justice to the distinctness with which these granules appear under the microscope.

Photomicrographs Nos. 5 and 6 show the microstructures of alloys A.C.3 and 3.R, which are very similar to the lower arsenic alloys structurally except for the presence of larger quantities of free arsenide.

That the embrittling effect of arsenic may be more clearly understood, an analogy may be drawn from the influence of tin on such brass.

Ordinary Muntz metal is capable of retaining in solution approximately 1.2% tin, and when this amount is exceeded, a third constituent, which may be termed " γ ", makes its appearance. With the advent of this constituent, which is hard and brittle and has, in general, the same physical properties as the arsenide formed in the arsenical series, we consequently have a similar reduction in the ductility of the brass; with 3% tin the effect of this " γ " constituent is such that the brass is commercially useless, giving the following tests:

1.

2.

3.

4.

5.

6.

7. (mag. $\times 1350$.)

8.

9.

10.

11.

12.

13.

14. (mag. $\times 630$.)

15.

16.

Yield point.	Maximum stress.	Elongation	Reduction of area %.	Alternating impact no.
Tons sq. in. 16.5	Tons sq. in. 21.25	1.5	3.2	1

These results are somewhat similar to those obtained in the test with alloy A.C.3 which contains 1% arsenic.

From this comparison the deleterious influence of small percentages of arsenic on hot-working brass is clearly understood, but it must be borne in mind that though the action of tin and small quantities of arsenic is very similar on the physical properties, through the introduction of a third micro-constituent, the formation of this third micro-constituent originates very differently.

In the arsenical series the arsenic exists as free arsenide; this arsenide incites a slight nucleus action on the two phase " β " constituent but does not tend to dissociate it in any way; this is clearly demonstrated by photomicrograph No. 7

which was taken from alloy A.C.3 in the cast condition, the groups of arsenide granules being shown gathered in a chain-like formation mainly in the " β " constituent; this latter-mentioned constituent in is no way resolved by the arsenide and even at the high magnification at which the photograph was taken only a slight internal lamellar structure can be revealed. Tin, however, exercises a different effect in promoting a dissociation of the two-phase " β " constituent.

Conclusions.

(1) The inherent brittleness of arsenical $\alpha\beta$ brass is due to the formation of a third micro-constituent which exists in a chain-like fashion mainly in the β -constituent.

(2) That hot work is detrimental to their physical properties is due to the arsenide, which forms or tends to form at the crystal junctions, being enveloped in the β -constituent; this separates each crystal grain from its neighbours by a weak, brittle compound; hence the typical intercrystalline fracture of forged arsenical Muntz metal.

Series 1.

In directing our attention to this series of alloys, it is necessary to bear in mind that α -brasses owe their high commercial value to the great ease with which they can be cold worked, and to the ready recovery of their ductility after a simple heat-treatment.

As nil.

CURVE 5.

An idea of the plastic flow of alloy A.C.8—which is the standard non-arsenic alloy—can be gained from the fact that a chill cast slab 6 ft. \times 1 ft. may be cold rolled from 1.05 in. thick to a strip 0.18 in. thick, in six passes, without exhibiting any traces of overwork; this treatment raises the Brinell hardness from 57 to 171. Thus in an α -brass, not only have we a metal which readily lends itself to plastic deformation, but one possessing a good range of physical properties easily controlled by suitable mechanical work and heat-treatment. An idea of the range of physical properties obtainable from the effect of cold-work and heat-treatment can be gained from the physical tests obtained during the working-down of an 18 pdr. cartridge case blank, these tests being as shown in test-sheet No. 4, after each subsequent operation. The figures are displayed graphically in Curve No. 5.

This treatment having long been standardised, and the nature of the accompanying physico-chemical changes having received considerable attention from various investigators, it was regarded as an ideal treatment to adopt for the present investigation, as one yielding complete information in the cast, worked, and heat-treated conditions, and so demonstrating in a practical manner the influence of varying amounts of arsenic in all possible physical conditions; while it also shows actually to what extent arsenic may be present in cartridge case brass without detriment.

Complete details of these tests are tabulated alongside the tests obtained from the standard non-arsenic alloy in Test Sheet No. 4, and shown in a lucid manner by Curves 6, 7, 8, and 9.

Before discussing these results, it must be pointed out that the tensile test from each alloy in the "as cast" condition was made in accordance with the specification of the Engineering Standards Committee, 0.564 in. \times 2 in. length parallel, all subsequent tests being 0.309 in. \times 1 in., this latter size test-piece being procurable from all strips after each subsequent operation.

The effects wrought by arsenic on the cast samples are somewhat striking, alloy A.C.7 containing 0.09% arsenic displaying an all-round superiority over the standard non-arsenic alloy. A further increase in the arsenic content now produces a reversal effect, 0.12% arsenic reducing the elongation from 58% to 50%, while the shock-resisting properties are reduced 58%.

The presence of 0.18% arsenic is sufficient to reduce the ductility to a figure of very low order, and at the same time is responsible for a slight drop in the tenacity.

As 0.09%.

CURVE 6.

Accompanying further increases in the arsenic content, both the tenacity and ductility suffer, till in the presence of 0.5% arsenic, the general physical properties render the alloy of little value in the "cast" condition; whilst 1% arsenic results in the chill cast slab being hopelessly weak and brittle and the shock-resisting properties reduced almost to zero.

In spite of such embrittlement of the arsenic in the chill cast slabs, all the alloys were cold-rolled with equal ease, alloy A.C.7 displaying no superiority over alloy A.C.6.

These unexpected results introduced the question to what extent did arsenic affect the cold flow of the metal? It was decided to determine this, and details of the results obtained will be dealt with in a later part of the paper.

The influence of arsenic as displayed on these alloys after such combined cold work and heat-treatment is most striking, not only resulting in an all-round improvement of the physical properties, but raising them so that a decided superiority is revealed of alloys A.C.4 and 5 over alloy A.C.8; this is most interesting when we consider the physical properties obtained in the "as cast" condition, particularly in regard to alloy A.C.5, which contains 0.5 % arsenic.

CURVE 7.

The physical tests after the final treatment of alloy A.C.6, which contains 1% arsenic, are more or less as expected. Its elongation is slightly improved from the cast state; whilst the percentage reduction of area is somewhat reduced.

In all, the ductility and shock-resisting properties are little affected, while the tenacity is improved six tons per square inch, but even this does not attain the value recorded by any of the other alloys, after the same physical treatment.

Structural changes due to the presence of arsenic.

Having detailed the changes that accompany the presence of small quantities of arsenic on the physical properties, it becomes necessary to explain these results *a priori*; and the microscope has again been used as affording a ready means whereby the structural changes due to arsenic can be followed in all the respective physical conditions.

The technique of the preparation of the micro-sections does not call for special mention, but the following method of etching is necessary: after preparing the specimen in the ordinary way, the

CURVE 8.

surface is completely freed from any trace of dirt or grease and immersed in a solution consisting of potassium bichromate 40 grms., sulphuric acid (sp.gr. 1.81) 1 c.c., water 100 c.c., until a slight attack is observed to the naked eye.

CURVE 9.

The specimen is rinsed in water and immersed in a dilute solution of acid ferric chloride until a faintly coloured film is seen to cover the specimen. It is then at once withdrawn and washed in water, a little absolute alcohol being used to assist in drying rapidly.

The formation of a peculiar brownish coloured deposit in all the arsenical series (the intensity of which increases with an increasing arsenic content), makes it almost impossible to etch, by the use of a single reagent, with any measure of success; the specimen is either spoilt or rendered extremely dull and difficult to decipher. But by the double attack aforementioned the trouble is completely overcome. Alloy A.C.8 was etched in this manner for the purposes of comparison only.

A magnification of 63 diameters has been found convenient for revealing the general microstructure together with some detail and was used for all the original photomicrographs unless otherwise stated. The illustrations shown here, however, are on a somewhat smaller scale, viz., $\times 34$.

Photomicrograph No. 8, which illustrates the microstructure of alloy A.C.8 (arsenic *nil*) in the chill cast condition, does not demand special mention. It is a typical example of the shadowy, indefinite ghost-like structure of all " α " brasses that display "coring" when chill cast from high temperatures; the cores taking their formation from a copper-rich centre to zinc-rich envelope at the outer edge in each primary crystal.

The presence of small amounts of arsenic, however, exercises quite a marked effect on this indefinite cored-like structure. Their arborescent formation becomes more conspicuous while the "coring" of the copper-zinc solid solution is not so clearly revealed, but a new type of coring or heterogeneity makes its appearance.

Alloy A.C.4 "as cast" shows clearly both types of coring:—

(1) The coring due to the heterogeneity of the copper-zinc solid solution, and

(2) The coring due to the formation of free arsenide granules, the depth of diffusion of the arsenide into the surrounding material being clearly marked.

As the arsenic content increases this duplex structure becomes more marked by the formation of more free arsenide (see photomicrographs Nos. 10 and 13).

The last-mentioned photograph displays an almost perfect cellular structure, consisting of dark-coloured cells surrounded by thick light-coloured cell walls, and all the photographs show not only the value of the mode of attack used for revealing the microstructure, but the value of the reagent in clearly revealing the most minute traces of arsenic in brass, with its consequent structural effects.

By carefully examining photomicrographs Nos. 10 and 13, with the aid of a hand glass, the formation of small specks of free arsenide can be traced in alloy A.C.4, which gradually become clearly and definitely marked in alloy A.C.5; while in alloy A.C.6 they are shown to be continuous and completely surrounding the crystal grain.

The continuity of the films of free arsenide is best displayed in photomicrograph No. 14, taken at a higher magnification.

From these we see that free arsenide develops exactly as in the 59/41 series, and that these films become continuous at 1.0% As, forming practically complete envelopes to the crystal grains, whence the gradual embrittling effect accompanying a rising arsenic content in α -brass.

That this is not so severe in this series of alloys as in the $\alpha\beta$ series is self-explanatory when it is borne in mind that the arsenide in the $\alpha\beta$ -brass exists mainly in the β -material, which is a

hard, tenacious micro-constituent possessing little ductility, while in the series under consideration it can only exist in the α -material, which is a soft, ductile micro-constituent.

Hard-rolled structures.

As the metal is deformed by the cold rolling of alloys A.C. 8, 7, 4, 5, and 6, each of the crystal grains elongates, the orientation from one point to another of the same grain remaining identical, so that after the second pass through the rolls the arsenide granules become broken up into more or less continuous fine threads surrounded by attenuated arsenide cores, until eventually the structure appears to be made up of alternating layers of the dark-coloured arsenide-free zone with the light etching arsenide cores. Photomicrographs 11 and 15 illustrate this and represent the alloys A.C.5 and 6 respectively.

The physical tests from all these alloys at this stage is as anticipated from the microstructure. Their high tenacity and low ductility is due to the cold work applied which removes the crystalline structure and replaces it with an amorphous one in which are shown numerous slip-bands (see photomicrographs 11 and 15).

The presence of these slip-bands is always indicative of plastic deformation; they owe their formation to the cold work causing plastic strain in each crystal grain due to the slipping of one layer of crystals on its adjacent partners.

The surface steps so formed by this slipping are shown on etching in the form of black lines in a striated and cross-like fashion through several systems of planes, and at all these internal surfaces of movement the material becomes decrystallised. These amorphous layers are harder than the crystalline substance from which they are formed, the intensity of their formation determining the hardness figure and tenacity. Hence the similarity in the physical tests obtained from both the non-arsenical alloy and the arsenical alloys after the second pass through the rolls.

Annealed structure.

Photomicrograph No. 9 illustrates the microstructure of alloy A.C.8 after the first anneal, the worked cored structure being replaced by a homogeneous structure consisting of polygonal twin crystals, this structure being typical of all worked α -brasses after annealing.

In the arsenical series, however, the first anneal does not effect such complete removal of the cored structure, in consequence of which we have formed a complex microstructure consisting of a ghost-like pattern of the original cast and worked "core-banded" structure overlain by the polygonal twin structure obtained in alloy A.C.8. This double structure is more marked as the arsenic content increases.

In this condition the alloy A.C.4 exhibits very slight traces of free arsenide, while alloys A.C.5 and A.C.6 exhibit free arsenide, but in much less quantities than those shown in the original cast samples, and it is the presence of this remaining free arsenide that is responsible for the reproduction of the original cored cast structure *in situ*. So we see that while cold work, followed by annealing, rectifies the heterogeneity of the copper-zinc cores it does not effect complete interdiffusion of the arsenide cores.

With the aid of further work, followed by a second annealing, however, homogeneity is obtained, for it is possible to detect only a few very minute specks of free arsenide even in alloy A.C.6, which contains 1% arsenic.

Hence the microstructure now consists of homogeneous polygonal twin crystals, illustrated by photomicrograph No. 9 (see photomicrographs

Nos. 12 and 16, which show the microstructures of alloys A.C.5 and 6 respectively).

It is, therefore, because of the complete removal of this free arsenide and the homogeneity obtained that such a marked improvement is exhibited in both the tenacity and ductility, which goes to prove that arsenic in solution confers increased ductility on brass. But the quantity permissible is very limited, as may be determined by the tests obtained from alloys A.C.5 and A.C.6 after the second anneal, the latter alloy being hopelessly intercrystalline. This intercrystallinity is due to the ternary intermetallic compound acting, when present in sufficient quantities—as do all intermetallic compounds—by conferring on the alloy in which present their own inherent poor physical properties.

The cold-working properties of arsenical α -brass.

To ascertain to what extent arsenic affects the cold-working properties of α -brass, sections (3 in. by 1 in. by 1.05 in.) were cut from alloys A.C.8, 7, 4, 5, and 6, and each cold rolled in successive passes of $\frac{1}{8}$ in. reduction per pass until incipient cracking commenced through overwork.

Complete data obtained are tabulated in Test Sheet No. 5.

These results show that:—

(1) Arsenic in quantities not exceeding 0.20% is beneficial to the cold-working properties, for alloys A.C.7 and 4, containing 0.09% and 0.18% arsenic respectively, permit a greater reduction by cold rolling than is possible with the standard non-arsenical brass A.C.8, without displaying any traces of over work.

(2) Between 0.20% and 0.50% arsenic no material effect is noticed, for alloy A.C.5, containing 0.49% arsenic, withstands the same reduction as alloy A.C.8.

(3) In the presence of an arsenic content exceeding 0.50%, the cold rolling properties are somewhat deteriorated, alloy A.C.6 breaking down at a thickness of 0.20 in.

This reversal effect which occurs with an increasing arsenic content is similar to that shown to have occurred in the tensile tests (see Test Sheet No. 4) although the changes are not so drastic. It is possible to cold roll alloy A.C.6 almost to the same extent as alloy A.C.8, while the superiority of alloys A.C.7 and A.C.4 over alloy A.C.8 is very small.

That it should be possible to cold roll alloy A.C.6 to such an extent is not altogether unexpected in spite of its inherent brittleness, when we bear in mind the almost liquid-like flow of α -brass; also that metals which are completely shattered by rapidly-applied stress may readily be made to extend slowly under a comparatively low stress.

Thus, when the arsenide is present in sufficient quantities to separate the crystal grains by more or less continuous envelopes, its action is to promote or tend to promote rupture at the crystal junctions when the cleavage slip in the crystal grains has been sufficient to render the amorphous material formed less mobile than the material at the crystal junctions.

Hence the type of defect subsequently determining an overworked arsenical brass of this nature presents itself in the form of fissures at the crystal junctions.

When the free arsenide does not predominate, but exists as in brasses containing under 0.5% arsenic, the limit of overwork is determined very differently.

After each pass slipping will occur which counterbalances the new stress by an increased area across which the internal forces can act. Thus the material stiffens until its limit of accommodation of these stresses is reached, when the severe com-

pound internal stresses—tensional in the cores and compressive in the superficial layers—give rise to longitudinal rupture. The fracture takes a cup and cone formation.

The Brinell and Scleroscope hardness numbers obtained after each reduction through the rolls bear out the comments previously made on the hardness being a direct measure of the extent that crystalline metal is replaced by amorphous metal.

The annealing of arsenical brass.

The numerous operations through which α -brasses pass during the working up into a desired form, whether as rod, strip, tube, or cartridge case, etc., necessitate numerous annealings between successive operations, or a combination of successive operations, depending upon the intensity of the cold work applied per operation, the annealing being such that a maximum ductility is obtained at the lowest temperature in the shortest possible time, so reducing to a minimum any possibility of dezincification or scaling which so readily occurs owing to the large surface generally exposed of objects made from α -brass.

Recrystallisation accompanied by a complete restoration of the ductility of non-arsenical 70/30 brass is obtained at a temperature of 650° C., when the period of heating does not exceed 10 minutes. In general works' practice a slightly lower temperature than this is used, the period of annealing being longer, and such that the same results are obtained.

In the presence of arsenic the temperature was found to be somewhat raised, so the following experiment was conducted:—Sections were taken from the original strips of each alloy after cold rolling to a thickness of 0.55 in., when the Brinell hardness number in every case was in the proximity of 155. Two specimens from each alloy were annealed at 600°, 650°, 700°, 750°, and 800° C. for ten minutes. One sample was cooled in air, the other quenched rapidly in water. Brinell hardness tests were then made on each specimen, with the results given on page 439.

That the annealing temperature is raised is undoubtedly shown by these results, while the temperature at which complete annealing occurs is that at which the arsenide just passes into complete solution in the brass; this goes to prove that it is the presence of free arsenide which retards the rate of crystal growth.

From experiments at present in hand on the crystal growth of arsenical brasses which are micro-chemically homogeneous, no differences can be discerned from that of "non-arsenical" brass in the same physical condition, and as far as these experiments have been conducted, they substantiate the forementioned conclusions.

General conclusions.

1. Arsenic embrittles all copper-zinc alloys, commercially known as "brass," when it is present as free arsenide, which arsenide is a weak, brittle constituent, and if present in sufficient quantities, completely envelopes each crystal grain, resulting in a crystalline mass, the grains of which are stronger than the junctions, so acting as do antimony, bismuth, and other metals which form definite intermetallic compounds the presence of which produces "intercrystallinity."

2. These films of arsenide do not affect the cold-working properties of α -brasses to any appreciable extent owing to the ready accommodation of this class of brasses to plastic deformation without rupture.

3. Small quantities of arsenic—under 0.10%—are beneficial to α -brasses, no matter what their physical condition, due to the arsenic

entering mainly into solid solution, the amount remaining as free arsenide being negligible when considered as a mechanical enclosure.

4. A complete recovery of the ductility of all essentially cold-working arsenical brasses, containing under 0.5% arsenic, is effected by cold-working and subsequent annealing, this treatment bringing about a complete solution of arsenide which is beneficial to the quality of the brass when present in quantities not exceeding 0.20%; exceeding 0.20% and up to 0.50% As, the brass possesses the same physical properties as non-arsenical brass.

Exceeding 0.50% arsenic, the brass becomes intercrystalline no matter the physical condition of the arsenide, going to prove that the physical properties of arsenical α -brasses containing under 0.50% arsenic are governed by the physical condition of the brass; when exceeding that amount the percentage of arsenic governs the physical properties no matter what be the physical condition of the alloy.

5. The temperature at which α -phase brasses containing free arsenide will anneal is 30°–50° C. higher than that of pure non-arsenical brass, data not yet being to hand concerning the influence of arsenic on re-crystallisation when present in perfect solid solution in the copper-zinc as a perfectly homogeneous alloy.

6. Arsenic when present even in the most minute quantities is detrimental to the physical properties of hot-worked brass, although it in no way affects the hot-working properties.

7. Arsenic does not assist in any structural inversion of the " β "-constituent, when cooled under normal conditions.

In closing I wish to express my thanks to the Directors of Messrs. Sir W. G. Armstrong, Whitworth & Co., Ltd., for their permission to publish these data, and also to recognise the valuable assistance rendered by Messrs. J. W. Craggs, R. N. Richardson, and R. L. Granville-Johnston.

Industrial Notes.

RESEARCH AND THE COTTON INDUSTRY.

At the end of July of last year, at the instance of the Advisory Council of the Committee of the Privy Council for Scientific and Industrial Research, a meeting of representatives of some of the larger firms engaged in the various branches of the cotton trade and others interested in textile research was called by the Lord Mayor of Manchester to consider the possibility of establishing a scheme for the scientific investigation of the various problems presented by the cotton-using industries, and it was agreed that there is great need for research bearing on the cultivation and manufacture of cotton, and in the dyeing, printing, bleaching, and other finishing processes. It was also thought that efforts should be made to increase and to improve the system of textile education. At an adjourned meeting it was decided that some practical steps should be taken to organise a complete scheme for these two purposes. A Provisional Committee was appointed and this, in due course, was constituted a Committee of the Advisory Council of the recently formed Government Department of Scientific and Industrial Research.

This Committee is largely representative of the various interests concerned. Its function is to formulate a preliminary scheme of a comprehensive character and to report to the Advisory Council and then to lay before the trade, for its consideration, definite proposals for the establishment of a Research Association, eligible for recognition by the Government Department and consequently for monetary grants from the National Exchequer.

The Provisional Committee consists at present of the following members:—Mr. J. W. McConnoil (Fine Cotton Spinners' Association, Ltd.), Chairman; Mr. H. R. Armitage (Bradford Dyers' Association, Ltd.); Dr. W. Lawrence Balls (late of the Khedivial Agricultural Society of Egypt and the Egyptian Ministry of Agriculture); Messrs. T. D. Barlow (Messrs. Barlow & Jones, Ltd.), P. W. Barwick (Manchester Chamber of Commerce Testing House), Stanley Bourne (cotton doubler, representing the Nottingham Chamber of Commerce), Lindsay Cropper (Messrs. J. & P. Coats, Ltd.), Henry P. Greg (Messrs. R. Greg & Co.), J. C. M. Garnett (Manchester School of Technology and the University of Manchester), A. E. Hawley (dyer, representing the Leicester Chamber of Commerce), Forrest Hewit (Calico Printers' Association, Ltd.), E. L. Hoyle (Messrs. Joshua Hoyle & Sons, Ltd.), Alfred J. King (Bleachers' Association, Ltd.), Kenneth Lee (Messrs. Tootal Broadhurst Lee Co., Ltd.), J. H. Lester (late of the Manchester Chamber of Commerce Testing House), James Prestwich (Federation of Master Cotton Spinners' Association), Fred. J. Smith (British Cotton and Wool Dyers' Association, Ltd.), and Charles H. Turner (Cotton Spinners' and Manufacturers' Association). Mr. A. Abbott, H.M. Inspector of Technical Schools, has been appointed by the Advisory Council, with the concurrence of the Board of Education, to act as Secretary *pro tem*.

The Provisional Committee are holding fortnightly meetings.

They have to consider the place for research in each branch of the cotton industry, whether in the cultivation of cotton, in spinning, doubling, manufacturing, knitting, lace-making, bleaching, dyeing, printing, finishing, or in the technology of cellulose. They have also to ascertain what facilities now exist for the education of boy

entering any of these branches, and what opportunities are likely to be offered by the trade for the employment of highly-trained men. They will also have to formulate a scheme both for an Institute to undertake research work in collaboration so far as practicable with existing bodies, and for an Association of firms and individuals willing to make donations and subscribe regularly for a period of years to promote research and improve technical training.

The terms and limitations under which the Association can obtain its share of the million pounds granted by the Treasury to promote scientific and industrial research will be ascertained by the Provisional Committee.

Any suggestions relating to the researches to be undertaken or to any other matters coming within the scope of the proposed Association will be welcomed by the Committee, and should be sent to the Secretary, Provisional Committee on Cotton Research, 108, Deansgate, Manchester.

SOCIETY OF DYERS AND COLOURISTS.

At the annual meeting of the Society of Dyers and Colourists, at Manchester, on March 30th, Dr. Alfred Rée was re-elected President, and dealt in his presidential address with the subject of patent law reform.

Dr. Rée said the number of well-trained chemists in this country was only one-fortieth of the number in Germany and one-fiftieth of the number in Switzerland in proportion to the population. It was high time that the old prejudice against the study of chemistry should be overcome. Much could be done by improving the remuneration of the well-trained chemist, though that was enormously better than it was a few years ago. The conception of the training necessary for a "chemist" and a "pharmacist" required to be legally defined. Without in any way decrying the latter, a well-trained chemist required a far longer and more thorough training and education, and some means should be found whereby the difference between them should be definitely established, as it was in other countries. With regard to the work of German chemists, Dr. Rée was assured by well-informed authorities that many of the most brilliant discoveries connected with the coal-tar colour industry were not made even in Germany so much by Teutons as by people of French, Alsatian, or Swiss origin, or of Polish and even Anglo-Saxon origin. Some of the most clever and expert German industrial chemists had spent years in England and benefited by a close study of English ways and methods before attempting to accomplish their great work in their own country. It was also to be pointed out that some of the greatest discoveries were made and rendered valuable to industry by relatively untrained men. Some of the first works in the world to produce aniline colours were situated near London.

Our patent laws, Dr. Rée said, had been a serious deterrent to the development of the chemical industry. He had no hesitation in saying that their influence for evil had been far greater than could be realised except on a rather exhaustive examination of the whole question. He even went so far as to assert that had we had no patent laws at all with regard to chemical processes and products our progress in the British colour and allied industries would have been quite satisfactory in the last 40 years. To the bad effect on industry of the patent laws generally

there was the further one with regard to the compulsory working of patents in this country, especially foreign ones. Proposals for the compulsory working of patents in this country, granted to persons who might afterwards work or manufacture the articles outside the United Kingdom, had emanated from the Manchester Chamber of Commerce, and had been fought for by the late Mr. Ivan Levinstein with a great degree of skill and perseverance. Had the warnings of the Chamber been heeded years ago our position to-day and since the outbreak of the war would have been very different. Not only would the aniline colour industry have been established on a firm and adequate scale, but the same statement would have applied to a number of other chemical industries with which high explosives were so intimately associated. It was, indeed, deplorable to what a serious extent the interests of the British chemical industry had been mishandled from a legislative point of view before the war. When the war was over we must not re-establish wealthy German firms in the privileges they had possessed and render their position more secure and lasting than before. He hoped we had learned our lesson, and would not fall into that kind of trap. The newly-formed Association of British Chemical Manufacturers, acting as a united body, would, he trusted, be able to prevent in the future a perpetuation of such an evil.

The President, at the close of his address, presented to Professor Arthur G. Green, F.R.S., the Perkin Gold Medal of the Society in recognition of his valuable researches in dyestuff chemistry, and particularly for his discovery of primuline in 1887. This was the fourth award of the medal, which was instituted by the Society in commemoration of the late Sir William Perkin, and is awarded triennially for investigations and inventions of high scientific or industrial importance. Professor Green is the first Englishman to receive the honour.

THE CANADIAN COBALT INDUSTRY.

A report of the special Committee on Metal Industries to the Canadian Mining Institute contains the following particulars of the cobalt industry:—

Almost the entire cobalt supply of the world is drawn from the mines of Ontario. This metal was formerly largely a German product, and for two or three hundred years that country controlled the supply, but prior to the discovery of the Canadian product the ores of New Caledonia had become the main source of supply. These mines, however, were forced to close when brought into competition with the cheaper supply from Ontario. The ore and concentrates produced in the Temiskaming district of Ontario contain from 4 to 10% cobalt, 2 to 8% nickel, 15 to 40% arsenic, and from 500 to 5000 oz. of silver per ton.

During the early days of mining in the Cobalt district much ore was exported to the United States and treated for its silver contents, the cobalt being slagged and lost. Now, only a small amount of the rich cobalt ores is exported to that country, but a considerable tonnage of low-grade concentrates, low in silver, nickel, and cobalt, still goes to the American smelters and is treated for its silver contents only. Two or three of the mining companies at Cobalt have erected plants for desilverizing their high-grade ores and concentrates, leaving the cobalt, nickel, and arsenic in residues for shipment to cobalt smelters.

Germany received some of this product before the war. A small quantity is now sold in England, while the larger portion is handled by southern Ontario smelters. During the past years the smelting industry of Ontario has been steadily developing and handling a larger percentage of the ores and concentrates from the Temiskaming district. Cobalt is largely sold as cobalt oxide, but also in the metallic form and to a limited extent in salts. The output is largely controlled by the demand for cobalt, as production could readily be increased if circumstances warranted it. A few years ago practically the only market for cobalt was in the ceramic industry, where it was employed for whitening the body of china and in the production of blue colour. It is employed in the enamelling trade, the manufacture of blue-coloured signs, the colouring of glass, and to a small extent in the manufacture of pigments such as cobalt blue. These industries could consume only three or four hundred tons of cobalt per year. In the last few years, however, new uses have been found for the metal, and there has been an increase in the consumption of cobalt salts for such purposes as the manufacture of cobalt driers for paints.

The use of cobalt in the metallic form is increasing. It has been found that it has several advantages over nickel for electroplating, a smaller quantity having a greater resistance to abrasion, and with use of a proper bath it can be deposited much more rapidly. In the manufacture of high-speed steels, cobalt has been used as an alloy to considerable advantage, as for instance in the manufacture of the so-called Becker steel, which became of some little commercial importance in Germany just before the war. Other brands of cobalt steel are also on the market. A new cutting metal called "stellite," composed of cobalt, chromium, and tungsten, without iron, has proved to be superior to high-speed steel for many operations. It is claimed that this metal is to high-speed steel what high-speed steel is to ordinary carbon steel; that is, it will allow of increasing the rate of cutting on the lathe from 20% to 50% and minimizes the time consumed in sharpening tools. The development of the cobalt industry in Ontario has been greatly assisted through the action of the Ontario Government in granting, some years ago, a bounty of 6c. per lb. for all cobalt and nickel refined in that province. The Dominion Government, also through the Department of Mines, assisted in the attempts to develop new uses for this metal by a vote for research work conducted in the metallurgical laboratories of Queen's University. It was here that cobalt plating was developed (see this J., 1915, 619).

MINERAL PRODUCTION OF CANADA FOR 1916.

The preliminary report on the mineral production of Canada, during 1916, prepared by John McLeish, chief of the division of Mineral Resources and Statistics, has been issued by the Canadian Department of Mines. The table on page 442 summarises the statistics given.

The war had a most pronounced effect in stimulating the production of nickel, copper, and zinc, iron and steel, molybdenum, etc., used so extensively for war purposes, and also in increasing the production of other products, such as chromite and magnesite. The general industrial activity in metallurgical operations and in the manufacture generally of munitions of all kinds, including the freight movements required, increased the demand

for fuel, which was met in Western Canada at least by large increases in coal production.

Considerable progress was made during the year in establishing and increasing smelting and refining capacities, of which the installation of electrolytic zinc and copper refineries at Trail and the beginning of construction of a nickel refinery at Port Colborne, Ont., are conspicuous examples. In addition, mention is made of the production of metallic magnesium at Shawinigan Falls, of ferromolybdenum at Orillia and Belleville, of metallic arsenic at Thorold, and of stellite, the cobalt alloy for high-speed tool-metal, at Deloro, and of the increased capacity for the production of steel.

The mining output was restricted and the efficiency of operation considerably reduced by the withdrawal for war service of such a large proportion of the more experienced labour and engineering

smelteries and reduction plants in Canada and 3,466,665 oz. estimated as recovered from ores exported to the United States smelteries.
